MISSISSIPPI RIVER CUTOFFS

By Gerard H. Matthes,[1] Hon. M. ASCE

With Discussion by Messrs. W. E. Elam, C. L. Hall, H. D. Vogel, Harry N. Pharr, Lytle Brown, Anson Marston, E. J. Williams, Jr., and Eugene A. Graves, and Gerard H. Matthes

Synopsis

Natural and artificial cutoffs on the Lower Mississippi River in the 50-mile stretch north of Vicksburg, Miss., are described with respect to their effect on river shortening and flood-stage lowering. Historical and physical facts are given which explain why, during the period from 1884 to 1932, natural cutoffs were dreaded and engineering measures were taken to prevent their occurrence, thus permitting the river to become considerably lengthened. The paper describes the unforeseen circumstances which caused a cutoff at Yucatan Bend to occur unexpectedly during the low-water season of 1929; and it relates how the satisfactory manner in which the cutoff developed unassisted gave impetus to the launching of a program of river shortening by artificial cutoffs, the first of which, across Diamond Point, was opened on January 8, 1933. The technique adopted avoided making cutoffs across narrow necks, except where conditions made this necessary, and also avoided the pitfalls of European practice. Since that date fourteen additional cutoffs have been constructed, making a total of sixteen. In connection with other forms of channel rectification and dredging operations, these cutoffs have shortened the Lower Mississippi a total of 170 miles between Memphis, Tenn., and Baton Rouge, La., in an original 680-mile river length, or 25%. The appreciable lowering of flood stages which resulted from the cutoffs has saved vast outlays in levee construction. The cutoff data presented are from the records of the Mississippi River Commission.

Historical

In early times, the Lower Mississippi River, operating without restraint, made cutoffs at the rate of from about thirteen to fifteen in the course of a century. These cutoffs usually occurred during very high stages when water

---

Note.—Published in January, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] New York, N. Y.; formerly Head Engr., Mississippi River Comm., and Director, U. S. Waterways Experiment Station, Vicksburg, Miss.

scoured out channels across the narrow necks of overdeveloped bends. Individual shortenings of the river channel so produced ranged between 6 miles and as many as 21 miles. An assumption of fifteen cutoffs and an average net shortening of 12 miles per cutoff would represent a total shortening of 180 miles in a century, or 1.8 miles a year. As applied to the 840-mile stretch of river between Cairo, Ill., and Baton Rouge (cutoffs have not occurred below the latter point, see Fig. 1) 1.8 miles per year, or any value like it, seems totally inadequate to compensate for the habitual lengthening of the river, which is known to be more nearly on the order of 4 or 5 miles per year. Thus, other shortening processes must account for the difference. The most obvious of these is the channel shortening effected by chute developments across point bars. These developments result from the gradual enlargement of shallow swales (which began during high stages) into channels deep enough to flow water even at low stages and, in time, the swales become main-river channels. Chute developments have been numerous; but, because they were mostly slow processes and therefore not as spectacular as natural cutoffs, they have attracted little attention. Appreciable river shortenings have resulted from them, however. In most instances, the gradual enlargement of chutes has been conducive to producing better channels than have resulted from quick-acting natural cutoffs. The latter, because of their disruptive nature, as a rule were followed by rapid and drastic channel changes often involving major property losses and inconvenience to navigation.

FIG. 1.—LOWER MISSISSIPPI RIVER

In addition to cutoffs and chute developments, river shortenings have resulted from bend flattening. This phenomenon has been of minor importance but is of interest in that it dispels the popular belief that river bends always tend to assume greater, and eventually excessive, curvature.

One cannot but marvel at the consistency with which these natural processes have operated to maintain the over-all length in the Cairo-to-Baton Rouge stretch about the same through the long course of time: 884 miles according to maps compiled from 1820–1825 survey data; 833 miles according to the first Mississippi River Commission survey of 1881–1882; 842 miles according to the 1916 survey; and 846 miles according to the 1929–1930 survey.

When, on January 8, 1933, Maj.-Gen. Harley B. Ferguson, M. ASCE, then President of the Mississippi River Commission, opened the first pilot cut across Diamond Point (Fig. 1), the erstwhile policy of "no cutoffs at any price" maintained by the Mississippi River Commission over a period of 48 years went into the discard. The events which originally caused the Commission in 1884 to adopt its "no cutoff" stand briefly were these: During the 1870's three natural cutoffs occurred above Memphis which produced drastic changes in the river's alinement, wiped large tracts of agricultural land literally off the map, and interfered seriously with navigation. In the 1870's also, Centennial Cutoff near Vicksburg came into existence (see Fig. 2), partly through human activity; and finally in 1884 another cutoff occurred near Water Proof, La., where nature again was aided by the hand of man. Collectively these five

FIG. 2.—CUTOFFS IN THE 50-MILE SECTION UPSTREAM FROM VICKSBURG

cutoffs shortened the river an aggregate of 50 miles within one decade. The engineers of the Mississippi River Commission were powerless to direct or control the river's rampaging.

The Commission's policy to permit no further natural cutoffs to occur found justification in the fact that the Commission in those days had neither the funds nor the dredging equipment at its command with which to make artificial cutoffs or to control their development. Moreover, natural cutoffs across narrow necks of land as a rule produced only temporary lowerings of flood stages and induced successions of channel changes extending upstream as well as downstream. To prevent impending cutoffs from taking place, the Commission caused dikes to be built on Ashbrook Neck and Leland Neck near Greenville, Miss., and on the neck of Cowpen Point near Natchez, Miss., later isolated by Giles Cutoff.

Proposals to improve the Lower Mississippi River by artificial cutoffs had been made from time to time dating as far back as 1850; in 1882 the late J. B. Johnson, M. ASCE, assistant engineer for the Commission, submitted such a recommendation. After the 1927 flood, the desire for making artificial cutoffs to lower the flood stages gained new impetus. The late John F. Coleman, Past-President and Hon. M. ASCE, strongly supported a well-coordinated cutoff program, but expressed the need for devising safe methods for executing such works. W. E. Elam, M. ASCE, discussed a paper[2] in which he showed the benefits that could be derived by cutting off the Greenville Bends—but always the question of how to execute and control such operations in as large a river as the Mississippi remained unanswered. Not until 1930 did General Ferguson, then Colonel, Corps of Engineers, and Division Engineer for the South Atlantic Coast, come forward with what appeared to be a sound plan of procedure. Instead of adopting the European technique of making cutoffs in the dry to full dimensions and then turning the river into them, he devised the pilot-cut plan. This plan permitted the slope adjustment incident to the river shortening to develop gradually over a period of years, and avoided creating high velocities and raising flood stages in the river downstream from the cutoff—two evils which had invariably resulted from the European method.

In adopting his plan General Ferguson was guided by the development of Yucatan Cutoff—which cut off Hard Times Bend unexpectedly in September, 1929. This cutoff occurred at a point about 40 miles downstream from Vicksburg (see Fig. 1) when the Mississippi River, through the caving of its banks, broke into its tributary, the Big Black River, at a point 2.5 miles above the latter's mouth. As the mouth was about 12 miles downstream from the break through by way of Hard Times Bend, the entire fall around this bend became concentrated in the 2.5-mile Big Black channel. Although the Commission's engineers had endeavored to close the break with willow mats, the flow gained so much headway that it could not be stopped. There resulted what subsequent events have shown to be the model cutoff on the Lower Mississippi. After two flood seasons the crooked little valley of Big Black River had become transformed into a wide and nearly straight cutoff channel fit for navigation. By

---

[2] *Transactions*, ASCE, Vol. 93, 1929, p. 937.

April, 1932, it was carrying 60% of the river's flow; it was more than 100 ft deep in places; and this great depth gave so ample a cross section that the rate of fall was almost the same as in the river above and below the cutoff. Consequently, velocities were moderate and offered no obstacles to navigation. Concurrently with this development, deterioration of the old channel around Hard Times Bend had progressed, through deposition of sand, until, by November 22, 1933, during a low-river stage, the entire flow was passing through Yucatan Cutoff and the writer was able on that date to walk dry-shod across the severed bend channel at its upper end.

The Yucatan incident, aside from being extraordinary as a natural avulsion (occurring during low-river, instead of high-river, stages) set a new precedent in cutoff history. It proved that a narrow channel a mile or two in length was superior, as a cutoff route, to a short cut across a narrow neck of land. Yucatan Cutoff developed without any assistance from the engineers, and has not upset the river either upstream or downstream in a detrimental way. Such channel changes as did result were not appreciably different from those ordinarily witnessed in the river's meandering.

The program of cutoffs inaugurated in 1933 has followed this precedent wherever conditions permitted it. It was aimed at shortening the river without, however, straightening it. Mild curvature was held to be essential for preserving a deep navigable channel as well as for effecting such channel stabilization as might be consistent with the meandering nature of an alluvial river. The main objective, however, was the lowering of flood stages; and, in this respect, the cutoff program has made an extraordinary contribution to the control of floods in the Lower Mississippi River. More than that, it was so planned as to make it incumbent on the waters of the Mississippi River to perform the major part of the work of excavating new channels and of filling abandoned ones. The program has effected stupendous savings in the construction costs of the levee system.

NATURAL CUTOFFS

Six cutoffs that have occurred in the 50-mile reach upstream from Vicksburg afford a unique opportunity to analyze this subject (see Fig. 2)—Centennial (1876), Yazoo (1799), Terrapin Neck (1886), Newman (1913), Marshall (1934), and Willow (1934). The first four were cut by nature whereas the remaining two were created by man. For the most part, the paper is concerned with the latter two—Marshall and Willow cutoffs.

Centennial Cutoff.—In 1876, at Vicksburg (see Fig. 2), the Centennial Cutoff moved the river away from Vicksburg and created De Soto Island, which still remains a part of the State of Louisiana. Although this is a natural cutoff, the process was aided artificially.

Yazoo Cutoff.—Only a small part of the original Yazoo Bend, which was cut off in 1799, remains as Yazoo Lake.

Terrapin Neck Cutoff.—This action, in 1886, eliminated 16 miles of the original river channel, creating Eagle Lake in the process. Australia Island, within the loop formed by the lake, remains as a part of the State of Louisiana.

Newman Cutoff.—This development was not a cutoff in the true sense, but a natural chute development caused by the enlargement of Albemarle Chute in 1913.

MARSHALL CUTOFF

Marshall Cutoff extends across Marshall Point around which the river formerly flowed in an almost perfect semicircular bend known as Paw Paw Bend. This bend had become subject to chronic bank caving and in 1932 threatened to effect a junction with the abandoned channel of the Yazoo River. It became necessary either to revet 3 miles of Paw Paw Bend or to make a cutoff. The decision was in favor of the cutoff.

The method of construction consisted in first excavating the high ground with dragline machines and then finishing the pilot cut down to a depth of 29 ft below mean low water with cutter-head dredges. Four draglines began operations on October 19, 1933, and worked a total of 80 machine days. On December 17, 1933, the high ground yardage removed was 1,841,000 cu yd. This cut was 6,000 ft long. Between November 12, 1933, and February 20, 1934, a cutter-head dredge worked 101 days removing 2,950,000 cu yd to open a pilot cut across the huge sand bar at the lower end for a distance of 4,400 ft. The cost of excavating this part of the pilot cut instead of trusting the river to wash out a channel of its own through the sand bar has been amply justified by the excellent performance of the cutoff channel in enlarging itself in the exact place it was designed to occupy. During February and March, 1934, a dredge worked 20 days removing 551,000 cu yd. The width of the completed pilot cut was 250 ft on the bottom, which represented the full swing that the dredges could make at one operation. The side slopes were left as steep as the soil would stand.

When the pilot cut was opened on March 12, 1934, the over-all length was 13,600 ft. However, to compute the amount by which the river was being shortened, it was necessary to add to the actual length of the pilot cut the distance to the axis of the main river at each end. This computation gave the navigable length of the cutoff as 3.1 miles. Deducting this length from the 7.3 miles around Paw Paw Bend made the net shortening 4.2 miles. The fall in the cutoff, at time of opening, was 2.2 ft or about 0.7 ft per mile. The river was not high and the resulting rush of water was not damaging, but the bed and banks of the pilot cut began to erode immediately, causing much earth to be entrained. Rising river stages augmented the flow through the cut; and, on March 27, 15 days after the opening, 60,500 cu ft per sec, or 8% of the flow in the Mississippi River, was passing through the cutoff. By April 10 the flow had increased to 84,000 cu ft per sec, or 10% of the river discharge. When river stages fell, the percentage of flow in the cutoff decreased. On May 28, at a low-river stage, only 18,600 cu ft per sec, or 7% of the river discharge, was passing and this percentage prevailed throughout the low-water season. Table 1(*a*) is a condensed record of how the discharge capacity increased during the course of time as the cutoff channel enlarged itself from a pilot cut 250 ft wide to a sizable river. While this enlargement progressed, the river channel in Paw Paw Bend shoaled and contracted without any aid from man.

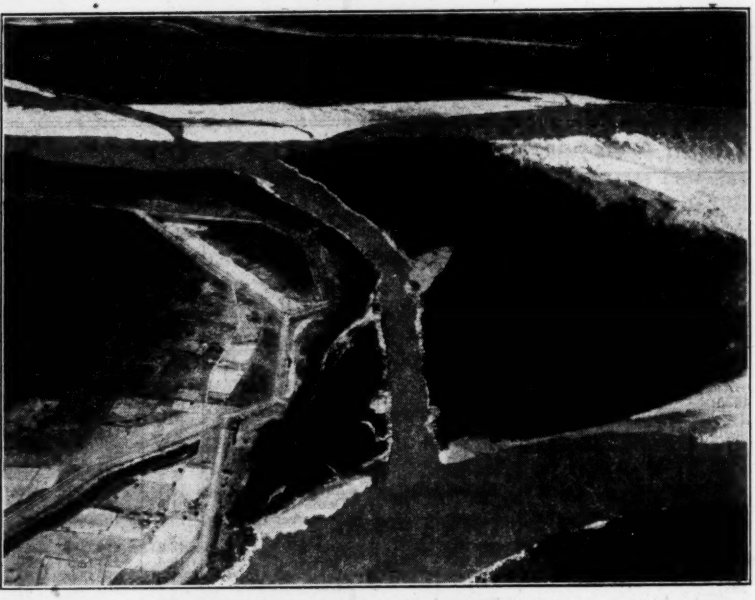

FIG. 3.—MARSHALL CUTOFF FACING UPSTREAM, LOW WATER, OCTOBER 25, 1935

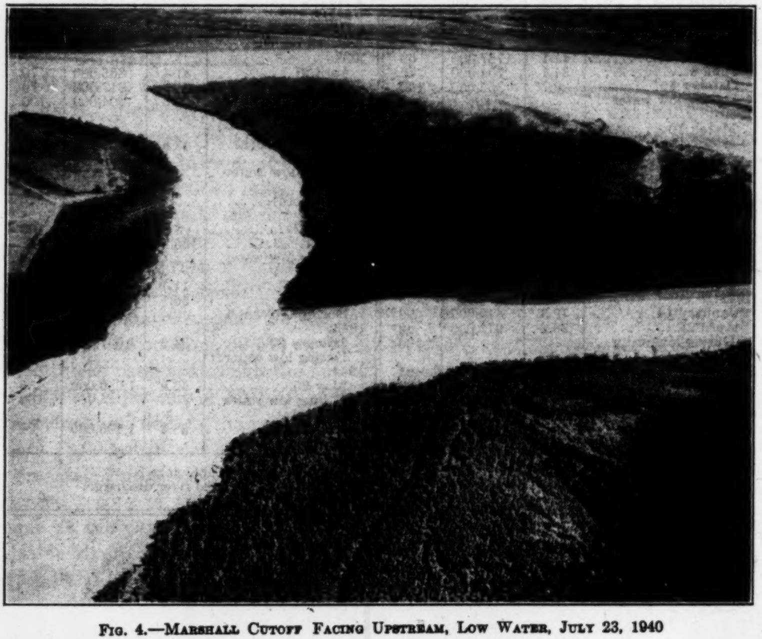

FIG. 4.—MARSHALL CUTOFF FACING UPSTREAM, LOW WATER, JULY 23, 1940

Marshall Cutoff, throughout, has been a well-behaved stretch of channel and has required very little assistance. Following the high-river stages in 1934, the upper end of the pilot cut silted for a short distance to the approximate elevation of mean low water. A pump barge removed 405,000 cu yd in 12 days, thereby restoring the cutoff to a depth of 25 ft below mean low water. During 1935, 355,000 cu yd of additional shoaling required removal. Following this cleaning, the cut continued to develop (see Fig. 3) and no further dredging has been done. A view of this cutoff as it appeared on July 23, 1940, is shown in Fig. 4.

WILLOW CUTOFF

About 1913 Willow Point (Fig. 2) was more than 7 miles long. It stuck out on the map "like a sore thumb." It had been lengthening itself year after year because of the caving habits of Albemarle Bend. During the great flood of 1913 the river made itself a new channel across the middle of Willow Point by washing out a shallow swale known as Albemarle Chute. The new river bend which thus came into existence became known as Newman Cutoff. The abandoned Albemarle Bend channel became a lake. Although the river shortened itself in this process nearly 5 miles, Newman Cutoff, according to modern terminology, amounts to a chute development and should not be dignified by the name "cutoff." The shortening was not destined to last long, for the new bend location was not favorable and it appeared that inevitably the bend would migrate again and Willow Point would probably lengthen as much as before. It was deemed advisable, therefore, to locate Willow Cutoff at a place where the resulting new channel would have no opportunity to migrate for a long time to come.

The lower end of Willow Cutoff overlaps the old Terrapin Neck Cutoff which divorced Eagle Lake in 1866. The combined effect of the two cutoffs has been to shorten the river 23.7 miles since 1866.

The method of constructing Willow Point Cutoff, in general, was similar to that employed on Marshall Cutoff, except that the greater length called for more equipment. From November 19, 1933, to January 28, 1934, seven dragline machines were operated for 322 machine days in excavating 2,392,000 cu yd, thereby lowering land elevations along the route of the pilot cut some 21 ft over a length of 13,000 ft. Between December 26, 1933, and May 15, 1934, hydraulic dredges removed 5,101,000 cu yd thereby extending the pilot cut to a depth of 14 ft below mean low water over a distance of 5,800 ft at the upper end, and to depths ranging from 10 ft to 15 ft below mean low water over other stretches. At the lower end of the cut a wide flat sand bar lay between the high bank through which the pilot channel had been dug and the river. A low slough separated this bar from higher ground and it was feared that the new cutoff channel might tend to follow this slough. It became necessary, therefore, to dredge through the bar a distance of 5,800 ft, thus making the total low-water length of the cutoff more than 20,000 ft.

Opened on April 8, 1934, nearly a month after the opening of Marshall Cutoff, on a medium high-river stage, on April 10, Willow Cutoff discharged 68,000 cu ft per sec, representing 8% of the total for the river. During the

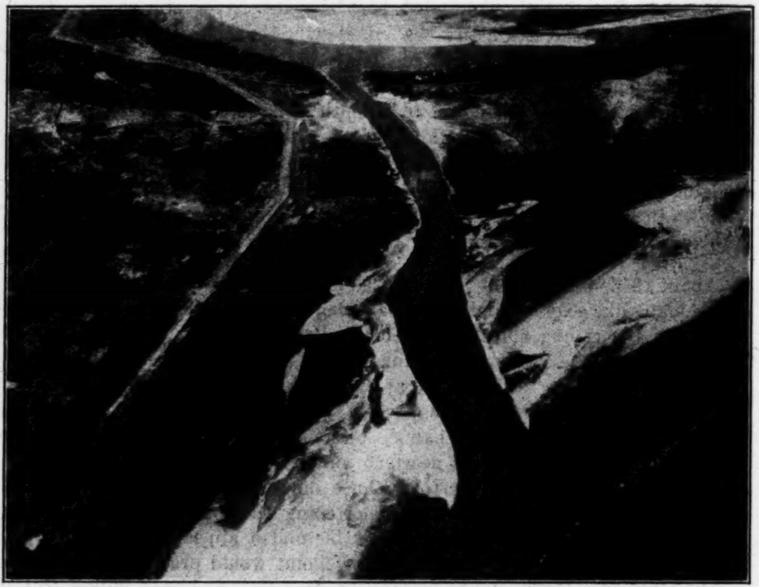

FIG. 5.—WILLOW CUTOFF FACING UPSTREAM, LOW WATER, OCTOBER 25, 1935

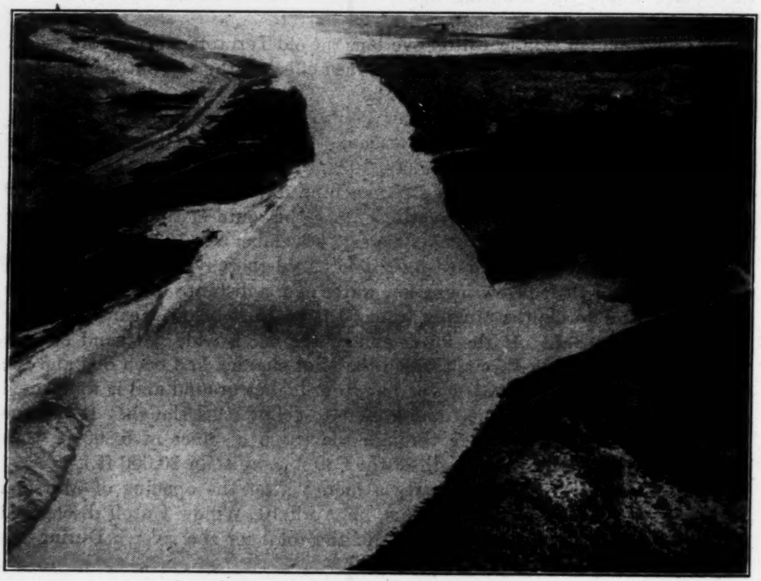

FIG. 6.—WILLOW CUTOFF FACING UPSTREAM, LOW WATER, JULY 23, 1940

low-river stages that followed in June, lack of depth caused the percentages to fall as low as 2% and 4%; but, after dredging, these percentages increased appreciably during increasing river stages. The development of the discharge capacity of Willow Cutoff is best gleaned from the data in Table 1(*b*).

As was the case for Marshall Cutoff some supplementary dredging was required soon after the cutoff began to function. It was necessary to cut the bottom to 40 ft below mean low water at the center and to 22 ft at the ends. A view of this cutoff photographed on October 25, 1935, is shown in Fig. 5. Later, in June and July, 1938, a dredge was returned to the cutoff to remove a tough clay deposit in the bottom at its upper end, which had resisted the cutting action of the current and retarded development. On one other occasion, in 1936, a dredge was operated to enlarge and shape up the entrance.

In 1933, prior to making the pilot cut, the distance around Willow Point was 13.1 miles measured from the head to the foot of the pilot cut. After the 1937 flood the cutoff channel had a length of 4.7 miles measured between the same points as in 1933, indicating a net river shortening of 8.4 miles. By 1939 distances had changed so as to make the shortening nearer 7.7 miles.

At the crest of the 1934 high water, shortly after the pilot cut began to function, the hydraulic slope in the cut was 1.18 ft per mile. During the crest of the great 1937 flood, this slope had flattened to 0.53 ft per mile. In 1939 the flattening had become complete, the slope at the crest of the flood being only 0.36 ft per mile—practically the same as that of the Mississippi River in that latitude. Previous to 1937, velocities in the cutoff during high stages ran as much as from 7 to 9 ft per sec, and boats at such times preferred to travel via the bend when headed upstream. Except for these first 3 years Willow Cutoff has been easy to navigate by commercial tows. Fig. 6 is a view of this cutoff as of July 23, 1940.

TABLE 2.—EFFECT OF CUTOFFS ON THE 50-MILE LENGTH OF THE RIVER SHOWN IN FIG. 2

Year	Interval (years)	LENGTH, IN MILES		Remarks
		River	Lengthening	
1765		71±		
	55		7	Only one cutoff, the Yazoo, occurred in this period. The net effect is not known, but is presumed to have been more than 10 miles.
1820		68		
	62		11	In this interval Terrapin Neck Cutoff shortened the river 16 miles and Centennial Cutoff, 6 miles—a total of 22 miles.
1882		57		
	34		6.8	Albemarle Chute (known as Newman Cutoff) shortened the river nearly 5 miles.
1916		58.8		
	13		0.7	No cutoffs occurred in this interval.
1929		58.1		
	16		2.7	Marshall and Willow cutoffs in 1934 shortened the river nearly 12 miles.
1945		48.8		

RIVER SHORTENING

The effect of these six cutoffs on the length of the stretch of river in Fig. 2 raised many questions, because the sum total of the shortenings amounted to more than the total present equivalent length of river. In the course of the 80 years under consideration the lengthening processes due to river meandering offset in part the total net shortenings effected by the six cutoffs (see Table 2). For this purpose the nearly 50-mile reach from Vicksburg to Lake Providence, La., had to be considered as no statistics were available for individual parts of it.

RIVER STEEPENING

Such steepening as was caused in the Mississippi River by the development of Marshall and Willow cutoffs, and by the cutoffs below, was slight and at most temporary. The river soon re-established its natural slopes in this section as may be seen from Table 3.

TABLE 3.—FLOOD-CREST SLOPES IN THE REACHES ABOVE CUTOFFS

Year	(a) UPSTREAM FROM WILLOW CUTOFF TO LOWER END OF OPPOSUM CHUTE		(b) UPSTREAM FROM MARSHALL CUTOFF TO LOWER END OF WILLOW CUTOFF	
	Distance, in miles	Slope, in ft per mile	Distance, in miles	Slope, in ft per mile
1929	33.62	0.333	14.45	0.339
1933	33.62	0.301	14.45	0.359
1935	30.46	0.334	7.65	0.340
1937	31.98	0.319	7.65	0.315
1939	30.25	0.341	7.38	0.355

FLOOD-STAGE LOWERING

The flood-stage lowering effected in the river immediately upstream from Willow Cutoff in April, 1936 (two years after the cutoff began to function), amounted to nearly 2 ft for about a bankfull flow. Marshall Cutoff similarly caused a reduction of about 1 ft. These data are based on the reduction in fall observed within the cutoffs.

Actually, the total amount of flood-stage lowering in this part of the river is on the order of that observed on the Vicksburg gage—that is, from about 7 ft to 8 ft, varying with stage conditions. The total lowering is transmitted upstream from the five cutoffs below Vicksburg, and represents a cumulative effect to which these cutoffs and various dredging operations have contributed, minus losses caused by the inability of the stream bed to lower itself in places. Upstream from Vicksburg seven cutoffs (including Marshall and Willow), plus channel improvements, increase the stage lowering progressively until on the Arkansas City, Ark., gage their cumulative effect amounts to a decrease of from 12 ft to 13 ft in flood stages as compared to equivalent river discharges in 1933.

Flood-stage reductions have been of inestimable benefit to backwater farmers; they have released millions of dollars for raising levees; and, by dispensing with a floodway on the west side of the river, they have saved a large area of productive lands from needless overflow. Furthermore, floodwater travel has become accelerated. In the reach from Arkansas City to Natchez alone, the time of travel of flood crests has been shortened several days.

The cutoff program was inaugurated in 1932 as part of the work of stabilizing the navigable channel of the Mississippi River. The first artificial cutoff to be opened was at Diamond Point below Vicksburg on January 8, 1933. The cutoff program progressed rapidly, as may be noted from Table 4. By 1939, thirteen river bends, totaling 156.5 miles, had been abandoned between the mouth of the Arkansas River and Baton Rouge. The aggregate length of the thirteen new channels across the necks amounted to 40.7 miles, thus accounting for a net shortening of 115.8 miles, measured at bankfull stage, in what formerly was a 462-mile river distance.

In 1946 there were sixteen cutoffs in operation, three having been constructed in 1941 and 1942 between the mouth of the Arkansas River and Memphis. The sixteen cutoffs together have shortened the Mississippi River 151.9 miles between Memphis and Baton Rouge; but, in addition, other river improvements (notably chute enlargements accelerated by dredging operations) have created further shortenings, decreasing the total length 170 miles between Memphis and Baton Rouge. This value represents the length by which the low-water navigation channel between these two cities has been shortened. In 1932 the river distance between Memphis and Baton Rouge was about 680 miles.

[a] "Above Heads of Passes," the starting point for river distances established in 1942. [b] As of date of opening cutoff. [c] At bankfull high water in 1937. [d] At bankfull high water in 1940. [e] In 1937 the high water fall was 4.7 ft. [f] Actual fall on August 28, 1936 was 10.6 ft, at low water. [g] Natural cutoff; no artificial channel was dredged.

In view of the undesirable aftereffects which have repeatedly been experienced at artificial cutoffs made on other rivers, concern has been expressed regarding the wisdom of launching an extensive cutoff program on the Mississippi River. Prior to the beginning of the present development, a study was made of the difficulties and liabilities experienced at cutoffs elsewhere, and a clear understanding was gained regarding the pitfalls to be avoided. In the first place, it became clear that the river should not be straightened unduly. To straighten it deliberately in time would have tended to convert the Mississippi River into a shallow stream 3 or more miles wide, interspersed with many islands and bars separated by interlacing channels. Such a "braided" river would have impaired navigability to the point of forcing its abandonment; yet a perfectly straight channel alinement from Cairo to the Gulf of Mexico has not been without its proponents.

The conception also existed that water flowing through a cutoff raised stages downstream by "piling-up." Instances were cited where this had been actually witnessed in early days when the river broke through a narrow neck of land during a high stage. It was important, therefore, to avoid inviting these "piling-up" effects and this result was readily accomplished through the adoption of the pilot-cut principle as previously explained.

Another "bête-noire" in cutoff procedure—namely, loss of valley storage—had to be avoided as much as possible. The retirement of a series of large river bends by cutoffs in time obviously would rob the river of millions of acre-feet of useful valley storage, and would tend to raise flood stages at points downstream. This problem was solved by leaving the retired bend-way channels wide open—thus permitting floodwaters to enter them, flow around the old bends, and flood the land back to the levees as in the past. The preservation of this valley storage, although diminished somewhat by a reduction in flood stages, proved to be a wise forethought on the part of General Ferguson. The valley storage remaining available still is vast and constitutes an important asset in the general plan. At cutoffs made as early as 1933 or 1934, which have since become full-size Mississippi River channels, water still continues to flow through the abandoned bend-way channels during high stages and may continue to do so for an indefinite number of years.

SUMMARY

The cutoff history of the 50-mile reach described was selected as the topic of the paper because it brings out strikingly the vast difference between the art of cutoff procedure as originated by General Ferguson, and nature's unrestrained art. It is the difference between a conservative, gradual process, at all times under complete control, and a cataclysmic way of producing a new channel in a matter of days.

Marshall and Willow cutoffs are examples of safe engineering practice applicable to large meandering rivers, but furnish no criterion for problems of this kind in small streams. The success and simplicity of the work at Marshall and Willow cutoffs must not be taken, however, as representative of all Mississippi River cutoff operations. In many instances, adverse physical conditions—some of them natural, others man made—called for considerable departure from the methods and principles employed at Marshall and Willow, and in some cases these departures affected, in large part, the cutoff project as a whole.

The original plan contemplated opening the principal cutoffs downstream from Vicksburg ahead of those planned at points upstream. This was for the purpose of developing, in the lower river, adequate capacity for transporting the increased sediment load that was expected to result from upstream operations. The plan of procedure has remained fundamental, but it was marred in a few instances by unforeseeable events. Thus, Leland Cutoff, at the foot of the famous Greenville Bends, had to be constructed more than a year ahead of schedule because of an unexpected break in Leland Neck during the summer of 1933. Adventitious as regards both time and place, Leland Cutoff forced a complete revision to be made of the original rectification plan for the Greenville Bends. Moreover, Leland Cutoff had severed an extremely narrow neck, which was contrary to the principles laid down. In the revised plan it became necessary to place a cutoff at the head of the Greenville Bends across Ashbrook Neck—another perilously slender neck. Complex problems have resulted from this situation which in turn have called for large expenditures in dredging and revetment work. Another cutoff that had to be constructed a year ahead of schedule was located across Worthington Point. Here, a rich agricultural area on the east bank had demanded relief from the rapid bank caving in Kentucky Bend, and hope had been entertained that the cutoff might alleviate this threat by causing the river to shift its main channel over to the west bank.

Contrary to plan, also, was the exceedingly slow development of the cutoff farthest downstream—Glasscock, the second artificial cutoff to be opened. In 1938, 5 years after it was opened, despite repeated dredging, Glasscock Cutoff was carrying only one third of the total river discharge. Resistance to erosion on the part of the thick mantle of claylike alluvium which prevails in the southern part of the valley was responsible for retarding its development. Agreeably contrary to expectation, however, little or none of the sand liberated at upstream cutoffs and at other rectification operations appears to have affected Glasscock Cutoff. It is presumed that this sand, in large part, was deposited by the river in the abandoned bends which purposely had been left open to serve as sand depositories.

In conclusion it is desired to emphasize that the principal objective of the cutoff program has been to lower flood stages, and that the lowerings that have been so effected have fully met the original estimates made in 1930. In future years, when river bends lengthen into new loops, additional cutoffs will doubtless be required to maintain the flood-stage lowerings effective as of 1946. The rate at which such new cutoffs will be needed of course will depend upon the rate at which river lengthening takes place, and cannot be forecast reliably. The 1944 plan[3] of stabilizing riverbanks by applying suitable revetments to resist bank caving, should be of material assistance in postponing the time when additional cutoffs will be needed in the stretch of river shortened by the sixteen cutoffs listed in Table 4.

ACKNOWLEDGMENT

The photographs in this paper were taken by the U. S. Army Air Corps and were made available, for use in this paper, by the Mississippi River Commission.

DISCUSSION

W. E. Elam,[4] M. ASCE.—As complete a summary of the Mississippi River cutoffs as could be desired is contained in this paper. However, the political situation involved was not revealed as much as merited.

Two great needs brought about this development in flood control plans. Protection from floods, beginning at New Orleans, La., about 1717 and gradually working northward, was the first factor and was undertaken solely by state and local interests. Flood control remained a local responsibility until about 1917, when the first Flood Control Act was passed by Congress and the federal government accepted about 50% of the burden of levee construction. The great flood of 1927 brought the realization that flood control was a national problem and responsibility.

Navigation is the second factor and had its inception in 1879, when the Mississippi River Commission was set up by Congress to foster and develop navigation. Flood control was not considered to be a function of the Commission. Local interests were left with this part of the problem; they willingly accepted the responsibility until recurring disasters demonstrated that the federal government had to solve the problem or this great alluvial valley would be destroyed as a national asset.

The effort by two agencies, with different objectives, resulted in confusion and failure to attain flood protection. Navigation interests caused the Mississippi River Commission to be established and probably were opposed to cutoffs, believing that lengthening the river would produce a sluggish river, which would best serve the needs of navigation. This could have been the reason the Commission adopted the policy of preventing cutoffs. Reports and papers supporting this policy have added confusion to an already complicated problem. Even the official reports after the 1927 flood specifically rejected cutoffs as aids to flood control. Local authorities followed the lead of the official reports and also condemned cutoffs. Too much credit cannot be given Maj.-Gen. Lytle Brown, M. ASCE, formerly Chief of Engineers, and Maj.-Gen. H. B. Ferguson, M. ASCE, formerly President of the Mississippi River Commission, for adding cutoffs to the flood control plan when the entire valley officially opposed their use. This one feature made flood control possible.

Only one small part of the problem was covered in the discussion of the Greenville Bends[2] mentioned by Mr. Matthes. However, the conclusions in that discussion broadened the scope of the paper considerably. An article in *Engineering News-Record*[5] went into the matter more fully and considered the problem of the entire river from Cairo, Ill., to the Gulf of Mexico. This same subject is also covered in a book.[6]

The conclusion that the river tends to return to a certain length may not be strictly true. The function of the river is to carry water to the sea. The Mississippi has always brought along soil, sand, and gravel which fills the alluvial valley to a gradual slope from the upper end to the Gulf of Mexico. This material is shoved out of the main channel or deposited in slack water to form bars, generally on the concave side of bends. Bars thus formed on the points cause the caving of opposite banks. Some of these caving bends above and below a point tend to approach each other and eventually to produce a natural cutoff. As Mr. Matthes has stated, some of these proved disastrous. However, if these same cutoffs had been laid out intelligently, they could have been beneficial.

[5] "Flood Control Through Slope Correction," by W. E. Elam, *Engineering News-Record*, June 28, 1928, p. 996.

"Speeding Floods to the Sea," by W. E. Elam, Hobson Book Press, New York, N. Y., 1946.

There is the possibility that man could well select a length of river that would produce a maximum flood control benefit with a minimum interference with navigation. Data to do this are probably in existence. Recognition should more often be made of the facts that the Mississippi River carries water, silt, sand, and gravel and that all these move irresistibly together and all must be taken into account if the caving bank situation is to be mastered. With the mass of reports and writings about the Mississippi, framed about the old theory that cutoffs would surely breed disaster, it is little wonder that much confusion still exists and progress is being halted by old theories based on erroneous assumptions. The Army Engineers and the Mississippi River Commission probably will eventually clarify this situation since these groups seem best qualified to work out a balanced long time program. They are on the right track, but many details yet remain to be fitted into the picture.

Mr. Matthes' estimate of the lowering of flood stages due to the cutoffs is about as accurate as any. There is no way to estimate the effect accurately. Flow conditions have been so altered that even the rates of runoff and of discharge are not comparable. What many engineers call "valley storage" is a part of the discharge area where the velocity is checked in the wide overbank channel. Valley storage is beneficial. Storage in the backwater areas is detrimental. The vast volume of water withdrawn into these areas in advance of the maximum discharge merely served to hold the river stationary at these points longer. If another flood formed in the valley in a week or ten days, as frequently happened, higher stages resulted than would have if the water had been kept out of the backwater areas.

The river seems to have done a much better job than expected in transporting and moving the detritus out of the channel. It is possible that the increase in velocity kept much of this material from dropping in unwanted places. It is noted that, in certain reaches, such as Sessions, or Francis (mile 604 to 612 "Above Heads of Passes"), there is a tendency for an excess of detritus to clog the channel and to cause excessive caving. Probably the best treatment for this condition would be to shorten the river, where possible, at these points. Thus, the carrying capacity of the river should become more uniform and at the same time the old channel should absorb a lot of the excess detritus. It may be that more shortening has been effected than is necessary; but, as Mr. Matthes states, gradual lengthening rapidly will compensate for this condition. It is far better this way.

C. L. Hall,[7] M. ASCE.—The reasons that led to creation of artificial cutoffs on the Lower Mississippi River are clearly stated in this paper, which also well describes the methods of accomplishing these channel changes. There seems to be nothing to criticize in the paper—as far as it goes.

---

[7] Col., Corps of Engrs., Beach Erosion Board, Washington, D. C.

Mr. Matthes states (see heading, "River Steepening") that "it became clear that the river should not be straightened unduly" and also that "a 'braided' river would have impaired navigability." Cutoffs are essentially instruments for straightening the river, although perhaps not unduly. Obviously, however, the tendency of the actions taken is toward "braiding" and the consequent impairment to navigability must be resisted by increased maintenance. Since the beneficial effect of the reduction of floods caused by the cutoffs is purely economic in character, there is no way of determining the net benefit except by comparing the value of the flood reduction secured with the additional costs of maintenance. Any flood control works made unnecessary, or any maintenance costs reduced in amount by the new scheme, constitute, of course, part of the value of flood reduction.

A judgment on the utility of the plan therefore requires answers to three questions:

(1) How much are costs of channel maintenance increased by cutoffs?
(2) What flood control works are made unnecessary by the plan?
(3) To what extent is levee maintenance reduced?

There is nothing in the paper to show that these questions have even been propounded: There is certainly no sign of an answer to them. Until the questions are answered, it is probable that the members of the profession will reserve opinion on the question of cutoffs.

H. D. Vogel,[8] **M. ASCE.**—Several reasons have been outlined for the earlier, uncompromising attitude of the Mississippi River Commission with respect to cutoffs. Principal among these was the fear engendered by observations on cutoffs that had occurred naturally during high water periods. However, it should also be recalled that, until the Flood Control Act of 1928, funds appropriated by Congress were too limited and restricted as to use to do the research and the investigational and experimental work necessary to find a solution to the problem. The only money available in any amount was that appropriated for the benefit of navigation; nevertheless, the existing levees had to be protected against incursions by the river at its bends. Revetments could be placed as aids to navigation; hence, revetments were placed and bends were held.

Plans for the United States Waterways Experiment Station were made in the summer of 1929 at Memphis, Tenn. By December of that year it was decided to build the station in Vicksburg, Miss. Early in December, as director-elect of the station, the writer visited Yucatan Point with the late Gen. T. H. Jackson, M. ASCE, then President of the Mississippi River Commission, who decided to desist from attempts to prevent the upper bend of the Mississippi River from cutting through into the channel of the Big Black River. Such a cutoff would develop slowly and would not endanger any levees. By permitting the break-through to occur, the Big Black River would act as a natural pilot channel across the neck of Yucatan Point to the lower bend. The cutoff of the Mississippi River into the Big Black River occured between December 25, 1929, and January 1, 1930. This, the first cutoff on the Mississippi River deliberately made by man (for the decision to withhold action against it constituted action for it), occurred quietly and without attendant catastrophe.

---

[8] Col., Corps of Engrs., U. S. Army, Washington, D.C.

Encouraged by observations on the Yucatan Cutoff, General Jackson ordered that a model of the Greenville Bends be built and tested by the U. S. Experiment Station as one of its first two studies. The Greenville Bends model was built during the summer of 1930 and operated throughout the succeeding fall and winter.

Results of tests with this model are indicated in the following excerpt from an article in *Engineering News-Record:*[9]

> "The [Greenville Bends] model showed a maximum lowering of 2.2 ft. due to a cutoff at Tarpley Neck, the influence being felt for a distance of 45 miles above with no change below. This was in almost direct contradiction to the old theory, offered first in this country by Humphreys and Abbott, that stages are increased below a cutoff by the same degree they are decreased above.
>
> "The model gave no indication of detrimental effects due to cutoff, but on the other hand showed a slight tendency toward improved conditions at Leland Neck. The reduced head above Leland Dike, produced by a cutoff at Tarpley, relieved the strain on that structure to some degree and resulted in lowered velocities through it. It is to be expected that Chicot Point will will be severely attacked by increased currents through the cutoff; but if erosion occurs, it will be along the line of a shallow chute now existent, and revetment of the east bank will resist attack. Erosional adjustments that follow will produce a sinuous channel in due course of time."

Encouraged by results of the experiments with models of the Greenville Bends, General Jackson began plans for an artificial cutoff across Diamond Point; and comprehensive model tests of an extensive river reach were ordered in the spring of 1932. Actual field work on the cutoff was begun during the following summer, shortly before General Jackson was relieved by Maj.-Gen. Harley B. Ferguson, M. ASCE, as President of the Mississippi River Commission. General Ferguson pushed the work on Diamond Point with such energy that the final break-through was effected on January 8, 1933.

General Ferguson, also, immediately upon taking office as President of the Mississippi River Commission, ordered comprehensive studies directed toward the creation of a whole series of cutoffs throughout the length of the lower river. Mr. Matthes, who came to Vicksburg with General Ferguson, has told the story from this point.

In commenting upon the work begun by General Jackson, there is no desire or intent to detract from the accomplishments of General Ferguson. The final result—control of the Mississippi—is important enough to provide undying glory for both. General Jackson pioneered the way, overcoming prejudices and fears of long standing; General Ferguson, with indomitable courage, applied the lessons developed by General Jackson's tests to the river as a whole. Mr.

[9] "Application of Model Research to Mississippi Flood Problems," by Herbert D. Vogel, *Engineering News-Record*, July 16, 1931, p. 87.

Matthes, in characteristic fashion, has declined to describe his own role in this great engineering development. It was he, however, who stood always beside General Ferguson when he was criticized for going too far and too fast. It was he who interpreted many of the laboratory results and put them to practical application. His present paper comprises a valuable contribution both to engineering knowledge and to the Mississippi River history.

Harry N. Pharr,[10] M. ASCE.—A statement of the purpose and a clear description of the effect of the cutoffs made on the Mississippi River are presented in this paper.

The conception that the effect of a cutoff is to raise the stage downstream arises from the fact that, as the stage rises in a stream of varying slopes, the water surface tends toward a uniform slope. Until the cutoff in its process of development regulates the disarranged alinement, slope, and section of the stream channel, the velocity of the current immediately below the cutoff is somewhat retarded, the impetus of the stream is diminished, and the tendency there is to increase the stage. This effect extends a short distance downstream to about the point where the regular alinement, slope, and section of the stream are reached. In a series of cutoffs within the influence of each other this result is modified except at the cutoff farthest downstream. The effect of the decrease in valley storage, because of stage reduction resulting from the cutoff, on the increase in stream discharge below the cutoff diminishes with the usual occurrence of slight daily rises and increase in duration of stage near the flood crest.

Immediately above its location the effect of a cutoff is to increase the velocity of the stream, to lower the stage, and, in some situations, to increase the tendency to cave the concave bank. Below bankfull stage the action of drawing the current away from the concave bank and across the toe of the opposite point bar is not effective in some situations beyond the influence of the cutoff, as at Hardin Cutoff (676 Above Heads of Passes), made in 1942. In Walnut Bend, the accelerated rate of caving along the concave bank necessitated installation of bank revetment, as the current was not materially deflected across the opposite point bar despite occasional dredging in an effort to assist in accomplishing that result.

James B. Miles was among the early advocates of cutoffs to reduce flood heights in the Lower Mississippi River. Following the disastrous flood of 1897, he proposed a plan to the Nelson Subcommittee of the Committee on Commerce of the United States Senate which made an examination, inquiry, and report on the problems of flood control and improvement of the Mississippi River.[11] Mr. Miles stated:

> "I find there are 26 places at which cutoffs could be made. Of these about 16 are such as could be made at but little cost or time * * *. The distance across these necks or narrow places is from one to three miles, except one of five miles. The cost would be in digging a ditch or canal across these necks. Some would require large and some small ditches * * *. The ditch or canal should be dug so as to turn the current of the river above as

---

[10] Civ. Engr., Member, Mississippi River Comm., War Dept., Memphis, Tenn. (Mr. Pharr died on November 3, 1947.)

[11] *Senate Report No. 1433*, 55th Cong., 3d Session, December 15, 1898, pp. 296–301.

> directly as possible into the channel or current below. About all the cutoffs have been made where the neck was narrowest. This, in most instances, has thrown the current against the bank on the opposite side so as to cause great destruction. * * * I do not claim that the river can be made straight but I claim that the distance can be reduced * * *. The distance from Cairo to the Gulf could be shortened by cutoffs some 170 miles. * * * The cutoffs between Arkansas River (mouth) and Greenville should lower the water at the Arkansas nearly or quite 10 feet."

The plan which Mr. Miles advocated is somewhat similar to the plan executed. He was not a professional engineer, but he was a student of the river. It is remarkable that, 50 years ago, he selected the exact number of cutoffs and estimated both the exact mileage reduction in length of river and about the amount of reduction in stage as that of the plan executed.

To the reasons given by the author as to why natural cutoffs were not permitted to occur during the period from 1884 to 1929 should be added the fact that, previous to the first Flood Control Act of 1917, the appropriations by Congress of funds for the improvement of the Mississippi River were generally restricted to works in aid of navigation; works solely for the purpose of flood protection were prohibited. Levees had been constructed as auxiliaries to the plan of channel improvement. This resulted in the adoption of a policy of stabilization rather than a change of channel location, and any benefit to flood control resulting from works designed to aid navigation was considered incidental. Since 1917 Congress has authorized works in aid of flood control as well as works for the improvement of navigation. The principal objective of the cutoffs is the control of floods and any resulting improvement aiding navigation is usually incidental.

LYTLE BROWN,[12] M. ASCE.—The idea of making artificial cutoffs on the Mississippi River is an old one and has been put forward in the past by various people, mostly by those who had but little experience with the river.

In 1859, two officers of the Corps of Engineers, U. S. Army (Capt. A. A. Humphreys, Hon. M. ASCE, and Lt. Henry L. Abbot) made the first comprehensive study of the lower river. These two officers were among the most distinguished that the Corps of Engineers has ever furnished to the United States. Their massive report for many years was regarded as a standard in river hydraulics.[13] It contains an elaborate discussion of cutoffs based on both analysis and on the observation of natural cutoffs. The conclusion reached was unfavorable to cutoffs, but was cautiously stated, and ended with the remark that further discussion was not necessary since it was not practicable to make artificial cutoffs. At that time it was not practicable because the dragline on the hydraulic dredge had not then been developed. Gen. U. S. Grant tested the practicability of this theory opposite Vicksburg, Miss., in 1863.

The fear of injuring navigation by either artificial or natural cutoffs in 1859, when navigation was of supreme importance, made experiments with cutoffs a risky business. Experience with natural cutoffs and the authoritative report of Messrs. Humphreys and Abbot made a policy against cutoffs unshakable until 1933.

---

[12] Maj. Gen., U. S. Army (Retired), Franklin, Tenn.

[13] "Report on the Physics and Hydraulics of the Mississippi River," by A. A. Humphreys and Henry L. Abbot, *Professional Paper No. 13*, Corps of Engrs., U. S. Army, 1876.

The plan for flood control on the Mississippi following the flood of 1927 (sometimes called the Jadwin Plan) contemplated no cutoffs; and, since that plan received the sanction of Congress, radical departures from it were frought with danger.

From 1929 until 1933 there existed among some of the authorities on the river an attitude of hostility toward anything that might in any way alter the Jadwin Plan. This attitude tended toward discouraging further study of new attacks on the problem of flood control. Col. (later Maj.-Gen.) Harley B. Ferguson, M. ASCE, an officer well known to the writer (then Chief of Engineers, U. S. Army) as an able engineer willing and capable of developing a new attack on the flood control problem or other hydraulic problems, was accordingly appointed President of The Mississippi River Commission in the hope that he would not be crippled by adherence to any hard and fast ideas. General Ferguson was the first and only responsible man who ever brought to the Chief of Engineers the serious proposition to make artificial cutoffs on the Mississippi River. Whatever credit is due for a courageous effort to lower the height of floods on the confined waters of the Mississippi is due to Maj.-Gen. Harley B. Ferguson. There are many who project an idea where danger is involved but there are few with the courage to give it effect and to assume the responsibility. According to the writer's knowledge, Mr. Matthes' paper cannot be questioned in any important particular.

ANSON MARSTON,[14] PAST-PRESIDENT AND HON. M. ASCE.—The writer is keenly interested in this paper on "Mississippi River Cutoffs." Early in 1932, Maj-Gen. Lytle Brown, M. ASCE, then Chief of Engineers, appointed a three-man Mississippi River Engineering Board of Review to restudy and to report upon the "Jadwin Plan" for Mississippi River flood control, which had been adopted by Congress after the great 1927 flood. The Board members were the then Brig-Gen. Harley B. Ferguson, M. ASCE, President; the then Col. George B. Spalding, U. S. Division Engineer at St. Louis, Mo.; and the writer, as a civilian engineer.

It should be emphasized that General Ferguson is entitled to full credit for originating in 1932, and later as President of the Mississippi River Commission for constructing, the extensive and highly successful cutoff program so well described by Mr. Matthes. That the previous Mississippi River Commission policy and much engineering professional opinion had been hostile to cutoffs was demonstrated in the 1929 ASCE Symposium[15] on flood control. Therein Col. Edward H. Schulz, M. ASCE, United States Corps of Engineers, long engaged in Mississippi flood control work, stated: "Cutoffs * * * would be a detriment to the river and are decidedly inadvisable." This had been the long continued policy of the Mississippi River Commission and was supported by prevailing engineering opinion.

John F. Coleman, Past-President and Hon. M. ASCE, stated:

---

[14] Dean Emeritus of Eng., Iowa State College, Ames, Iowa.

[15] *Transactions*, ASCE, Vol. 93, 1929, pp. 655–969.

"For the reasons stated, the writer is of the earnest conviction that levees, with auxiliary works for the protection of banks from caving, will afford the only certain method of controlling the floods of the Mississippi River."

However, in a preceding discussion,[16] Mr. Coleman indicated an open mind on trying out cutoffs "gradually," and "with caution." W. E. Elam, M. ASCE, assistant engineer, Mississippi Levee Board, and a few others advocated trying out cutoffs, but it remained for General Ferguson to begin in 1932 to design, and in 1933 to construct, the cutoffs shown in Fig. 1.

One of the early acts of General Brown's Board of Review in 1932 was to ask Brig.-Gen. T. H. Jackson, M. ASCE, then President of the Mississippi River Commission, for suggestions concerning the work. He said nothing to the Board to indicate that he was in favor of making any cutoffs to improve the river. The Yucatan Cutoff (1929) into the Black River Channel has been mentioned (see heading, "Historical") as demonstrating how a properly designed cutoff could improve the river. However, it appears that General Jackson "desisted" from efforts to close the break only after efforts to do so by willow mats failed.

By that time it had become evident that there was danger that the river would break also through the Ashbrook and Leland Greenville Necks (Miss.) in spite of the Commission's costly preventive dikes. In 1933, the river did break the Leland Neck; the writer rode through the break on a government launch down a deep and wide raging torrent within less than 48 hours after it happened.

Construction of the model of the Greenville bends was a wise move, so successful that before the Board of Review concluded its work in 1933 the model was extended to include the whole distance from the Arkansas River to Old River. However, getting ready to quit losing fights to prevent Greenville bend cutoffs was quite different from starting a planned program to improve the river by making many cutoffs. In 1933, it was the writer's privilege during a conference in Washington, D. C., with General Brown, to advise him to approve General Ferguson's plans for the other Greenville bend cutoffs, shown in Fig. 1.

The Board of Review concluded its work in 1933, by which time the cutoff program described in the paper was well under way. Evidently its success had been all that was forecast. The advantage to navigation of shortening the river 170 miles between Memphis (Tenn.) and Baton Rouge (La.) is obvious. It also is obvious that the cutoffs have materially improved the flood-carrying capacity of the river in that reach, although the exact extent is not obvious.

Also, at each cutoff two channels—the cutoff and the still open channel around the old bend—are now available to carry the flow. The advantage of having the bends open to get rid of silt is obvious, but in the past such bends eventually have silted full, or at least have become blocked off from the river by silt. It would be of interest for the author to add some discussion of this matter to his valuable paper. Are there any actual measurements proving continuing scour of the river's bed in the reaches north of Old River?

---

[16] *Engineering News-Record*, June 28, 1928.

There are some other questions on which the author doubtless can give valuable fact or opinion information. Table 1 shows that the greatest flood to June, 1945, in the Mississippi River reaches from Arkansas City (Ark.) to Vicksburg (Miss.) since the cutoffs therein were made occurred in 1937, and was about 2,000,000 cu ft per sec. It is stated[17] that the 1927 maximum flood flow at Arkansas City was 2,662,000 cu ft per sec, and a still larger future flood is possible. It would be of great interest to readers if the author would add information on the following three points:

1. What, in the author's judgment, is the present maximum flood flow in the Arkansas City-Vicksburg Mississippi River channel reaches which will not dangerously decrease the adjacent levee freeboards?
2. When the Board of Review concluded its work in the fall of 1933 it was of the opinion that, in addition to the completion of the cutoff program, an adequate floodway west of the river from below Arkansas City to Old River would be necessary to insure that part of the Mississippi Valley from flood damage by a future "super flood" of the magnitude then thought possible; it was hoped that the future developments of reservoirs above Arkansas City on the Mississippi River and its tributaries (including Arkansas River) might in time have some measurable value in reducing floods. What is the author's current opinion on this matter?
3. Fig. 1 indicates a well-developed Atchafalaya River channel from Old River to Grand Lake, although in 1932 such channel existed only part way south of Old River. Does this mean that General Ferguson's big dredges have succeeded in extending such channel clear to Grand Lake?

In conclusion, the writer wishes to say that the author is entitled to much credit for his own indispensable services in helping to plan and develop the entire admirable Mississippi River cutoff program described in the paper.

E. J. Williams, Jr.,[18] and Eugene A. Graves,[19] Assoc. Members, ASCE. —An insight into the planning and execution of the cutoffs on the Lower Mississippi River, the results as far as high-water stage reductions are concerned, the technique employed, and the pitfalls to be avoided are all presented in this interesting paper. The main objective of the cutoffs, as stated by the author, was to lower flood heights. In this they have been highly successful. Effects on low-water flow have been slight, but perhaps warrant consideration.

The low-water profile (Fig. 7) is composed of a series of alternately steep and flat slopes, which become more accentuated at lower stages. Steep, low-water slopes generally occur at the foot of shallow crossings, whereas pools between the crossings are generally so deep that very little slope is required to handle the low-water flow. The least depth available varies greatly from year to year, and in a random manner. This is more or less the nature of the river, which normally builds up its crossings during periods of high water and scours them during falling stages and low water in a varying degree, depending on a number of conditions cataloged hereafter. The slopes at the crossings are variable as they depend on: How much the crossings were built up during high stages; the rapidity of the fall; the length of crossing; the toughness of material on the bottom; the amount of dredging; and, possibly, other factors.

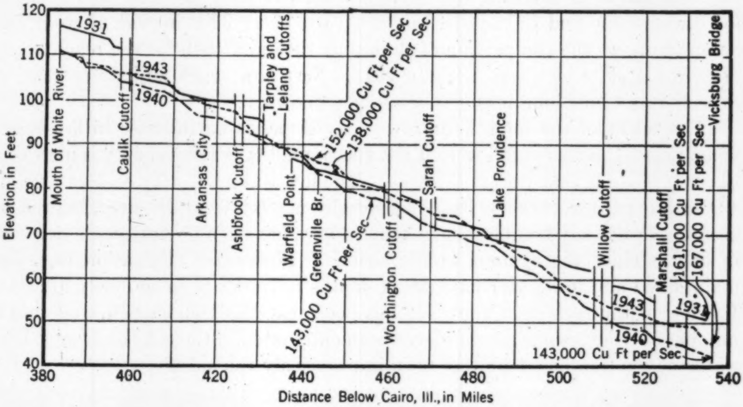

FIG. 7.—COMPARISON OF LOW-WATER PROFILES BEFORE AND AFTER CUTOFFS ON MISSISSIPPI RIVER; MILEAGE BASED ON 1937 SURVEY, BUT MEASURED THROUGH ALL CUTOFFS

The easily erodible crossings are lowered first and a large part of the fall transferred to the ones which do not erode so easily, thus making dredging necessary to assist the natural action of the river at these points. During the low-water periods immediately following the creation of each cutoff, it was necessary to perform more than the normal amount of dredging at the crossings in the upstream reach affected by the cutoff. The excess dredging requirements

[a] Distance from head of cutoff to foot of next cutoff above, measured by 1930 low-water mileage for the 1931 conditions and by 1940 low-water mileage for the 1937 and 1944 conditions. [b] Approximate discharge.

reduced rapidly from year to year, however, as the local drawdown occasioned by the cutoff was gradually distributed over a considerable reach of the river.

Table 5 shows, by comparison, the changes in slopes in the reaches immediately above the heads of the cutoffs. The slopes above the cutoffs have naturally retained some increase, but there is a tendency for the river to adjust the low-water slope and to improve the steep reaches. This is evident from Fig. 8, which shows the comparison of slopes for 1944 and 1946 for the reach above Hardin Cutoff, which was made in 1942. Just how much adjustment can be expected and how long it will take are not known.

The result of the increase in low-water slopes is an increase in low-water velocities. It does not follow that the maximum low-water velocity is increased but it is possible that such is the case. The low-water velocity seldom exceeds 4 ft or 5 ft per sec, however, and is generally much lower; also dredging can be used to correct any troublesome reach. There has been no noticeable decrease in depths since the opening of the cutoffs. Low-water navigation has been maintained and low-water navigation depths have not been seriously affected. In view of the facts that the river has been materially shortened, and that a number of troublesome reaches have been eliminated in the old bend ways, low-water navigation has definitely been improved by the cutoffs.

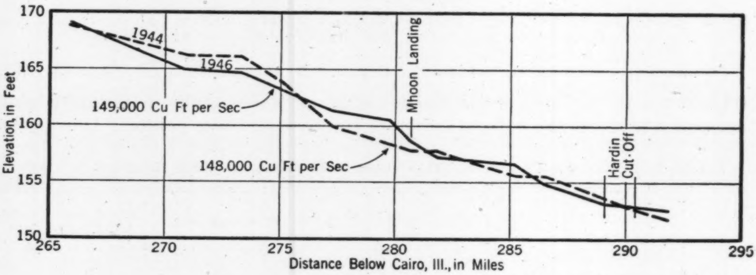

Fig. 8.—Low-Water Profiles Above Hardin Cutoff to Show Slope Adjustment After Cutoff Development

Loss of valley storage tends to increase flood flows below the cutoffs, as stated by Mr. Matthes. Leaving the old bend ways open saves only a small part of the storage, as lowerings in the backwaters, where large areas have been unwatered, have reduced the available flood storage by a considerable amount. Computations indicate that there is some increase in peak flow as a result of the cutoffs. However, cutoffs below the backwater areas combined with other developments, such as the increased capacity of the Atchafalaya River, in Louisiana, have more than compensated for the increased flow and no resultant stage increase is apparent.

In time of high water the greater depth provides over the wide crossings a large and efficient cross section for flow. The high-water slopes are more uniform than the low-water slopes, being largely independent of those channel features which predominate during low water. For this reason, during high water the lowering effect may extend a considerable distance upstream immediately after the development of the cutoff. To show any progressive changes in high-water slopes, a base year preceding the opening of each cutoff was selected and the slope for this year has been compared with the slopes for years after the opening of the cutoffs.

High-water slope data, in the form of increments of slope over the slope for the base year, are summarized in Table 6 according to the number of years intervening between the opening of the cutoff and the year in question. It will be noted that the increments shown are, in each case, the total increase since the base year and not the annual increase. Practical difficulties have precluded obtaining strictly comparable slope data over a long period of years. This has resulted in the omission of a number of cutoffs from the tabulation, which shows that the average increase in high-water slope resulting from the cutoffs is about 0.1 ft per mile. The average slope for these reaches before the cutoffs was about 0.3 ft per mile and after the cutoffs, about 0.4 ft per mile.

GERARD H. MATTHES,[20] **HON. M. ASCE.**—The discussions of this paper have served to widen the scope of the original subject matter and have been valuable in focusing attention on certain important phases of the cutoff problems not covered in the paper, as well as in calling for additional information.

Early advocates of cutoffs appear to have been numerous; among them were laymen who had become thoroughly acquainted with the Mississippi River and its modus operandi. The late Mr. Pharr, in his discussion, called attention to the plan proposed by James B. Miles in 1897. It showed a remarkably clear conception of what might be accomplished by making twenty-six cutoffs. An even earlier proposal, noteworthy for revealing the problems and trends of thought of that time, appeared in the *Weekly Vicksburg Whig* of December 28,

---

[20] New York, N. Y.; formerly Head Engr., Mississippi River Comm., and Director, U. S. Waterways Experiment Station, Vicksburg, Miss.

1859. It evidently was prompted by the occurrences of the great flood of 1858, which was followed by two more floods in 1859. It is quoted in full:

> "Cut-Offs—To the Members of the Mississippi Legislature—Gentlemen: —The subject of a general system of cutoffs on the Mississippi River, is rapidly gaining interest throughout the whole swamp country. In making laws upon this subject, the great object is to adopt a general system and not legislate for any special locality. The statute of Mississippi making it a penal offense to make cutoffs would be advocated upon the ground, that an isolated cutoff disconnected with the general system will do a great injury to the planters on either bank of the river—immediately below—nine-tenths of swamp planters are perfectly willing for such a law to remain on the statute books of both Mississippi and Louisiana—provided the legislatures of the two states make laws for a general system of cutoffs to commence below, and made whenever practicable along the river throughout the two states. I defy anyone to bring forward the names of twenty respectable swamp planters who would oppose such a measure. CATO
>
> Madison Parish, Louisiana, Dec. 19, 1859."

These two proposals show that the fruitlessness of making local changes in the river's course had been recognized early. The necessity for making continuous any corrective treatment by channel shortening was obvious. However sound, and however well accepted by many engineers, the magnitude of any comprehensive plan required deferment because of a lack of suitable dredging equipment and the great risks involved. Moreover, as pointed out by the late Mr. Pharr and by Major-General Brown, prior to 1917 federal appropriations were restricted to works in aid of navigation; flood control by use of cutoffs and levees had not then been recognized as a proper federal function. It seems appropriate to mention here that the first powerful dredge built specifically for use on the Mississippi River was designed by a member of the Mississippi River Commission, the late Henry Flad, Past-President, ASCE, who personally supervised its construction (1891–1892).[21]

Dimming recollections of the events that took place fifteen years ago apparently have caused conflicting statements to creep into some of the discussions. For the sake of historic accuracy, an effort is made herein to set divergent opinions at rest by reference to the writer's personal diaries, which fix dates and events beyond controversy. These show that the first comprehensive study of the cutoffs on the Lower Mississippi River dates back to October 24, 1930. The writer, then employed at the United States District Engineer's Office in Norfolk, Va., in charge of surveys[22] (navigation, water power, flood control, and irrigation) of certain rivers in Virginia and North Carolina, was called by Maj.-Gen. Harley B. Ferguson, M. ASCE, then Colonel and Division Engineer, to the South Atlantic Division Office at Norfolk to assist him with starting this study. It was aimed at effecting major flood-stage reductions in the Lower Mississippi River by cutoffs, and also contemplated stabilization of the new channel by the revetment of banks.

General Ferguson's conception was a bold one and without precedent for such a large meandering river. Fundamentally, however, his plan was sound, as it was aimed at preserving hydraulic gradients so as not to exceed those prevailing in stretches where the river was known to possess an "orderly channel." This term was applied by General Ferguson to designate a channel having mild curvature, free from islands and back channels, and whose shifting tendencies involved no excessive bank caving and bar building. Fundamentally sound, also, was that part of his plan which called for promoting the lowering of the river bed (and therefore the low-water profile) sufficiently, so that low-water depths needed by navigation would not become reduced. In these respects General Ferguson set up criteria which, so far as is known to the writer, had never before been promulgated in projects contemplating river shortening by cutoffs. Certainly, none of the earlier advocates of cutoffs for the Mississippi River had ever insisted on, or even suggested, the importance of lowering the river bed as an integral part of any cutoff program, or of keeping water surface slopes within the range of natural slopes.

---

[21] "Early Presidents of the Society," *Civil Engineering*, July, 1937, p. 529.

[22] *House Document No. 308*, 39th Cong., 1st Session, 1926.

He recognized that the energy developed by a body of water flowing at the rate of 1,000,000 cu ft per sec (which at that time represented the bankfull discharge of the river) on gradients of only from ¼ ft to ⅓ ft fall per mile was of tremendous magnitude; any work planned without regard to maintaining proper slopes for both bed and water surface could create conditions which, once out of hand, might well become uncontrollable. Therefore, his criteria amounted (physically) to the necessity of reconstructing the river channel at a lower elevation. To this end he planned his operations with a view to enlisting to the fullest possible extent the river's own energy in enlarging the cutoff channels and also in degrading its bed, assisting this with adequate dredging wherever clay beds or highly compacted silts resisted erosion. In 1930 a great deal of thought was devoted by him to the types of dredges that would be particularly suited to these phases of work, and by 1932 two special dredges were being outfitted. Profiles of the river bed had been prepared to study the characteristics of the succession of pools and crossing bars typical of the river.

Subsequent events have since proved the correctness of General Ferguson's judgment in regard to the ability of the Lower Mississippi River to erode its bed where it is composed of sand, and to alter its curvature in response to slight changes in hydraulic gradient. It is deemed pertinent to state that the river actually has shown itself sensitive to changes in gradient as slight as 0.01 ft per mile. This had been perceived when the early office computations in Norfolk were made. Slope figures from the start were carried out to three decimal places, and the practice developed there was generally adopted later in the office of the President of the Mississippi River Commission. The cutoff program from its inception required continuous study of slopes throughout the period that General Ferguson was connected with it. To implement this study, General Ferguson, after he became President of the Mississippi River Commission, ordered gages maintained at 5-mile intervals throughout the many hundred miles of river affected by his operations. The cost and labor involved in maintaining these gages (all referenced to sea level datum), the reading of them twice a week or more often, and the computing of the slopes represented a large investment that was felt indispensable in order that nothing be left to chance.

The chronology shows that by November 22, 1930, General Ferguson had completed for submission to the Board of Rivers and Harbors a 38-page memorandum report recommending cutoffs in the 370-mile stretch between the mouths of White River and Old River. It included provisions for extensive revetting of banks which were deemed in need of protection against the effects of the increased energy released by slope steepening. This report received consideration by the Board of Rivers and Harbors at its sessions on December 2, 1930, and January 5 and February 3, 1931 (which the writer was required to attend); on the latter date the board approved General Ferguson's report, including his recommendation for undertaking a certain amount of experimental dredging aimed at expediting the lowering of the river bed.

At this time there had developed among engineers two distinct schools of thought—those who favored cutoffs, but who felt that extended flood-stage lowerings could result only when a reasonable amount of bed lowering could be brought about, and those who opposed cutoffs, because they felt the river would not lower its bed acceptably, and that, therefore, any flood-stage lowering effected by a cutoff would soon dwindle to zero upstreamward in accordance with customary backwater computation. Col. E. H. Schulz, M. ASCE, a member of the board, went to considerable trouble to prove this limitation mathematically to the board at its session on January 5. Also, in this second school of thought were many of the engineers—both military and civil—stationed on the Mississippi River. Finally, many engineers insisted that the meandering habits of the river would soon restore the river to its former length and thus nullify all stage lowerings effected.

General Brown, then Chief of Engineers, United States Army, recognized the importance of reducing the height of floods by cutoffs, but felt that any channel improvements so accomplished should be maintained through adequate bank protection works. His attitude is clearly stated in an article[23] wherein he commented on the economic height of the levees that had been reached, and expressed the need for reducing flood heights as follows:

> "Our hope is to solve this problem satisfactorily. There are three phases of it that require careful consideration as well as physical research. They are: (1) Economical bank protection to stabilize the levee system and improve the channel conditions for navigation; (2) storage reservoirs; and (3) increased channel capacity by the elimination of bends. Of these three phases of the question, (1) and (3) are interdependent, (3) not being practicable unless (1) is solved."

The soundness of his logic has since been amply demonstrated, particularly that contained in the last sentence. Bank protection works have constituted an important phase of the cutoff project from the start. Under the direction of Maj.-Gen. Max C. Tyler, M. ASCE (then Brigadier-General), who succeeded General Ferguson in 1939 as President of the Mississippi River Commission, the cutoff work was extended farther upstream and considerable effort was devoted to developing better forms of bank protection. This effort was resumed under his successor, Maj.-Gen. R. W. Crawford, and today forms an important assignment receiving study at the Waterways Experiment Station (Vicksburg, Miss.).

---

[23] "Flood Control Work on the Mississippi," by Lytle Brown, *Scientific Monthly*, June, 1930, p. 499.

In marked contrast with the objectives of Generals Brown and Ferguson in 1931 was the attitude toward any plan involving cutoffs on the part of the late Gen. T. H. Jackson, M. ASCE, then President of the Mississippi River Commission. In an article,[24] under the heading "Channel Shortening," General Jackson recited all the disadvantages of rectification by cutoffs, but he did not so much as mention the benefits of the stage lowering that could be derived from it, concluding with:

> "In flood-control plans of the past the cutoff has played an unimportant role, and there is little prospect of it playing a more important one in the future."

Colonel Vogel evidently labored under a misapprehension when he stated in his discussion that "General Jackson pioneered the way [for the Mississippi River cutoff program], overcoming prejudices and fears of long standing * * *" and that General Ferguson "* * * applied the lessons developed by General Jackson's tests to the river as a whole." The writer can testify to the fact that General Ferguson, upon taking office at Vicksburg on June 15, 1932, found practically his entire staff strongly prejudiced against cutoffs, and, in addition, this prejudice had become extended to include many state officials and engineers of levee boards, as stated by Mr. Elam in his discussion. It is necessary also to correct certain misapprehensions regarding the cutoff experiments made at the Waterways Experiment Station in 1931. These had been ordered by General Jackson in a memorandum, dated January 2, 1931, in furtherance of a directive to him from General Brown, dated December 29, 1930.

These experiments have been referred to as helpful to the cutoff program. Aside from having demonstrated that cutoffs did not increase river stages downstream from them, the results obtained from the models were far from encouraging, and the summary of the report thereon was adverse to undertaking most of the cutoffs proposed, except for those at the Greenville Bends. Made in solid concrete models, and incapable of simulating bed and bank erosion, these experiments did little more than confirm what had previously been arrived at by that school of thought which clung to backwater computations and assumed that no changes in river cross sections would take place. In this respect these early experiments ignored the very issues that were basic to General Ferguson's plan of channel rectification and bank stabilization, particularly in regard to the importance of promoting bed erosion. Some use was made of sand and sawdust in these tests to determine where deposits were likely to form, but no thought appears to have been given to investigating the effect of lowering the river bed.

The tenor of the Waterways Experiment Station findings are best gaged by quoting from a report[25] as follows:

> "Item *e*: Any cutoff across Ashbrook Neck should be studiously avoided because of its probable effects on upstream velocities and downstream

[24] "Flood Control on Alluvial Rivers with Particular Reference to Flood Control on the Mississippi River," by T. H. Jackson, *Engineering-News Record*, January 15, 1931, pp. 107–108.

[25] "Experiment to Determine the Effects of Proposed Dredged Cut-Offs in the Mississippi River," *Report No. I*, U. S. Waterways Experiment Station, Vicksburg, Miss., April 15, 1932, pp. 13–14.

> directions of currents. * * * Cutoffs at Caulk and Tarpley Necks can do little material good in reducing stages where desired, and although no objection can be seen to letting Caulk cut through by itself, there seems no valid reason for encouraging it.
>
> "Item *f*: The cutoffs between Vicksburg and Lake Lee would be valueless and extremely expensive to dredge. No further thought should be given to them. [This relates to Marshall, Willow and Sarah cutoffs.]
>
> "Item *g*: A cutoff at Diamond Point would have several good features and no apparent bad ones. Further tests will definitely indicate the advisability of assisting, or allowing it to occur naturally. As to the other three below Vicksburg: Yucatan is already accomplished; a cutoff at Natchez [later called Giles] would be of dubious value in an already fairly stable reach; and one at Esperance [later called Glasscock] of no value at all."

In the same report[26] the model of the Greenville Bends is stated to have produced a "Maximum lowering of 9.7 feet at mile 442.9" (which was then the head of the bends) as the result of simulating fully developed cutoffs across Leland, Tarpley, and Ashbrook necks. In contrast with this an observed lowering of more than 13 ft was actually realized at that point during the great flood of 1937, and this has since increased somewhat. Similar lowerings were registered also on the Arkansas City (Ark.) gage 6 miles farther upstream in 1937. This is illustrative of the marked increase in stage reduction effected wherever bed erosion and channel adjustment were made to play their parts, assisted where necessary by dredging.

Again, Caulk, Tarpley, Giles, and Glasscock cutoffs, contrary to model results, have proved effective. Glasscock, although greatly hampered in its early development due to the tenacious character of the soil which resisted erosion to a marked degree, has caused flood stages to become lowered all of 3 ft at Natchez, Miss., 18 miles upstream, corresponding to an increase in flood discharge of 200,000 cu ft per sec for rising river conditions. In regard to the Marshall and Willow cutoffs, which the report called valueless and extremely expensive to dredge and not worthy of further thought, it is only necessary to refer to the description in the paper of the case with which the pilot cuts were made (considering their lengths), and the satisfactory results obtained. Where the laboratory results showed a flood-stage lowering of a scant 3 ft at Vicksburg, General Ferguson brought about a lowering of 7 ft (which later increased to 10 ft) by lowering the bed profile along Racetrack Towhead by dredging.

The foregoing may indicate that these early experiments were of no help to General Ferguson, being in essence entirely at variance with the latter's conception of executing the work. It was not until after General Ferguson had taken office as President of the Commission, on June 15, 1932, that the Experiment Station received instructions to prepare river models with erodible beds. A series of studies of Mississippi River problems were undertaken that summer with erodible bed models.

In further reference to Yucatan Cutoff (an occurrence long considered inevitable), the writer's mention of its having been unexpected related to the fact that the break was caused by low-water caving at a time when no one was aware of it. Not an engineer, surveyman, or pilot of the Engineer Department was present to witness it. It was many days after the break that its occurrence became known to officialdom. The exact date of the occurrence of this remarkable natural avulsion has never been established.

[26] "Experiment to Determine the Effects of Proposed Dredged Cut-offs in the Mississippi River," *Report No. 1*, U. S. Waterways Experiment Station, Vicksburg, Miss., April 15, 1932, p. 40.

It devolved upon General Brown to find a man to carry out the cutoff program together with all that was consistently and inseparably connected with it in the way of channel improvement and bank protection. Illuminating in this connection is General Brown's appraisement of the qualifications such a man should possess, as stated by him: "There are many who project an idea where danger is involved but there are few with the courage to give it effect and to assume the responsibility." He found a man who combined these qualities in General Ferguson, who not only had projected the idea, but possessed the indomitable nerve to tackle such a stupendous job and to see it through. General Ferguson stuck to his task more than seven years, until his retirement on August 15, 1939.

The location for a cutoff across Diamond Point, the first of the artificial cutoffs, was determined by General Ferguson on June 17, 1932, two days after he assumed office. In the presence of the writer he drew the center line and the width of the right of way on a map, and dictated a directive "to have work initiated this summer with a view to acquiring right-of-way and completing a cut by dredging before next high water" (from the writer's personal diary dated June 17, 1932). A conference was held on that date in his office to discuss procedure. Those present were: Col. J. N. Hodges, District Engineer, New Orleans, La., in whose district the cutoff was to be made; his military assistant, the late Lt. J. P. Dean, United States Corps of Engineers; and Maj. P. S. Reinecke of the Commission staff. If any surveys or borings had been made previously, as mentioned by Colonel Vogel, these did not come to the writer's attention.

The writer is indebted to Dean Marston for presenting the work of the Mississippi River Engineering Board of Review on which he served. Credit is due the Board of Review for having given the practicability of the cutoff program very careful consideration. Its recommendations were in large measure responsible for the promptness with which authority for the work was granted by the Chief of Engineers. The Board of Review was appointed by General Brown by Special Orders No. 16, dated March 1, 1932, by order of the Secretary of War in furtherance of a resolution by the Committee on Flood Control of the House of Representatives, dated January 28, 1932, requesting that the Chief of Engineers

> "* * * examine and review the present status and condition of the works now in progress as authorized by the Flood Control Act of May 15, 1928 * * * with a view of determining if changes or modifications should be made in relation to the project and its final execution."

The Board of Review was directed by General Brown to determine, among other things,

> "* * * (d) the practicability and desirability of increasing the discharge capacity of the main leveed channel in flood time, and at the same time improving conditions for navigation. Measures for protection against flood waters that must of necessity escape from the main leveed channel of the river as modified by any conclusions as to channel enlargement."

These items had not previously been specifically authorized, except as covered under the broad head of channel stabilization. In addition to the three Board of Review members mentioned by Dean Marston, the Special Orders designated Lieutenant Dean to serve as "Recorder and Executive." Lieutenant Dean's services, due to his familiarity with the valley and its river problems, proved of inestimable assistance to the Board of Review on its inspection trips. The writer accompanied the board as civilian assistant to General Ferguson.

The Board of Review convened at Memphis (Tenn.) on March 9, 1932, at the office of the District Engineer, the then Maj. Brehon Somervell, Hon. M. ASCE, and almost immediately started on its first trip down the Mississippi River on board the steamer *Inspector*. The flood of that year was past the crest, and the river had dropped 20 ft, permitting an excellent view of bank and revetment conditions. In the lower valley, however, stages were still very high, and General Brown was at New Orleans to study the river while it was at danger stage. The trip of the Board of Review extended down the main river to the mouth of Old River, thence through Old River down the Atchafalaya River. It included visits to two crevasses in the Atchafalaya Basin levees, the closure of which was in progress. After a visit to the Bonnet Carré spillway the trip ended at New Orleans on March 12, 1932. A second inspection trip, from May 8 to May 18, 1932, started from Cairo (Ill.) and was made partly by steamer and partly by automobile with much attention being given to problems in the St. Francis, Tensas, and Atchafalaya basins. The proposed enlargement of the Atchafalaya River to which Dean Marston referred was given considerable study on that occasion.

Answering Dean Marston's question regarding the development of the proposed enlargement as the result of the dredging operations performed, the Atchafalaya has been provided with two main channels emptying into Grand Lake by fairly direct routes. By 1940 these channels had become efficient outlets gradually replacing the previous labyrinth of bayous, thereby greatly improving flood-water outflow. The upper 56 miles of the original Atchafalaya River channel have been widened and deepened considerably through erosion by flood flow aided by supplementary dredging in places where tough bottom materials resisted erosion. The materials so scoured out in large part came to rest in the shallow waters of Grand Lake and are rapidly filling it. Two main outlets have been provided through these deposits—one by way of the old channel past Morgan City, La., and the other through a dredged channel into Wax Lake, and thence into the Gulf of Mexico. The discharge capacity of the Atchafalaya River proper has become greatly increased. During the flood of 1937 its maximum discharge confined between levees was in excess of 450,000 cu ft per sec. During the flood of 1945 discharge measurements showed further increases, the maximum flow being in excess of 600,000 cu ft per sec.

In regard to the question of leaving open the abandoned bend channels of the Mississippi River to serve as depositories for sediment and as high-water carriers and also for valley storage—these advantages are, of course, greatest and do the most good during the early development of a cutoff, but thereafter diminish in time. The resulting effects on the river are well described in the discussions by Mr. Pharr and by Messrs. Williams and Graves, and need not be restated, except to add that the Mississippi River is amply capable of transporting the entire load after the storage capacities of the bend ways become exhausted. The river is not a heavy sediment carrier compared to other western rivers; in fact, expressed in terms of parts per million of suspended load, it carries on an average only one tenth as much as the Missouri River.

Dean Marston's further requests for data are answered as follows: The planned flood-carrying capacity of the river between levees in the Arkansas City-Vicksburg reach now is 3,065,000 cu ft per sec. This is the maximum flood-crest flow estimated as possible of occurrence in that reach and was officially adopted as the revised project flow by the act of August 19, 1941. The capacity of 3,065,000 cu ft per sec is consistent with a similar maximum of 2,450,000 cu ft per sec provided for between Cairo and Arkansas City, and with a maximum of 3,000,000 cu ft per sec in the latitude of Angola (La.). The 3,065,000 value is appreciably larger than the 2,662,000 cu ft per sec, representing the estimated maximum confined flood-crest flow in 1927. The act of 1941 also provided for increases of freeboard on the main-line levees, which had become facilitated by the increases in discharge capacity. These increases made possible the further abandonment of the proposed floodways between the Arkansas River and the Red River. The 1941 standard levee requirements provided for a widening of the levee crowns to 25 ft to serve as roadways. Although much yardage remains to be placed to meet fully all these requirements, the height of the main-line levees in the Arkansas City-Vicksburg reach is now sufficient to take care of the new project flood flow.

In order to present as concisely as possible the picture of the development in channel capacity that has taken place since the first artificial cutoff was made in 1933, the approximate bankfull discharges at key points have been listed, year by year, in Table 7. The figures were estimated by inspection of the stage discharge relations for rising flood stages only, as these afforded the only meaningful comparison. The point is that falling flood stages, because of the variability they exhibit in their stage discharge relations, are not useful for comparative purposes. Falling stages, moreover, are characterized by momentary changes in discharge, corresponding to changes in the rate at which the crossing

TABLE 7.—INCREASES IN BANKFULL DISCHARGE CAPACITY AND REDUCTION IN FLOOD STAGE FOR RISING RIVER

bars are being built up, characteristic of rivers flowing in mobile beds. In interpreting Table 7 it is important to keep in mind that for falling bankfull stages the channel capacity is much less than shown, the reductions ranging from about 200,000 cu ft per sec to as much as 250,000 cu ft per sec, in some instances.

Statistically, flood-stage lowerings should be predicated on crest stages, but since no two floods are of the same magnitude in regard to crest discharge, a direct comparison is seldom feasible. In Table 8 an attempt has been made to compare the approximate increases in flood-crest stages that occurred in the past due to confinement by levees with the approximate flood-stage lowerings that have resulted since 1932 from the cutoff and channel improvement program.

The lowering of the river bed is in an entirely different category, being caused by scour, which in turn is affected by increased slope and lessened depth during floods—two factors which partly offset each other's effects. Since the bed of a meandering stream is a succession of deeps and shoals, it gives the low-water profile a step-like appearance quite unlike the smoothly curving high-

water profile. Available data show that the low-water lowering, although not as large in amount or as uniform as the high-water lowering, extends equally far upstream. Both eventually run out, and in each case the new over-all slope is steeper than the original slope before cutoffs were initiated. Table 5, supplied by Messrs. Williams and Graves, who have given this phase detailed study, shows the increases in low-water slopes that have resulted. Supplementing their data by reference to actual discharge measurements, it appears that the low-water plane for a uniform discharge of 150,000 cu ft per sec has been lowered as follows: Columbus, less than 1 ft; Memphis, about 3 ft; Helena, about 2¼ ft; Arkansas City, more than 3 ft; and Vicksburg, all of 10 ft.

As pointed out by Messrs. Williams and Graves, there has been no noticeable decrease in the low-water depths on the crossing bars since the opening of the cutoffs; what is more significant, low-water navigation has not been seriously inconvenienced. In fact, the depths on the crossing bars, throughout the length of river affected, have improved as the result of the work done, and in 1941 minimum depths of 12 ft were found to exist over most of the bars. At the few shallower crossings 12-ft depths were readily maintained by making cuts with dredges of the "dust-pan" type. In consequence, the previously prescribed 9-ft project depth between Cairo and Baton Rouge was authorized to be increased by an act of Congress on December 22, 1944, to 12 ft, leaving the 300-ft navigable width unaltered. Below Baton Rouge the old 35-ft project depth for sea-going vessels has remained in effect.

The continuity of the river-bed profile in the reaches north of Old River (to answer Dean Marston's inquiry) shows a decided improvement over that existing previous to 1933. The largest humps in the old profile have been eliminated, and the step-like succession of pools and crossings has become a gradually ascending series which possesses a considerable degree of regularity. An example of the nature of the adjustment that takes place is shown in Fig. 8. The new low-water profile shown by the heavy black line tends to approach, in the matter of spacing of pools and crossing shoals, the 5-mile interval, which in the early studies was found to be a characteristic of the river bed in its "orderly" reaches. A thin rubber band stretched over the 1946 profile in Fig. 8 will show that it averages a straight line, which is normal for a 25-mile distance.

The probable effect on the Lower Mississippi River of the flood control reservoirs in the Arkansas River watershed and on other Mississippi River tributaries is at present unpredictable. This is the writer's opinion, requested by Dean Marston. These reservoirs, however great their number eventually may become, are designed for the express purpose of providing protection to the lives and property in the valleys of the tributaries on which the dams are built, or are to be built. Operation by any coordinated plan still remains to be worked out, more particularly in regard to timing the release of the impounded floodwaters. The huge model of the Mississippi River watershed under construction by the Waterways Experiment Station at a site near Clinton, Miss., is designed specifically for shedding much-needed light on this complex problem. Furthermore, it is the opinion of the writer that the safety provided by the existing project for the Lower Mississippi River, although it may benefit incidentally from the operation of these reservoirs, is not dependent on such operation.

In answer to Colonel Hall's request for information concerning the economic aspects of the cutoff project, a segregation of costs would not be helpful because of the close interrelation of the several phases of the work. A statement follows which describes what the cutoff project has accomplished, what additional work it has entailed, and what additional improvements it has made possible that previously had remained unattainable.

River Channel.—The shortening by cutoffs and chute enlargements has eliminated excessive curvature in a river length of about 500 miles without straightening the channel unduly, or creating any tendency toward channel braiding. It has eliminated annual maintenance on 199.2 miles of abandoned bend channels, and has increased channel discharge capacity and reduced flood stages as shown in Table 7. The river bed has been lowered so as to leave low-water depths unreduced. It has made possible channel improvements by dredging which previously were not warranted economically. The amount of dredging involved runs into large quantities but has produced permanent results essential, in most cases, to insuring the full measure of benefit derivable from the cutoffs. Further operations of this kind will reduce progressively as channel stabilization advances. The yardage excavated in the pilot cuts is a small item in relation to the yardage eroded by the river in the enlargement of the pilot cuts to full-sized river channels. Likewise, the yardage dredged for improving the river channel is a fraction of what the river has removed additionally.

Banks and Revetments.—Annual maintenance on 59.3 miles of existing revetments rendered inactive in abandoned bends has been largely eliminated. On the other hand, channel deepening upstream from cutoffs, in addition to the increased force of the current due to local profile steepening, has been responsible for local bank caving and the sliding and destruction of several revetments. Further trouble of this kind must be expected until hydraulic gradients become stabilized and the attack on the banks affected ceases. In this connection it seems pertinent to emphasize again the fact that as yet no adequate type of revetment has been devised for use on the Lower Mississippi River.

Control of Floods.—Major benefits have resulted from the lowering of flood stages. Only a meager conception of the magnitude of these lowerings is afforded by reference to Table 7. It is best conveyed by stating that they have made practicable of attainment the protection against the greatest flood estimated as likely to occur without having to raise the entire levee system. In the large backwater areas, where the most fertile soils are to be found, the reductions in the frequency, duration, and depths of flooding that have resulted have insured better returns from the land and have increased land values. Along the levees, the dangers from underseepage and landside boils have been lessened as flood heights have been reduced and the passage of flood crests has been expedited. In two respects no gains have been made—namely, the total length of the main-line levees has not become reduced by the channel shortenings; and the bank caving above newly made cutoffs or by readjustments in channel alinement will continue to require setting back levees, in places, until a less vulnerable type of revetment is evolved. Perhaps the greatest economic benefit that has been derived from the reduction of flood stages is the ability to dispense with a floodway on the west side of the valley between the Arkansas River and the Old River. This has removed the threat of inundation from many thousands of acres of valuable farming land and from large stands of hardwood timber. Finally, from the viewpoint of the citizens of Greenville, the removal of the river from their door by cutting off the Greenville Bends ranks as the outstanding benefit that has accrued to any community in the valley.

Navigation.—Distinct benefits have accrued to commercial navigation. Shortening the river has reduced the time of travel at ordinary stages appreciably, especially for ascending tows, despite the slight increase in current velocities due to slope steepening. Low-water depths are better than before cutoffs were made. Time lost at points where rapid channel changes were in progress has been a temporary inconvenience. Only during flood stages is there some increase in running time, but this is offset in part by the shortened duration of high flood stages. Thus summarized, a fair conclusion must be that the benefits by far outweigh the disadvantages, and, as a federal project, the investment is economically sound.

A RATIONAL EXPLANATION OF COLUMN BEHAVIOR

BY FREDERICK L. RYDER,[1] ESQ.

WITH DISCUSSION BY MESSRS. R. ROBINSON ROWE, GEORGE WINTER, ROBERT M. MAINS, CHI-TEH WANG, ERNEST L. ROBINSON, AND FREDERICK L. RYDER

SYNOPSIS

The general method of approach is to analyze, mathematically, the elastic behavior of the simple ideal column, and then to apply the results, with suitable modifications, to the practical column. The basic differential equation is first set up, and then is integrated to yield the fundamental column formula relating axial force, moment of inertia, modulus of elasticity, length, and center deflection (Section 1).

For a given P/A-value, the variation of center deflection with the L/r-ratio is studied, for conditions above the critical point. The projected length corresponding to any value of center deflection is calculated, thus affording an approximate idea of the deflected column shape. A chart relates values of P/A, L/r, projected length, and center deflection. Finally, the exact shape of a typical ideal column is computed, and is shown to be similar for all ideal columns having the same relative center deflection (Section 2).

It is next shown that, above the critical point, the basic differential equation is satisfied if the column is (*a*) straight, or (*b*) deflected to the position dictated by the fundamental column formula. The stability of the column in these two positions, and in fact in any position, is analyzed by a detailed study of the internal moments caused by deflection and the external moments caused by the axial force. It is shown that only one position of the column is stable—the position corresponding to the fundamental column formula. The analysis also re-emphasizes the well-known fact that at the critical point the deflection is indeterminate (Section 3).

For conditions below the critical point, a chart relates the factor of safety of an ideal column to the P/A-value and the L/r-value. The differences between the practical and the ideal column are next discussed; and the analytical

NOTE.—Published in March, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Development Engr., Shirgun Corp., New York, N. Y.

solution for the deflection and stresses of a column having end eccentricity, initial deflection, and transverse loading is obtained. The "step-by-step" method for the numerical solution of practical column problems is then presented in detail and is applied to two typical problems (Section 4). Stresses and factor of safety in a column loaded above the critical point are discussed (Section 5).

INTRODUCTION

Most of the familiar and widely used column formulas are essentially based on the results of tests. They are convenient for predicting column action under certain important conditions, but they are not intended to present the rationale of column behavior. For example, some questions that cannot be answered by ordinary column formulas are:

A. Why do columns buckle suddenly at the critical load?
B. What are the actual stresses in the column?
C. How do columns act above the critical load?

These questions, and others of similar interest, can be answered by an a priori mathematical analysis, without recourse to test results. In fact, a complete solution of the elastic behavior of a simple column can be deduced mathematically from the given statical condition of the column. It is the writer's purpose to trace the mathematical steps leading to this solution and to interpret the results in terms most useful to the average engineer.

As a supplement to the theoretical discussion, the powerful and universally adaptable step-by-step method of solving practical column problems is included in the argument on actual stress and factor of safety.

The scope of this paper, then, is twofold:

1. To explain the mechanism of column behavior by mathematical analysis; and
2. To present a widely applicable method for the solution of practical column problems.

Notation.—The letter symbols in this paper are defined where they first appear, in the text or by diagram, and are assembled alphabetically in the Appendix. Discussers are requested to adapt their notation to this form.

1. THE FUNDAMENTAL DIFFERENTIAL EQUATION AND ITS INTEGRATION

The column shown in Fig. 1(*a*) is assumed to be perfectly straight initially, and is of homogeneous material having the modulus of elasticity, E. The cross section and therefore the moment of inertia, I, are constant. The resultant of the load P acts through the centroid of the cross section, thus insuring that P does not produce moment at the ends of the column. The length of the column, measured along the curve, equals L.

The column is shown in a transversely deflected position, δ being the deflection at the center. At any point, such as A, the column feels the moment:

$$M = P\,y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1a)$$

According to familiar theory in the strength of materials, the moment at any point of an initially straight member equals:

$$M = -E\,I \times \text{(curvature)} \ldots\ldots\ldots\ldots\ldots\ldots (1b)$$

For present purposes, curvature is advantageously considered the "rate of change of slope per unit of length along the curve." Referring to the triangle of infinitesimals, Fig. 1(*b*):

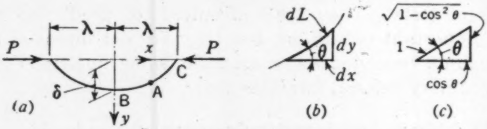

FIG. 1

$$\text{(Curvature)} = \frac{d\theta}{ds} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1c)$$

in which ds is the differential of length of the curve; and θ is the angle of slope or

$$\theta = \tan^{-1}\frac{dy}{dx} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Combining Eqs. 1:

$$P\,y = -E\,I \times \frac{d\theta}{ds} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Eq. 3 is the fundamental differential equation of the elastic curve of the column, and forms the basis for the present analysis.

Certain assumptions and omissions are implicit in Eq. 1*b*:

a. Only the curvature caused by bending moment is considered in Eq. 1*b*. With the column in a deflected position, the curvature will be somewhat affected by shearing forces. However, the curvature caused by shear is usually very small compared to the curvature caused by moment, and will therefore be neglected.

b. Eq. 1*b* is not strictly true for a member with appreciable curvature.[3] The error is not important, however, if the ratio ρ/c remains larger than about 10, in which ρ is the radius of curvature and c is the distance from the neutral axis to the extreme fibers. For small deflections this error is negligible. Large deflections, and consequently large curvatures, will affect the results slightly.

c. The modulus of elasticity, E, is assumed to be constant, necessitating the maximum stress in the column to be less than the proportional limit of the material.

---

[3] "Advanced Mechanics of Materials," by Fred B. Seely, John Wiley & Sons, Inc., New York, N. Y., 1932, Chapter VII.

Eq. 1*b* is often used in the simplified form:

$$M = -EI\frac{d^2y}{dx^2} \qquad (4)$$

in which $\frac{d^2y}{dx^2}$ is made equal to the curvature. The true expression for the curvature in terms of $\frac{d^2y}{dx^2}$ and $\frac{dy}{dx}$ (see any calculus text) is:

$$(\text{Curvature}) = \frac{\frac{d^2y}{dx^2}}{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2}} \qquad (5)$$

The curvature is $\frac{d^2y}{dx^2}$ only when $\frac{dy}{dx} = 0$—that is, when the member is perfectly straight. Therefore, Eq. 4 is not valid when the member has an appreciable deflection. The simplified Eq. 4 yields limited and imperfect results in the case of an ideal column, but is basically important in the solution of problems involving the practical column.

The first step in the integration of Eq. 3 is the elimination of one of its three variables. By Fig. 1(*b*),

$$ds = \frac{dy}{\sin\theta} \qquad (6a)$$

Substitution in Eq. 3 yields:

$$Py = -EI\frac{d\theta}{dy}\sin\theta \qquad (6b)$$

In Eq. 6*b*, if—

$$k^2 \equiv \frac{P}{EI} \qquad (6c)$$

—it follows that

$$k^2\,y\,dy = -\sin\theta\,d\theta \qquad (6d)$$

Integrating Eq. 6*d*,

$$\frac{k^2y^2}{2} + C = \cos\theta \qquad (7)$$

in which C is an arbitrary constant. If $y = \delta$ then $\theta = 0$ (by symmetry), and $\cos\theta = 1$. Substituting these values in Eq. 7:

$$C = 1 - \frac{k^2\delta^2}{2} \qquad (8a)$$

Rewriting Eq. 7:

$$\cos\theta = 1 - \frac{k^2}{2}(\delta^2 - y^2) \qquad (8b)$$

Eq. 8*b*, the result of the first integration, expresses a relation between the angle of slope (θ), the deflection at the center (δ), and the deflection (y) at any point. The object of the next integration is to eliminate θ, an unknown, and to introduce L, the total length of the deflected column, into the equations. By similarity (Figs. 1(b) and 1(c)):

$$\frac{ds}{1} = \frac{dy}{\sqrt{1 - \cos^2 \theta}} = \frac{dy}{\sqrt{(1 + \cos \theta)\,(1 - \cos \theta)}} \quad \ldots\ldots\ldots\ldots (9a)$$

Using Eq. 8b:

$$ds = \frac{dy}{\sqrt{\left[2 - \frac{k^2}{2}(\delta^2 - y^2)\right]\left[\frac{k^2}{2}(\delta^2 - y^2)\right]}} \quad \ldots\ldots\ldots\ldots (9b)$$

Eq. 9b may be simplified by writing:

$$y \equiv \delta \cos \phi \quad \ldots\ldots\ldots\ldots (10a)$$

$$dy = -\,\delta \sin \phi \, d\phi \quad \ldots\ldots\ldots\ldots (10b)$$

and

$$\delta^2 - y^2 = \delta^2 - \delta^2 \cos^2 \phi = \delta^2 \sin^2 \phi \quad \ldots\ldots\ldots\ldots (10c)$$

Then

$$ds = \frac{-\,\delta \sin \phi \, d\phi}{\sqrt{\left(2 - \frac{k^2\,\delta^2}{2}\sin^2 \phi\right)\left(\frac{k^2\,\delta^2}{2}\sin^2 \phi\right)}} = \frac{d\phi}{k\sqrt{1 - \frac{k^2\,\delta^2}{4}\sin^2 \phi}} \quad \ldots (11)$$

The minus sign disappears in the numerator of Eq. 11 because $\sqrt{\delta^2}$ is selected as $-\,\delta$. Writing:

$$q \equiv \frac{k\,\delta}{2} \quad \ldots\ldots\ldots\ldots (12a)$$

it follows that

$$k\,ds = \frac{d\phi}{\sqrt{1 - q^2 \sin^2 \phi}} \quad \ldots\ldots\ldots\ldots (12b)$$

The integral of the right-hand term of Eq. 12b is known as an elliptic integral.[3] It can be evaluated only between definite limits. Points B and C in Fig. 1(a) are selected as the lower and upper limits, respectively.

Applying Eq. 10a at point B where $y = \delta$, it is found that $\cos \phi = \frac{y}{\delta} = \frac{\delta}{\delta} = 1$, from which $\phi = 0$. Likewise, at point C, $y = 0$, $\cos \phi = \frac{0}{\delta} = 0$, and $\phi = \frac{\pi}{2}$. The arc lengths s are 0 and $L/2$ at points B and C, respectively. With these quantities in Eq. 12b:

$$k \int_0^{L/2} ds = \frac{k\,L}{2} = \int_0^{\pi/2} \frac{d\phi}{\sqrt{1 - q^2 \sin^2 \phi}} \equiv K \quad \ldots\ldots\ldots\ldots (13)$$

Tabular values of K for different values of q have been prepared by B. O. Peirce.[4]

[3] "Advanced Calculus," by E. B. Wilson, Ginn & Co., Boston, Mass., 1912, p. 507.

[4] "A Short Table of Integrals," by B. O. Peirce, Ginn & Co., Boston, Mass., 3d Ed., 1929, p. 121.

Eq. 13, the fundamental column formula, expresses a relation between q, k, and L. For example, if $k^2 \equiv \frac{P}{E\,I}$ and L are known, then it becomes possible to solve for $q \equiv \frac{k\,\delta}{2}$, and hence δ can be ascertained. The implications of Eq. 13, with regard to practical engineering problems, are treated in Section 2.

2. Column Deflections Under Various Conditions

A pressing question confronts the engineer in regard to the behavior of the column: "What is the relationship of the deflection to the load P and to the physical constants E, I, and L?" With the aid of the fundamental column formula, Eq. 13, it is possible to answer this question by plotting δ/L, the relative deflection at the center, against $L/\bar{r}$, the ratio of the length to the minimum radius of gyration of the cross section. The ratio $L/\bar{r}$, of course, is the accepted criterion of stiffness for a column. (Incidentally, $\bar{r}$ should be regarded as a measure of the efficacy of distribution of the elements of cross-sectional area of the column, in so far as resistance to buckling is concerned.)

TABLE 1.—Center Deflection and Projected Length of a Simple Column

$\sin^{-1} q$ (degrees) (1)	K[a] (2)	q (3)	$L/\bar{r} = 245\,K$ (4)	$\delta/L = q/K$ (5)	J[a] (6)	$\lambda/L = \frac{J}{K} - \frac{1}{2}$ (7)
0	1.57	0	384	0	1.57	0.50
30	1.69	0.5	415	0.296	1.47	0.37

89	5.43	1.0	1,330	0.185	1.00	−0.316
90	∞	1.0	∞	0	1.00	−0.50

[a] "A Short Table of Integrals," by B. O. Peirce, Ginn & Co., Boston, Mass., 3d Ed., 1929, p. 121.

To introduce $\bar{r}$ into Eq. 6c, substitute $I = A\,\bar{r}^2$ and solve for k:

$$k = \frac{\sqrt{\frac{P}{A}}}{\bar{r}\sqrt{E}} \quad \text{.........................} (14)$$

in which P/A is familiar to engineers as the direct compressive unit stress caused by P when the column is straight.

Consider a steel column with $E = 30{,}000{,}000$ lb per sq in. and $P/A = 2{,}000$ lb per sq in. Then, by Eq. 14:

$$k = \frac{\sqrt{2{,}000}}{\bar{r}\,\sqrt{30{,}000{,}000}} = \frac{1}{122.5\,\bar{r}} \quad \text{................} (15a)$$

Referring to Eq. 13: $K = \frac{k\,L}{2} = \frac{L}{2 \times 122.5\,\bar{r}}$, or

$$\frac{L}{\bar{r}} = 245\,K \quad \text{.......................} (15b)$$

By solving Eqs. 12a and 13 to eliminate k:

$$\frac{\delta}{L} = \frac{q}{K} \quad \text{...........................} (16)$$

Eq. 16 makes it possible to compile Cols. 1 to 5 of Table 1. The value of K corresponding to $\sin^{-1} q = 90°$ does not appear in Mr. Peirce's table;[4] but it can be derived easily by using Eq. 13, thus: $K = \int_0^{\pi/2} \frac{d\phi}{\sqrt{1 - 1 \sin^2 \phi}} = \int^{\pi/2} \sec \phi \, d\phi$ $= \frac{1}{2}\left[\left(\log \frac{1 + \sin \phi}{1 - \sin \phi}\right)\right]_0^{\pi/2} = \frac{1}{2} \log \frac{\frac{1+1}{1+0}}{\frac{1-1}{1-0}} = \infty$. The values of δ/L are plotted against those of L/r in Fig. 2. To assist in the interpretation of this curve, some idea should be formed as to the actual shape of the column corresponding to various plotted points. This is possible by solving for the different values of λ/L, in which λ is half the projection of the column on the x-axis (see Fig. 1(a)). Having found λ/L, and knowing δ/L from the curve of Fig. 2, the shape of the column, between the end points and the center, can be sketched. It is possible to derive the exact shape of the entire column (see Section 2 under "Exact Shape of the Deflected Column"), but this is not necessary for present purposes.

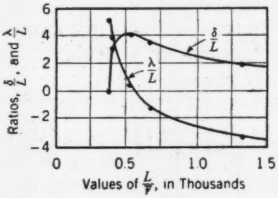

FIG. 2

Referring to Eq. 8b, and noting the similarity between the triangles of Figs. 1(b) and 1(c), the quantity x is introduced into the equations by writing:

$$\frac{dx}{ds} = \cos \theta = 1 - \frac{k^2}{2}(\delta^2 - y^2) \quad \ldots\ldots\ldots\ldots\ldots\ldots (17a)$$

To eliminate s (see Fig. 1(b)):

$$ds = \sqrt{(dx)^2 + (dy)^2} = dx \sqrt{1 + \left(\frac{dy}{dx}\right)^2} \quad \ldots\ldots\ldots\ldots (17b)$$

Substituting Eq. 17b in Eq. 17a: $\frac{dx}{dx \sqrt{1 + \left(\frac{dy}{dx}\right)^2}} = \cos \theta$;

$$\frac{dy}{dx} = \sqrt{\frac{1}{\cos^2 \theta} - 1} = \sqrt{\frac{1 - \cos^2 \theta}{\cos^2 \theta}}; \quad \text{or} \quad \frac{dy \cos \theta}{\sqrt{(1 + \cos \theta)(1 - \cos \theta)}} = dx.$$

In other words,

$$dx = \frac{\left[1 - \frac{k^2}{2}(\delta^2 - y^2)\right] dy}{\sqrt{\left[2 - \frac{k^2}{2}(\delta^2 - y^2)\right]\left[\frac{k^2}{2}(\delta^2 - y^2)\right]}} \quad \ldots\ldots\ldots\ldots (18)$$

Substituting from Eqs. 10 and 12a, $dx = \frac{(1 - 2 q^2 \sin^2 \phi)(- \delta \sin \phi \, d\phi)}{\sqrt{k^2 (1 - q^2 \sin^2 \phi)(\delta^2 \sin^2 \phi)}}$; or (selecting $\sqrt{\delta^2} = -\delta$):

$$k\,dx = \frac{(1 - 2\,q^2 \sin^2 \phi)\,d\phi}{\sqrt{1 - q^2 \sin^2 \phi}} \qquad (19a)$$

Eq. 19*a* can be integrated in terms of elliptic integrals, but first some manipulation is necessary. In Eq. 19*a*, the quantity in parentheses can be written: $2\,(1 - q^2 \sin^2 \phi) - 1$, from which:

$$k\,dx = \frac{2\,(1 - q^2 \sin^2 \phi)\,d\phi}{\sqrt{1 - q^2 \sin^2 \phi}} - \frac{d\phi}{\sqrt{1 - q^2 \sin^2 \phi}} \qquad (19b)$$

Integrating Eq. 19*b* from point B to point C, Fig. 1(*a*):

$$\int_0^{\lambda} k\,dx = k\,\lambda = 2\int_0^{\pi/2} \sqrt{1 - q^2 \sin^2 \phi}\,d\phi - \int_0^{\pi/2} \frac{d\phi}{\sqrt{1 - q^2 \sin^2 \phi}} \qquad (19c)$$

In other words,

$$k\,\lambda = 2\,J - K \qquad (19d)$$

in which J and K are elliptic integrals defined by the last two terms of Eq. 19*c*. Substituting $k = \frac{2\,K}{L}$ (see Eq. 13) in Eq. 19*d*, and manipulating:

$$\frac{\lambda}{L} = \frac{J}{K} - \frac{1}{2} \qquad (20)$$

Values of J corresponding to certain values of q are listed in Col. 6, Table 1. The value of J for $\sin^{-1} q = 90°$ can be obtained as follows:

$$J = \int_0^{\pi/2} d\phi\,\sqrt{1 - 1\sin^2 \phi} = \int_0^{\pi/2} d\phi\,\cos\phi = \sin\frac{\pi}{2} = 1 \qquad (21)$$

The values of λ/L corresponding to certain values of q, and hence corresponding to certain values of δ/L and $L/\hat{r}$ are shown in Col. 7, Table 1, and are plotted in Fig. 2. Using these values the center and end points of the column can be located on a scale drawing, and rough sketches of the column can thus be drawn for various values of δ/L and $L/\hat{r}$, as shown in Table 2.

The sketches are largely self-explanatory. Case 6 corresponds to a limp string, for which the effective value of $\hat{r}$ is zero.

It should be remembered that the results illustrated by Table 2 do not hold true if the stress exceeds the elastic limit of the material.

Graphical Solution for δ/L and λ/L.—To simplify numerical work, curves will be derived by which the values of δ/L and λ/L can be obtained quickly if the values of E, P/A, and $L/\hat{r}$ are known.

The method used to derive the curve of δ/L versus $L/\hat{r}$ in Fig. 2 can readily be extended to derive the curves of δ/L versus P/A for various values of $L/\hat{r}$. Also, by Fig. 2, the curve of λ/L versus δ/L can be drawn. (The latter curve will presently be shown to be independent of the dimensions of the column.) These curves, shown in Fig. 3, can be used to obtain practically all the information that may be desired about the column. For example, with a given column, if a load P is assumed, δ/L can be determined; hence, the maximum moment,

$P\,\delta$, and the maximum bending stress, $\frac{P\,\delta}{Z}$, can be evaluated (Z is the section modulus). Also, with δ/L determined, the value of λ/L can be selected immediately, and the general shape of the column can be approximated.

TABLE 2.—IDEAL COLUMN SHAPES UNDER VARIOUS CONDITIONS
(E = 30,000,000 LB PER SQ IN. AND P/A = 2 KIPS PER SQ IN.)

Case	$\frac{L}{r}$	$\frac{\delta}{L}$	$\frac{\lambda}{L}$	Column shape
1......	384	0	0.50	2......	415	0.296	0.37	
3......	529	0.401	0.06	
4......	676	0.35	−0.11	
5......	1,330	0.185	−0.316	
6......	∞	0	−0.50	

In selecting a value of λ/L corresponding to a particular value of δ/L, the value of λ/L should lie to the left of the crest of the λ/L-versus-δ/L curve if the value of δ/L lies to the left of the crest of the δ/L-versus-P/A curve, and vice versa.

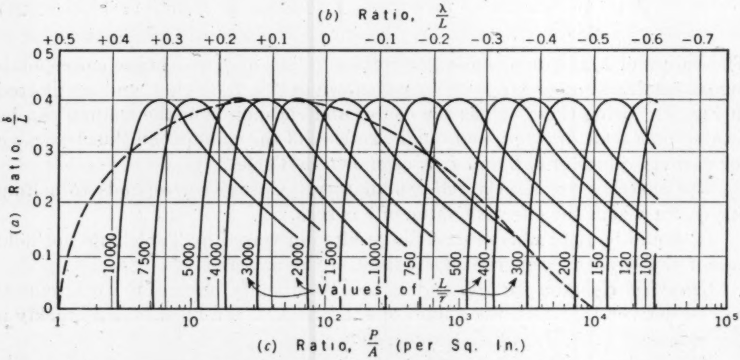

FIG. 3.—GRAPHICAL SOLUTION FOR δ/L AND λ/L

The curves of Fig. 3 are for steel (E = 30,000,000 lb per sq in.). For other values of E, the following relationship should be used:

$$\left(\frac{P}{A}\right)_{\text{indicated}} = \frac{30{,}000{,}000}{E} \times \left(\frac{P}{A}\right)_{\text{actual}} \qquad \text{(22)}$$

The use of Fig. 3 can be illustrated by a numerical example. Consider a machine member of spring bronze ($E = 15{,}000{,}000$ lb per sq in.), 24 in. long and 0.1 in. in diameter, D, loaded according to the conditions of Fig. 1(a) with $P = 1.25$ lb. The problem is to find the approximate shape of the elastic curve and the maximum stress. The slenderness ratio is $L/r = \frac{L}{D/4} = \frac{24}{0.1/4} = 960$; and $P/A = \frac{P}{\pi\, D^2/4} = \frac{4 \times 1.25}{\pi\,(0.1)^2} = 160$ lb per sq in. From Fig. 3, $\delta/L = 0.15$ ± and $\lambda/L = 0.46$. The shape of the column corresponds roughly to the shape shown as case 2, Table 2. The maximum bending stress is equal to $\frac{P\,\delta}{Z} = \frac{P \times \delta/L \times \mathrm{L}}{\pi\, D^3/32} = \frac{32 \times 1.25 \times 0.15 \times 24}{\pi\,(0.1)^3} = 46{,}000 \pm$ lb per sq in.

In this case the direct stress, $P/A = 160$ lb per sq in., is negligible compared to the maximum bending stress.

Exact Shape of the Deflected Column.—To illustrate the completeness of this mathematical solution the exact shape of the elastic curve of a typical column can be derived by finding the values of y/L corresponding to various values of x/L, as x (see Fig. 1(a)) is varied between the values of 0 and λ.

First, integrate Eq. 19b between points B and A, Fig. 1(a), letting $\phi = \beta$ (see Eqs. 10) at point A, as follows:

$$k\int_0^x dx = k\,x = 2\int_0^\beta d\phi\,\sqrt{1-q^2\sin^2\phi} - \int_0^\beta \frac{d\phi}{\sqrt{1-q^2\sin^2\phi}} \equiv 2\,G - H \quad \text{. . (23a)}$$

In other words,

$$k\,x = 2\,G - H \quad \text{. . . . . (23b)}$$

in which G and H are elliptic integrals. From Eq. 13, $k = 2\,K/L$—which value, substituted in Eq. 23b, yields:

$$\frac{x}{L} = \frac{2\,G - H}{2\,K} \quad \text{. . . . . (24)}$$

Assume that the physical constants are such that $q \equiv \frac{k\,\delta}{2} = \sin 75°$. Then, by Table 1, $K = 2.77$. The constants G and H can be evaluated for different values of β by tables,[5] and the corresponding values of x/L can be determined by Eq. 24. Eq. 16 yields $\frac{\delta}{L} = \frac{q}{K} = \frac{\sin 75°}{2.77} = 0.35$. Therefore, the values of y/L corresponding to the various values of β can be determined from Eqs. 10 by writing:

$$\frac{y}{L} = \frac{\delta}{L}\cos\beta = 0.35\cos\beta \quad \text{. . . . . (25)}$$

The computations and the elastic curve are presented in Table 3. Note that the relationship between x/L and y/L depends only on q. This fact leads to an important conclusion, derived as follows:

By referring to Eqs. 13 and 16, it can be seen that q is specified if $\delta/L = q/K$ is specified. Hence, the shape of the column is independent of the column dimensions and depends only on the value of δ/L. (Since there are two load conditions corresponding to each value of δ/L (see Fig. 3), it is necessary to specify whether the column is loaded below or above the crests shown in Fig. 3.)

---

[5] "A Short Table of Integrals," by B. O. Peirce, Ginn & Co., Boston, Mass., 3d Ed., 1929, pp. 122 and 123.

3. Equilibrium Positions of a Loaded Column

Several difficulties now require attention. First, the fundamental column formula, Eq. 13, is obviously not valid for values of P/A less than the value corresponding to $\delta/L = 0$ in Fig. 3. (The values of P/A and L/r corresponding to $\delta/L = 0$ are termed "critical" values.) For values of P/A below the critical, the solution $y = 0$ is first tested. Substituting the trial solution—

TABLE 3.—Exact Shape of the Deflected Column ($q = \sin 75°$)

β	G	H	$\frac{x}{L}$	$\frac{y}{L}$	Elastic curve
0.......	0	0	0	0.35	15.......	0.259	0.264	0.046	0.338	
30.......	0.502	0.548	0.0822	0.3025	
45.......	0.713	0.873	0.099	0.247	
60.......	0.881	1.28	0.0866	0.1745	
75.......	0.999	1.87	0.0231	0.0904	
90.......	1.08	2.77	−0.11	0	

$$y = 0 \quad \text{(26)}$$

—in the fundamental differential Eq. 3, and noting that $\frac{d\theta}{ds}$, the curvature, must equal zero if y is zero everywhere: $P \times 0 \equiv -E\,I \times 0$.

Then, the solution $y = 0$ must be considered a possible solution of Eq. 3 under all admissible conditions. In other words, the column may remain perfectly straight for all values of P/A, whether above or below the critical. Summing up the solutions, Eqs. 13 and 26, the conclusion follows that, with values of P/A less than the critical, the column must remain straight; whereas with values of P/A greater than the critical, the column either can remain straight, or can assume the form dictated by the curves of Fig. 3 and illustrated in Table 2.

It is possible to identify the critical values in this paper with Euler's well-known critical point. By Table 1, the critical value corresponds to $q = 0$, for which value Eq. 13 becomes

$$\frac{k\,L}{2} = \int_0^{\pi/2} \frac{d\phi}{\sqrt{1 - 0}} = \frac{\phi}{2} \quad \text{(27a)}$$

Substituting Eq. 6c in Eq. 27a, $\frac{L}{2}\sqrt{\frac{P}{E\,I}} = \frac{\pi}{2}$; or

$$P = \frac{\pi^2\,E\,I}{L^2} \quad \text{(27b)}$$

which is Euler's familiar expression for critical loading of a simple column. The meaning of the word "critical" will be discussed in detail presently.

As demonstrated, when the value of P/A exceeds the critical, there are two widely different solutions for the shape of the column, one corresponding to a perfectly straight column and one to a shape similar to those sketched in Table 2. Do both of these solutions represent a stable condition? To prove mathematically what is already known from experience—that the straight column is unstable, and the bent column stable—proceed as follows:

In any deflected position (see Fig. 1(*a*)), not necessarily an equilibrium position, the column feels certain internal moments as a result of its curvature. Similarly, the load P applies certain external moments at all points of the deflected column. If, at all points, the internal moment equals the external moment, then the column will be in equilibrium; if the internal moment is greater than the external moment, the curvature will tend to decrease and the column will straighten; and, if the internal moment is less than the external moment, the curvature will tend to increase and the column will assume a sharper bend.

To understand the meaning of the stability of the column, suppose that a loaded column is slightly displaced from its equilibrium position by small transverse forces and that the transverse forces are then removed. If, with the column in the displaced position, the difference between internal and external moments at all points is such as to tend to restore the column to its original position, then the column is stable; otherwise, it is unstable. To simplify the analysis, compare the internal and external moments at the center of the column only. It will then be possible to judge the stability of the column as a whole by inspection.

In evaluating the internal and external moments at the center for different values of δ/L, the internal and external moments at the center are analyzed in units of inch-pounds per unit of cross-sectional area and per unit of length, $\frac{M_i}{A\,L}$ and $\frac{M_e}{A\,L}$, respectively.

First, for a particular value of δ/L, by Fig. 1(*a*):

$$\frac{M_i}{A\,L} = \frac{P'}{A} \times \frac{\delta}{L} \qquad (28a)$$

in which P'/A is the value of P/A which would hold the column in equilibrium, with δ/L equal to the value chosen. Substituting Eq. 14 in Eq. 13,

$$K = \frac{L\sqrt{P'/A}}{2\,r\sqrt{E}} \qquad (28b)$$

from which

$$\frac{P'}{A} = \frac{4\,K^2\,E}{(L/r)^2} \qquad (28c)$$

Substituting Eq. 28*c* in Eq. 28*a*:

$$\frac{M_i}{A\,L} = \frac{4\,K^2\,E}{(L/r)^2} \times \frac{\delta}{L} \qquad (28d)$$

Also, by Fig. 1(*a*):

$$\frac{M_e}{A\ L} = \frac{P}{A} \times \frac{\delta}{L} \qquad \text{(28e)}$$

in which P is the actual load applied to the column.

Consider a typical column subject to various values of the loading, P/A, with $E = 30{,}000{,}000$ lb per sq in.; $L/r = 384$; and $P/A = 1{,}000$, 2,000 (critical), 3,000, and 8,000 lb per sq in. By Eq. 28*d*: $\frac{M_i}{A\ L} = \frac{4\ K^2 \times 30{,}000{,}000}{(384)^2} \times \frac{\delta}{L} = 815\ K^2 \times \frac{\delta}{L}$.

Using methods similar to those for preparing Table 1, the values of $\frac{M_i}{A\ L}$ corresponding to certain values of $\frac{\delta}{L}$ can be tabulated, as shown in Table 4.

TABLE 4.—VALUES OF $\frac{M_i}{A\ L}$

$\text{Sin}^{-1}\,q$ (degrees)	$\delta/L = q/K$	K	$\frac{M_i}{A\ L}$
0..........	0	1.57	0
30..........	0.296	1.69	690
60..........	0.401	2.16	1,520
75..........	0.35	2.77	2,200
89..........	0.185	5.43	4,450
90..........	0	∞	∞

The curve of $\frac{M_e}{A\ L}$ versus $\frac{\delta}{L}$ will be a straight line passing through the origin. Also, if $\frac{\delta}{L} = 0.4$, then by Eq. 28*e* the values of $\frac{M_e}{A\ L}$ corresponding to the different values of P/A will be as follows:

$\frac{P}{A}$	$\frac{M_e}{A\ L}$
1,000..................	400
2,000..................	800
3,000..................	1,200
8,000..................	3,200

The values of $\frac{M_i}{A\ L}$ and $\frac{M_e}{A\ L}$ can now be plotted against those of $\frac{\delta}{L}$, as in Fig. 4. The stability of the column, as revealed by these curves, can be studied as follows:

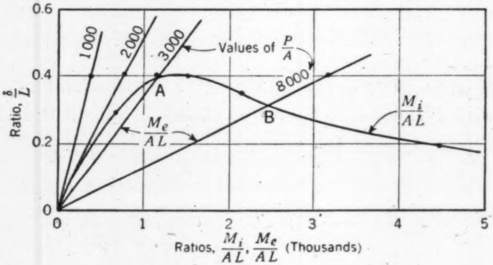

FIG. 4

First, suppose that $\frac{P}{A} = 1$ kip per sq in., a value that is less than the critical. Assume that the column is in the straight position, $y = 0$. If transverse forces are applied to cause the column to take a shape approximately corresponding to some value of δ/L and if these forces are then removed, at the instant of removal of the forces $\frac{M_i}{A\ L}$ will always be larger than $\frac{M_e}{A\,L}$, according to Fig. 4, and the column will return to the position $y = 0$. Therefore, with P/A less than the critical value, the column can have only one possible shape—perfectly straight. This result agrees with previous conclusions in this paper.

Next, suppose that $\frac{P}{A} = 3$ kips per sq in., a value that is greater than the critical, and which will cause the column to be in equilibrium at a value of δ/L corresponding to point A, Fig. 4. The shape of the column at this value of δ/L corresponds roughly to case 3, Table 2. If, by transverse forces, the column is slightly displaced in such a direction as to increase δ/L, then $\frac{M_i}{A\,L}$ will be larger than $\frac{M_e}{A\,L}$; and, by comparison with case 3, Table 2, it is seen that the column will return to the equilibrium position as soon as the transverse forces are withdrawn. On the other hand, if the column is displaced in such a direction as to decrease δ/L, then $\frac{M_i}{A\,L}$ will be smaller than $\frac{M_e}{A\,L}$; and, by comparison with case 3, Table 2, it is seen that the column will again return to the equilibrium position when the transverse forces are withdrawn. Point A, therefore, is a point of stable equilibrium.

If $P/A = 8$ kips per sq in., equilibrium point B will lie on the descending section of the $\frac{M_i}{A\,L}$-versus-$\frac{\delta}{L}$ curve of Fig. 4. The shape of the column at point B corresponds roughly to case 4, Table 2. Point B can be proved to be a point of stable equilibrium by the methods just used to investigate point A, but the details of proof will be left to the reader.

Consider that P/A equals either 3 kips per sq in. or 8 kips per sq in., and that the column is in the perfectly straight position. At any value of δ/L less than the equilibrium value at either point A or point B, $\frac{M_e}{A\,L}$ will be larger than $\frac{M_i}{A\,L}$. Therefore, the slightest disturbance of the column will suffice to cause a sudden large deflection corresponding to point A or point B. (The deflection cannot proceed past point A or point B, for reasons discussed in the preceding paragraphs.) This sudden large deflection is called "buckling." It is familiar to engineers, but its mathematical and physical reasons are generally not clearly understood.

Finally, let $P/A = 2$ kips per sq in., the critical value. The curves of $\frac{M_i}{A\,L}$ and $\frac{M_e}{A\,L}$ appear to be tangent at the origin. If this is true (and it is indeed true), then at any point close to the origin $\frac{M_i}{A\,L}$ and $\frac{M_e}{A\,L}$ are nearly equal. Therefore, the deflection of the column must be indeterminate. (This conclusion is proved in an entirely different manner in Section 4.)

The conclusions of this section can be summarized as follows:

(1) At values of P/A below the critical, an ideal column must remain perfectly straight.

(2) At values of P/A above the critical, the column may either remain perfectly straight or may assume a shape dictated by Fig. 3 and illustrated by Table 2. If the column is straight, the slightest displacement will suffice to cause the transverse deflection to change suddenly from zero to the deflection corresponding to the the curves of Fig. 3.

(3) At values of P/A close to the critical, the deflection is indeterminate, and may assume any fairly small value.

It remains to prove the assumption that, at the critical load, the $\frac{M_i}{A\,L}$-versus-$\frac{\delta}{L}$ curve is tangent to the $\frac{M_e}{A\,L}$-versus-$\frac{\delta}{L}$ curve at $\frac{\delta}{L} = 0$. By Eq. 28*e*, the the slope of the $\frac{M_e}{A\,L}$-versus-$\frac{\delta}{L}$ curve at $\frac{\delta}{L} = 0$ equals:

$$\frac{d\left(\frac{M_e}{A\,L}\right)}{d\left(\frac{\delta}{L}\right)} = \frac{d\left(\frac{P_e}{A} \times \frac{\delta}{L}\right)}{d\left(\frac{\delta}{L}\right)} = \frac{P_e}{A} \qquad (29a)$$

in which P_e is the critical load. By Eq. 28*a*, the slope of the $\frac{M_i}{A\,L}$-versus-$\frac{\delta}{L}$ curve equals:

$$\frac{d\left(\frac{P'}{A} \times \frac{\delta}{L}\right)}{d\left(\frac{\delta}{L}\right)} = \frac{P'}{A} + \frac{\delta}{L} \times \frac{d\left(\frac{P'}{A}\right)}{d\left(\frac{\delta}{L}\right)} \qquad (29b)$$

Since at the critical point $\frac{P'}{A} = \frac{P_e}{A}$ and $\frac{\delta}{L} = 0$, then, by comparing Eqs. 29, it may be seen that the curves of $\frac{M_i}{A\,L}$ and $\frac{M_e}{A\,L}$ versus $\frac{\delta}{L}$ are indeed tangent at the origin.

This result leads to a further interesting conclusion in regard to the shape of the curves of Fig. 3 in the region close to the critical point: If $\frac{M_i}{A\,L}$ and $\frac{M_e}{A\,L}$ are equal near the critical point, then δ/L must be indeterminate, as has been stated; if δ/L is indeterminate, it is obvious that $\frac{d\left(\frac{P}{A}\right)}{d\left(\frac{\delta}{L}\right)}$ must be zero at the critical point. This conclusion agrees with the shape of the curves of Fig. 3.

4. Actual Stress and Factor of Safety Below the Critical Point

All structural columns, and most machinery columns, are designed to operate below the critical point. In these columns, the appreciable transverse deflection that occurs at the critical point constitutes failure. In the case of relatively short columns, the direct stress P/A reaches the yield point and causes failure before the load reaches the critical. The factor of safety, N, must therefore be based either on P_c, or on P_y (the load that produces a direct stress equal to σ_y, the yield-point stress)—whichever governs.

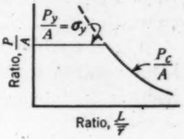

FIG. 5

In the case of steel columns, with E and σ_y taken at 30,000,000 lb per sq in. and 30,000 lb per sq in., respectively, the values of P_y/A and P_c/A may be plotted against the values of $L/\bar{r}$ (see Fig. 5). The ratio P_y/A $=$ a constant $= \sigma_y$, whereas P_c/A may be derived from Euler's formula by writing $P_c = \dfrac{\pi^2 E I}{L^2} = \dfrac{\pi^2 E A \bar{r}^2}{L^2}$; or

$$\frac{P_c}{A} = \frac{\pi^2 \times 30{,}000{,}000}{\left(\frac{L}{\bar{r}}\right)^2} = \frac{296{,}000{,}000}{\left(\frac{L}{\bar{r}}\right)^2} \quad \ldots\ldots\ldots\ldots\ldots (30)$$

The dotted section of the curve in Fig. 5 would be reached only after failure had already occurred, caused by a direct stress greater than σ_y. Neglecting this section, one may proceed to redraw the remainder of the curve for different factors of safety, simply dividing the values of P_y/A and P_c/A by the assumed values of N. In Fig. 6, if σ_y is not equal to 30,000 lb per sq in., or, if E is some value other than 30,000,000 lb per sq in., $N_y \propto \sigma_y$ and $N_c \propto E$.

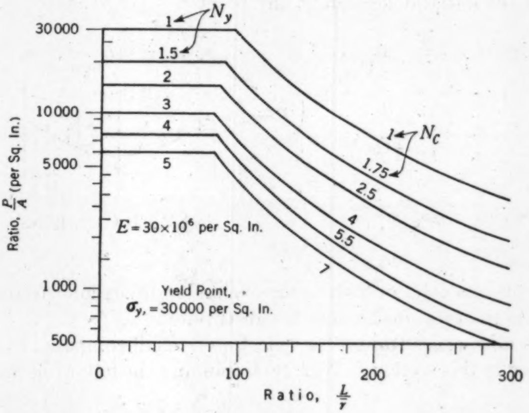

FIG. 6.—FACTORS OF SAFETY OF SIMPLE IDEAL COLUMNS (If $\sigma_y \neq 30{,}000$ LB PER SQ IN. OR $E \neq 30{,}000{,}000$ LB PER SQ IN., THEN $N_y \propto \sigma_y$ AND $N_c \propto E$)

It seems fair to assign larger values of N to the part of each curve based on P_c than to the part based on P_y, since failure at the critical point is much more violent and complete than is failure caused by the direct stress reaching the value σ_y. If the quantity $N - 1$ is considered as a "margin of safety," it seems desirable that:

$$N_c - 1 = 1.5\,(N_y - 1) \qquad (31)$$

in which the subscripts c and y denote whether the factor of safety is based on P_c or P_y. Accordingly, the values of N that are indicated for the straight and curved parts of each of the curves of Fig. 6 were chosen to agree with Eq. 31.

Fig. 6 enables the designer to determine the factor of safety of any simple, ideal column loaded below the critical point. According to the analysis in Section 3, the stress in such a column is nothing more or less than the direct stress. The actual column, however, differs from the ideal in certain important respects:

End Restraint.—The actual column is usually subjected to a certain amount of end restraint. This condition tends to strengthen the column, and may be taken advantage of in design when an appreciable degree of end restraint may be expected. In practice, however, it is often difficult to evaluate the amount of end restraint. It is shown in standard texts that the effect of perfect end restraint is to reduce the effective L/r-value by half.

External Moments and Irregularities of Shape.—External moments in addition to $P\,y$ (see Fig. 1(a)) may be applied to the column, because of eccentricity of the load P or because of forces applied anywhere on the column, or because of the weight of the column itself if it is not disposed vertically. The moment exerted at any point of the column by these external moments will be called $M(x)$, the notation signifying that M is a function of x. (For reasons of simplicity, external moments other than $P\,y$, which are functions of y, will not be considered.) Also, the column may have some initial irregularity of shape. Let y_o equal the initial deflection at any point.

(a) INITIAL SHAPE (b) LOADED CONDITIONS

FIG. 7

An example of a column such as the one under discussion is shown in Fig. 7, in which W is the total load uniformly distributed.

Only columns whose transverse deflection is small compared to their length are considered in this section. With such columns, the following simplifications are possible:

(a) The curvature may be expressed by $\frac{d^2y}{dx^2}$ (see Section 1, Eq. 4).

(b) The projected length of the column on the x-axis equals the developed length.

Eq. 4 can be extended to mean that M, the moment at any point, is equal to $-\,E\,I$ times the difference between the final and initial curvatures of the column. Then, since the initial curvature of the column is equal to $\frac{d^2y_o}{dx^2}$, Eq. 4 can be rewritten:

$$M = P\,y + M(x) = -\,E\,I\left(\frac{d^2y}{dx^2} - \frac{d^2y_o}{dx^2}\right) \ldots\ldots\ldots\ldots (32)$$

Letting $k^2 \equiv \frac{P}{E\,I}$, as before, Eq. 32 can be written:

$$\frac{d^2y}{dx^2} + k^2\,y = \frac{d^2y_o}{dx^2} - \frac{M(x)}{E\,I} \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

Eq. 33 is a linear differential equation of the second order with constant coefficients, and is treated in every standard work on differential equations. For the column shown in Fig. 7, the solution of Eq. 33 works out to be:

$$\begin{aligned} y = {} & \left(\frac{W}{P\,L\,k^2} + \frac{e_2 + e_1}{2}\right)\frac{\cos k\,x}{\cos \frac{k\,L}{2}} - \frac{e_2 - e_1}{2} \\ & \times \frac{\sin k\,x}{\sin \frac{k\,L}{2}} + \frac{\epsilon\,\pi^2}{\pi^2 - k^2\,L^2}\cos\frac{\pi\,x}{L} + \frac{W\,x^2}{2\,L\,P} \\ & + \frac{e_2 - e_1}{L}\,x - \frac{W}{P}\left(\frac{L}{8} + \frac{1}{L\,k^2}\right) - \frac{e_2 + e_1}{2} \ldots\ldots\ldots\ldots (34) \end{aligned}$$

Knowing y, the moment M can be determined by Eq. 32. Hence, the maximum bending stress at any section, $\sigma_b = \frac{M\,c}{I}$ (in which c is the distance from the neutral axis to the extreme fibers), can be calculated. The total stress is:

$$\sigma_t = \sigma_b + \frac{P}{A} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35a)$$

and its maximum value can be determined by setting $\frac{d\sigma_t}{dx} = 0$, according to the routine methods of the differential calculus. The factor of safety may be defined as the ratio between the external loading producing the yield-point stress σ_y and the actual external loading, and may be determined by trial.

If $e_2 = e_1 = e$, and $\epsilon = W = 0$, then, by Eqs. 34 and 32, it can readily be shown that the maximum bending stress equals:

$$\sigma_b = E\,k^2\,e\,c\sec\frac{k\,L}{2} \ldots\ldots\ldots\ldots\ldots\ldots (35b)$$

Eq. 35*b* is the well-known secant formula.

Again, if $e_2 = e_1 = W = 0$, then, by Eqs. 34 and 32, the maximum bending stress equals:

$$\sigma_b = \frac{E\,\epsilon\,c\,\pi^2\,k^2}{\pi^2 - k^2\,L^2} \ldots\ldots\ldots\ldots\ldots\ldots (35c)$$

Eq. 35*c* should prove useful in many practical cases. Most structural members are not fabricated perfectly straight, but have a camber. The actual shape of the column is usually roughly similar to a cosine curve, and the value of ϵ can be determined easily by stretching a string between the ends of the member. By substituting the highest probable value of ϵ in Eq. 35*c*, the highest probable bending stress caused by initial camber may be determined.

Eq. 35*c*, the camber formula, should be carefully distinguished from Eq. 35*b*, the secant formula, which gives the bending stress due to eccentricity of the load *P*.

It is possible to derive Euler's formula for critical loading from Eq. 34 because, if $e_2 = e_1 = W = \epsilon = 0$, then:

$$y = \frac{\epsilon\,\pi^2}{\pi^2 - k^2 L^2} \qquad (36)$$

If ϵ is reduced to zero and $k^2 = \frac{\pi^2}{L^2}$, then $y = \frac{0}{0}$, which is indeterminate, and $P = \frac{\pi^2 E I}{L^2}$, which constitutes Euler's condition.

In the case just mentioned, if $\epsilon = 0$ and $k^2 \neq \frac{\pi^2}{L^2}$, then Eq. 34 reduces to $y = 0$. Therefore, the simplified differential Eq. 4, from which Eq. 34 was derived, fails to give a satisfactory solution in the case of an ideal column. For that reason it was necessary to use the more exact, if more difficult, Eq. 3 in developing the theory of the ideal column.

The Step-by-Step Method.—The formal solution of Eq. 33, tedious under the best of conditions, becomes prohibitively complicated in certain cases, especially when *I* is variable or $M(x)$ is discontinuous. In such cases it is usually more practical to use some form of numerical integration. The step-by-step method of numerical integration, a mathematical weapon of long standing, has certain distinct advantages in connection with the solution of column problems:

(*a*) It is not a trial-and-error method, but leads directly to the solution.

(*b*) It is universally applicable to all columns whose relative deflection is small, enabling the designer to solve widely different types of column problems with only minor changes of technique.

(*c*) It may be used to obtain a rough solution fairly quickly or to obtain an accurate solution at the expense of more numerical work, as desired.

In the step-by-step method the column is divided into a number of intervals, not necessarily equal. All variable quantities are considered to be constant during each interval. The change, Δ, in any quantity in each interval is obtained numerically, and the value of any quantity at the end of any interval is obtained by adding Δ to the value of the quantity at the beginning of the interval.

Applying this process of reasoning to Eq. 32 and letting the order of differentiation be denoted by primes $\left(\text{for example, } y'' \doteq \frac{d^2y}{dx^2}\right)$:

$$y'' = y''_o - \frac{M}{E I} \qquad (37)$$

Integrate Eq. 37 from x = A to an indefinite point x = B, considering that the values of y and of its derivatives are known at point A. Then:

$$y'_B - y'_A = (y'_o)_B - (y'_o)_A - \int_A^B \frac{M\,dx}{E\,I} \ldots\ldots\ldots\ldots (38a)$$

Now, if the interval is small, $\frac{M}{E\,I}$ can be considered to be practically constant between points A and B. Then:

$$\Delta y' = \Delta y'_o - \frac{i\,M}{E\,I} \ldots\ldots\ldots\ldots\ldots\ldots (38b)$$

in which $i = x_B - x_A$.

Interpreted physically, Eq. 38*b* means that the change of slope of the elastic curve between point A and point B equals the change of slope of the unloaded column, plus the change of slope caused by moment—the latter term being equal to $-\frac{i\,M}{E\,I}$.

Next, integrate Eq. 38*a* over the interval, once more letting $(y'_o)_B = y'_o$ and $y'_B = y'$, remembering that $(y'_o)_A$ and y'_A are constant:

$$y_B - y_A - i\,y'_A = (y_o)_B - (y_o)_A - i\,(y'_o)_A - \int_A^B \int_A^B \frac{M\,dx\,dx}{E\,I} \ldots (39)$$

If $x_B = x$ and $\frac{M}{E\,I}$ is a constant during the interval, the last term of Eq. 39 can be expanded as follows:

$$\int_A^B \int_A^B \frac{M\,dx\,dx}{E\,I} = \frac{M}{E\,I} \int_A^B (x - x_A)\,dx = \frac{M}{E\,I}\left(\frac{x^2}{2} - x_A\,x\right)_A^B$$

$$= \frac{M}{E\,I}\left(\frac{x^2_B}{2} - \frac{x^2_A}{2} - x_A\,x_B + x^2_A\right) = \frac{M}{2\,E\,I}(x_B - x_A)^2 = \frac{i^2\,M}{2\,E\,I} \ldots (40)$$

Thus, Eq. 39 becomes:

$$\Delta y = \Delta y_o - i\,(y'_o)_A + i\,y'_A - \frac{i^2\,M}{2\,E\,I} \ldots\ldots\ldots\ldots (41)$$

Then, in physical terms, the change of deflection over an interval equals the change of deflection of the unloaded column, plus the change of deflection produced by the slope $y'_A - (y'_o)_A$ acting over the length i, plus the change of deflection caused by moment—the last term being equal to $-\frac{i^2\,M}{2\,E\,I}$.

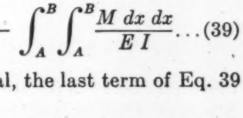

FIG. 8

Eqs. 38*b* and 41 are the keys to the method. The actual technique of procedure will be illustrated by a numerical example. The column shown in Fig. 8 is a steel rod 1 in. in diameter. The unloaded deflection may be expressed by

$$y_o = \epsilon \cos \frac{\pi\,x}{L} \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

Numerical values are as follows: $E = 30{,}000{,}000$ lb per sq in.; $I = 0.0491$ in.^{4}; $A = 0.785$ in.^{2}; $L = 30$ in.; $\epsilon = 0.1$ in.; $P = 2{,}700$ lb; and $e = 1$ in.

The column will be divided into 5-in. intervals, starting from the left end. Considering Eq. 38*b*, it is clear that y'_o and $\frac{i\,M}{E\,I}$ must be evaluated. The first of these terms can be calculated from the known initial deflection of the column, as follows: $y_o = \epsilon \cos \frac{\pi x}{L}$, $y'_o = -\frac{\epsilon \pi}{L} \sin \frac{\pi x}{L} = -0.01048 \sin (6\,x)^\circ$.

If $(y'_o)_n$ represents the value of y'_o at the beginning of the *n*th interval, then:

$$\Delta y'_o = (y'_o)_{n+1} - (y'_o)_n \qquad (43)$$

The calculations leading to the values of $\Delta y'_o$ are tabulated in Cols. 1, 2, 3, and 4 of auxiliary Table 5(*a*), and the values of $\Delta y'_o$ are listed in Col. 15 of main Table 5(*b*).

In cases where $\Delta y'_o$ cannot be derived analytically, it can always be obtained graphically, from the known initial deflection of the column.

Next consider the quantity $\frac{i\,M}{E\,I}$:

$$\frac{i\,M}{E\,I} = \frac{i\,M(x)}{E\,I} + \frac{i\,M(y)}{E\,I} \qquad (44)$$

in which $M(x)$ is a function of x and constants, and $M(y)$ is a function of y alone. Moment $M(x)$ can be calculated immediately, by the same methods that are used to calculate the moment at any point of an ordinary beam, whereas the calculation of $M(y)$ at any point must be deferred until the value of y at that point is known.

A word in regard to sign conventions will be in order at this point. If x is positive to the right, and y is positive downward, as in Fig. 8, then moments acting to the left of any section are positive if they are clockwise, and moments acting to the right of the section are positive if they are counterclockwise. This condition will be found to be in accordance with previous work in this paper. By Fig. 8:

$$M(x) = \frac{P\,e}{L}\left(\frac{L}{2} + x\right) = \frac{P\,e}{2} + \frac{P\,e\,x}{L} \qquad (45a)$$

Then:

$$\frac{i\,M(x)}{E\,I} = \frac{5}{30 \times 10^6 \times 0.0491}\left(\frac{2{,}700}{2} + \frac{2{,}700\,x}{30}\right) = 0.00459 + 0.000306\,x. \qquad (45b)$$

In calculating the value of $\frac{i\,M(x)}{E\,I}$, the value of x at the middle of the interval will be used. The value of $\frac{i\,M(x)}{E\,I}$ so obtained will be a good approximation of the average value of $\frac{i\,M(x)}{E\,I}$ over the entire interval. (The subscript i will be used where necessary to denote quantities which are taken at the middle of an interval.) The calculations for determining $\frac{i\,M(x)}{E\,I}$ are tabulated in Cols. 8, 9, and 10, Table 5.

The next step is to compute the value of $\frac{i\,M(y)}{E\,I}$. By Fig. 8, $M(y) = P\,y$, or

$$\frac{i\,M(y)}{E\,I} = \frac{5}{30 \times 10^6 \times 0.0491} \times 2{,}700\,y = 0.00918\,y \ldots\ldots (46a)$$

An approximate value y_i (the value of y at the middle of any interval) can be determined for use in Eq. 46*a*; thus:

$$y_i = y + \frac{i}{2}\,y' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46b)$$

in which the quantities without subscripts are taken at the beginning of the interval. From Fig. 8, at the beginning of the first interval, $y = 0$ (Col. 23) and $y' = \theta$ (Col. 18), in which θ is defined as the angle of slope at the left end of the column. Then $\frac{i\,y'}{2} = 2.5\,\theta$ (Col. 24), and $y_i = 0 + 2.5\,\theta$ (Col. 12). By Eq. 46*a*, $\frac{i\,M(y)}{E\,I} = 0.00918 \times 2.5\,\theta = 0.02295\,\theta$ (Col. 11). Adding Cols. 10 and 11: $\frac{i\,M}{E\,I} = 0.000766 + 0.02295\,\theta$ (Col. 16). By Eq. 38*b*, $\Delta y' = -\,0.002166 - 0.02295\,\theta$ (Col. 17). Adding Cols. 17 and 18, the value of y' at the beginning of the second interval is obtained; thus: $y' = -\,0.002166 + 0.97705\,\theta$.

It will be necessary to carry along the unknown, θ, in the computations until some known condition of the column makes a solution possible. For the present, θ will be treated exactly as any other of the values.

The next step is the utilization of Eq. 41. The value of Δy_o is equal to:

$$(y_o)_{n+1} - (y_o)_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47a)$$

and may be obtained analytically or graphically. In the present case,

$$y_o = 0.1 \cos\,(6\,x)^\circ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47b)$$

The values of y_o and Δy_o are listed in Cols. 5 and 6, Table 5. The values of y'_o have already been derived (Col. 4). Since $i = 5$, the values of $-\,i\,y'_o$ (Col. 7) can be obtained. Then the values of $-\,\frac{\Delta y_o}{i\,y'_o}$ are listed in Col. 20.

The first value of $i\,y' = 5\,y'$ can be obtained from Col. 18, and is shown in Col. 19. Also, the value of $-\,\frac{i^2\,M}{2\,E\,I} = -\,2.5 \times \frac{i\,M}{E\,I}$ can be obtained from Col. 16, and is shown in Col. 21. Referring to Eq. 41, Δy is equal to $-\,0.004316 + 4.9426\,\theta$ (Col. 22). Adding this value to the first value of y (Col. 23), the value of y at the beginning of the second interval is finally obtained; thus: $y = -\,0.004316 + 4.9426\,\theta$.

The reader will have noted that care was exercised in grouping and arranging the columns properly for easy numerical manipulation. The arrangement actually chosen was not based on any general rules, but was built up after a few trial calculations to suit the needs of this particular problem.

The calculations will now be traced through the second interval. Knowing y (Col. 23) and y' (Col. 18) from previous calculations, the values of y_i (Eq. 46*b* and Col. 12) and of $\frac{i\,M(y)}{E\,I}$ (Eq. 46*a* and Col. 11) can be found. Cols. 10 and 11 are added to find $\frac{i\,M}{E\,I}$ (Col. 16). By Eq. 38b, $\Delta y'$ (Col. 17) is found. From previous computation, $y' = -\,0.002166 + 0.97705\,\theta$ (Col. 18). Adding this value to the second value of $\Delta y'$, $y' = 0.008212 + 0.9094\,\theta$ at the beginning of the third interval.

The second values of $i\,y'$ (Col. 19) and $-\frac{i^2\,M}{2\,E\,I}$ (Col. 21) are easily obtained from Cols. 18 and 16, respectively. By Eq. 41 $\Delta y = -\,0.02513 + 4.716\,\theta$ (Col. 22). Adding this value to the second value of y results in: $y = -\,0.029446 + 9.659\,\theta$ at the beginning of the third interval (Col. 23).

Thus, the calculations are carried along until, finally, $y = -\,0.540026 + 22.29\,\theta$ at $x = 15$; but, according to Fig. 8, y at this point equals zero. Therefore, $0 = -\,0.540026 + 22.29\,\theta$, or $\theta = 0.0242$.

With this value of θ substituted in the computations, any numerical values desired can be determined. For example, the numerical values of y can be computed, and are shown in Col. 13. For the sake of comparison, the values of

y_e in Col. 14 are the values of y obtained by the "exact" equation (Eq. 34). The correspondence is remarkably close, in spite of the fact that the calculations were performed on an ordinary 10-in. slide rule. The discrepancy is less than 1%, an insignificant amount in engineering calculations.

With the value of θ known, the values of $\frac{i\,M}{E\,I}$ (Col. 16) can be determined. The maximum moment is found to occur at the right end of the column, and is found equal simply to $P\,e = 2{,}700$ in.-lb. The maximum bending stress is $\sigma_b = \frac{M\,c}{I} = \frac{2{,}700 \times 0.5}{0.0491} = 27{,}500$ lb per sq in. The direct stress, P/A, equals $2{,}700/0.785 = 3{,}500$ lb per sq in.; and the total stress equals $\sigma_t = \sigma_b + \frac{P}{A} = 31{,}000$—say, 30,000 lb per sq in.

Using a factor of safety of $N = 4$ based on a yield point of 30,000 lb per sq in., the allowable load is found equal to $P_a = \frac{P}{4} = \frac{2{,}700}{4} = 675 \pm$ lb in which P_a is the allowable load.

FOR THE COLUMN IN FIG. 8

This result can be compared with the result yielded by one of the rough formulas commonly used by engineers in designing columns subject to both axial load and moment. Such a formula is:

$$\left(\frac{P}{A}\right)_a = \frac{P}{A} + \frac{M\,c}{I} \quad \text{.....................} (48)$$

in which P/A is the direct stress, M is the maximum moment with the column at its initial deflection, and $\left(\frac{P}{A}\right)_a$ is the direct stress that would be allowed for the column if M were zero. Noting that $\frac{L}{r} = 120$, the proper value of $\left(\frac{P}{A}\right)_a$ to yield a factor of safety of $N = 4$ is 5,150 lb per sq in., by Fig. 6. The value of M can be shown to be a maximum at the right end of the column, where it is equal to $P\,e = P$. Then, by Eq. 48: $5{,}150 = \frac{P}{0.785} + \frac{P \times 0.5}{0.0491}$, or $P = 450$ lb.

Then, for a factor of safety of $N = 4$, the allowable value $P = 450$ lb, as obtained by the approximate formula (Eq. 48), is 33% smaller than the allowable value $P = 675$ lb, as obtained by the relatively accurate step-by-step method. Clearly, formulas which are of the same order of approximation as Eq. 48 are unsatisfactory in close design. They are very useful, however, as first approximations.

The versatility of the step-by-step method can be demonstrated by applying it to a very different type of problem. The column shown in Fig. 9 is fixed at its lower end and free at its upper end. The lower part, 200 in. long, is made of steel pipe (outside diameter, 4 in. and inside diameter, 3 in.). The upper part, 250 in. long, is made of steel pipe (outside diameter, 3 in. and inside diameter, 2 in.). A wind force, of 30 lb per square foot of projected area, acts transversely. A load P acts at the top with an eccentricity of e in. The distributed weight of the column acts vertically.

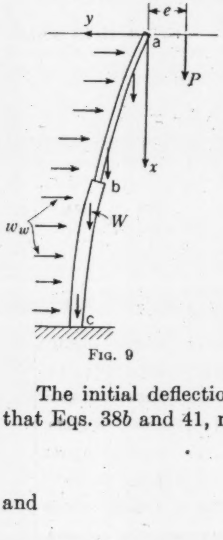

FIG. 9

The initial deflection of the column is assumed to be practically zero, so that Eqs. 38*b* and 41, respectively, reduce to:

$$\Delta y' = -\frac{i\,M}{E\,I} \qquad (49a)$$

and

$$\Delta y = i\,y'_A - \frac{i^2 M}{2\,E\,I} \qquad (49b)$$

For illustrative purposes the column is divided into only four intervals. Let $i = 125$ in. between points a and b, and 100 in. between points b and c. Also, let the wind force be represented by w_w pounds per linear inch, and assume that W, the weight of the column in each interval, is concentrated at the middle of the interval. (This last simplification is convenient rather than necessary; a closer approximation to the true condition could readily be obtained, if desired.)

The axes x and y have been chosen to agree with the adopted sign conventions. By rotating Fig. 9 through 90° counterclockwise, it can be seen that this column is really one half of a symmetrical column of the conventional type, with the left end at point a and the center at point c. Begin the computation at point a, where $y = 0$ and $y' = \theta$; then progress along the column as far as point c. At this point the knowledge that $y' = 0$ will permit a solution for θ. Knowing the value of θ, it is then possible to evaluate y, y', M, etc., at the various points of the column.

The numerical values are as follows: $P = 1{,}000$ lb; $e = 10$ in.; and $E = 30{,}000{,}000$ lb per sq in.

From point a to point b: $A = 3.93$ in.^{2}; $I = 3.19$ in.^{4}; $w_w = \dfrac{30 \times 3}{144} = 0.625$ lb per in.; $i = 125$ in.; $W = i\,A \times$ weight per cubic inch $= 125 \times 3.93 \times 0.2834 = 140$ lb; and $\dfrac{i}{E\,I} = 1.305 \times 10^{-6}$.

From point b to point c: $A = 5.5$ in.^{2}; $I = 8.59$ in.^{4}; $w_w = \dfrac{30 \times 4}{144} = 0.833$ lb per in.; $i = 100$ in.; $W = 100 \times 5.5 \times 0.2834 = 156$ lb; and $\dfrac{i}{E\,I} = 0.388 \times 10^{-6}$.

Also:

$$M(x)\Big]_a^b = P\,e + \frac{w_w\,x^2}{2} = 10{,}000 + 0.3125\,x^2 \dots\dots\dots\dots (50a)$$

and

$$M(x)\Big]_b^c = 10{,}000 + 250 \times 0.625\,(x - 125) + 0.833\,\frac{(x - 250)^2}{2}$$
$$= 0.4165\,x^2 - 52\,x + 16{,}500 \dots\dots\dots\dots (50b)$$

The expression for the value of $M(y)$ at the middle of the nth interval is derived as follows, remembering that the subscript i refers to values taken at the middle of any interval: $[M(y)]_n = P(y_i)_n + W_{n-1}\,[(y_i)_n - (y_i)_{n-1}] + W_{n-2}\,[(y_i)_n - (y_i)_{n-2}] + \cdots$; or

$$[M(y)]_n = P(y_i)_n + (y_i)_n \sum_1^{n-1} W - \sum_1^{n-1} W\,y_i \dots\dots\dots\dots (51)$$

Adding the quantity $0 = W_n(y_i)_n - W_n(y_i)_n$ to the right-hand side of Eq. 51:

$$M(y) = P\,y_i + y_i \sum W - \sum W\,y_i \dots\dots\dots\dots (52)$$

in which the quantities under the summation signs are to be taken from 1 to n.

The calculations are shown in auxiliary Table 6(a) and in main Table 6(b). Cols. 1 through 4, Table 6(a), lead to the values of $M(x)$ listed in Col. 11. To evaluate $M(y)$, it is first necessary to evaluate y_i. Knowing that $y = 0$ (Col. 19) and $y' = \theta$ (Col. 15) at $x = 0$, it is possible to obtain the first value of $y_i = y + \frac{i}{2}\,y'$ (Cols. 20 and 10). Next, since the different values of W are known, it is easy to tabulate the values of $\sum W$ (Col. 6). Then, the first values of $y_i\,(\sum W)$ (Col. 8), $W\,y_i$ (Col. 5), and $\sum (W\,y_i)$ (Col. 9) can be listed. Also, the first value of $P\,y_i$ can be listed (Col. 7). Then, by Eq. 52, the first value of $M(y)$ can be calculated (Col. 12). By adding this value to $M(x)$ (Col. 11), the first values of M (Col. 13) and of $\Delta y' = \dfrac{-\,i\,M}{E\,I}$ (Eq. 49a and Col.

14) can be listed. The latter value is added to the first value of y' (Col. 15) to determine the second value of y'.

Next, the value of Δy is calculated by Cols. 16 and 17 (see Eq. 49*b*), and is listed in Col. 18. This value is added to the first value of y (Col. 19) to obtain the second value of y. The second value of $y_i = y + \frac{i}{2} y'$ can be computed using the second values of y and y'. The computations then proceed as before.

Finally, at $x = 450$, y' is found to equal $-0.0695 + 0.4106\,\theta$. Since this quantity is known to be equal to zero, θ can be evaluated, and is found to equal 0.1692. Then, this value of θ may be substituted to yield the values of y, y', and M at the various points, as desired. These values may be plotted to obtain values at points other than those used in the computations. The details of this part of the procedure are omitted. Some of the numerical results are as follows:

[a] For $x = 250$ and 350,

Item	Description	Quantity
1	Deflection at point a, in inches	40.7
	Bending Stress, in Pounds Per Square Inch, at:	
2	Point b	31,000
3	Point c	29,000
	Percentage of the Total Bending Stress at Point c, for the Moment:	
4	Acting on the undeflected column	62.0
5	Caused by load P, disregarding e	32.5
6	Caused by the weight of the column	5.5
7	Total bending stress (%)	100.0

These numerical values should be considered illustrative rather than accurate, since only four intervals were used in the calculations.

General Remarks.—It is necessary to carry along an unknown in the calculations. In both of the numerical examples selected, this unknown has been θ, the value of y' at a certain point. In some types of problems, however, it is advantageous to choose for the unknown a value of y or of M. Then, with the aid of Eqs. 38*b* and 41, the computations are developed in much the same way as in the illustrative problems of the paper. Finally, a point is reached at which the value of y', y, or M is known, enabling the designer to evaluate the unknown. With the value of the unknown determined, it becomes possible to evaluate y', y, or M at any of the tabulated points.

The computations should be carefully grouped to save time and mental effort. The proper arrangement is determined by the needs of the individual problem.

these values are 0.4165 x^2_i.

The method is not self-checking. A procedure that will afford a check on the numerical work and that will at the same time give an indication of the accuracy of the method is to work through the computations first with a small number of intervals and then with a larger number of intervals. A comparison will reveal numerical errors quickly. Also, since the results generally converge very quickly toward exactness as the number of intervals is increased, the difference between the two sets of results gives an approximate indication of the error caused by choosing a finite number of intervals.

The step-by-step method can be applied directly to ordinary beam problems. In that case $M(y) = 0$, and the total moment at any point can be written immediately, thus greatly simplifying the procedure.

5. ACTUAL STRESS AND FACTOR OF SAFETY ABOVE THE CRITICAL POINT

Columns loaded above the critical point, of course, would never be used as structural members; but sometimes they occur in the form of springlike members in various types of machinery.

Only one such column—axially loaded at the ends with negligible end restraint, eccentricity, and irregularity of shape—will be treated. The direct stress will be neglected, since it is generally small compared to the bending stress. With a given column and a known load, δ can be determined immediately by Fig. 3, and the maximum bending stress, $\sigma_b = \frac{P\,\delta\,c}{I}$, can be evaluated readily. The factor of safety, N, may be defined as $\frac{P_y}{P}$, in which P_y is the load producing a bending stress equal to the yield stress. The safety factor may be determined by trial.

The difference between the ideal and the actual column is less marked above, than below, the critical point because, above the critical point, the large deflection is only little affected by minor eccentricities and irregularities of shape whereas, below the critical point, any small eccentricity or irregularity causes the column to depart from its ideally straight position and thus introduces an appreciable bending stress.

6. SUMMARY

The integration of the fundamental differential equation of the simple, ideal column leads to two solutions, one corresponding to a perfectly straight form and one corresponding to a certain deflected shape. Below the critical point, only the first of these solutions exists; consequently, the column must remain straight. Above the critical point both solutions exist, but the first is unstable and the second is stable; consequently, if the column is in the straight condition, the slightest disturbance will suffice to throw it into the deflected position.

With the column straight, the stress consists only of the direct stress P/A. With the column deflected, the stress is chiefly caused by the moment exerted by the applied load at the various points of the column.

In the actual column, end restraint, eccentricity of load, and irregularity of shape often reach appreciable values. If the load is less than the critical, deflections are small, and the elastic curve of the column can be represented accurately by a linear differential equation of the second order with constant coefficients. The solution of this equation is single valued and continuous within the practical range; hence, the shape of the actual column must vary continuously with change of load. In a strict sense, therefore, there is no critical point for an actual column. The sharp mathematical discontinuity that occurs in the critically loaded ideal column is leveled off, to a greater or less extent, by the irregularities of the practical column.

If the irregularities of the actual column are known to be small, the factor of safety at any load may be determined very simply by Fig. 6. Since even small irregularities may have an appreciable effect on the column, it is recommended that the values of Fig. 6 be modified according to judgment, to suit the known or expected irregularities.

The formal solution of the differential equation of the practical column is prohibitively tedious in many cases. Under such conditions, the versatile step-by-step method of numerical integration is suggested.

Above the critical point, the column is not greatly affected by minor irregularities. The numerical solution of columns loaded above the critical point is greatly facilitated by the curves of Fig. 3.

APPENDIX. NOTATION

The following letter symbols, adopted for use in the paper and for the guidance of discussers, conform essentially to American Standard Letter Symbols for Mechanics of Solid Bodies (ASA—Z10.3—1942), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:

A = area of cross section;
C = an arbitrary constant in Eq. 7;
c = distance from the neutral axis of a beam to the extreme fibers;
D = diameter;
E = modulus of elasticity;
e = eccentricity of axial load on a column;
G = an elliptic integral in Eq. 23*b*;
H = an elliptic integral in Eq. 23*b*;
I = rectangular moment of inertia;
i = the length of an interval in Eq. 38*b* $= x_B - x_A$;
J = an elliptic integral in Table 1, defined by Eq. 21;
K = an elliptic integral defined by Eq. 13;
k = a substitution constant $= \sqrt{P/(E\,I)}$ in Eq. 6*c*;
L = the total length of a deflected column;
M = bending moment:
    M_i and M_e = moments resulting from internal effects (M_i) and external effects (M_e); they are denoted "internal moments" and "external moments," respectively;
    $M(x)$ and $M(y)$ = moment (expressed as functions of x and y) at any point of a column, created by externally applied forces;
N = factor of safety; subscripts c and y denote whether the factor of safety is based on P_c or P_y;
n = a number in mathematical progression;
P = an external, concentrated load:
    P' = the value of P that would hold the column in equilibrium;
    P_a = allowable load;
    P_c = critical value of P;
    P_y = value of P that produces a direct stress σ_y;

q = a substitution constant defined by Eq. 12a;

r = least radius of gyration;

s = an indefinite arc length, part of the total length L of a deflected column;

ds = a differential of s;

W = a total weight or load uniformly distributed;

w = a unit, uniformly distributed load; w_w = a unit, uniformly distributed wind load;

x = distances parallel to the longitudinal reference axis of a column;

y = distances transverse to x-distances; lateral deflection of a column at any point:

y' and y'' = first and second derivatives of y with respect to x;

y_e = "exact" values of y (see Table 5);

y_0, y'_0, and y''_0 = initial deflection, slope, and approximate curvature at any point;

Z = section modulus;

β = upper limit of the angle ϕ;

Δ = a change in any quantity in a given interval of length i; thus, Δy = a change in the deflection y;

δ = total deflection at the center of a column;

ϵ = maximum deflection of an unloaded column;

θ = slope of a deflected column at a given point;

λ = half the projection of the deflected column on the x-axis (see Fig. 1(a));

ρ = radius of curvature;

σ = normal stress:

σ_b = bending stress at any point;

σ_t = total stress;

σ_y = yield-point stress; and

ϕ = a substitution angle defined by Eq. 10a.

DISCUSSION

R. Robinson Rowe,[6] M. ASCE.—The use of the more precise expression for the elastic curve of a uniform column, instead of the usual approximation, should be accompanied by a few words of its history and analogous applications in engineering. The particular curve is known as the "arch of Yvon-Villarceau" from the name of the mathematician who according to Rankine first investigated its properties by the use of elliptic functions. It is the curve whose curvature is proportional to distance from a directrix, or simply,

$$\rho\, y = \text{constant} \qquad (53)$$

James Bernoulli discovered this shape in the seventeenth century in his study of an indefinitely broad sheet supporting a liquid mass. This is the "hydrostatic cord" assumed by sheet metal flumes; and the constant is the unit tension divided by the unit weight of the liquid. Formulas equivalent to Eq. 19*d* for seven cases have been developed by J. B. Macphail,[7] M. ASCE.

Yvon-Villarceau found the same shape inverted for his arch, designed to support a fluid-like earth without moment. This is also called the "hydrostatic arch." The constant, of course, is the unit compression, or thrust, divided by the unit weight of earth. His formulas in elliptic functions and many special properties of the curve are quoted by Rankine.[8]

Rankine noted the analogy between the hydrostatic arch, the hydrostatic cord, and the elastic curve for a spring or column under the action of a pair of equal and opposite end forces.[9] Eq. 3 by Rankine is equivalent to the author's Eq. 3 and Rankine's Eq. 7, to the author's Eq. 27*b*. In addition to the author's six cases (Table 2), Rankine showed several representative forms of undulating distortion, which can actually develop in free-ended columns with intermediate lateral support. He did not repeat the elliptic expressions for the curve; but he referred to those for the hydrostatic arch, and noted that the constant was $\frac{E\,I}{P}$ and the directrix, the neutral position of the column.

George Winter,[10] M. ASCE.—An elegant and interesting analytical treatment of some general features in the theory of elastic stability is presented in this paper. It will be of value to men interested in this field, primarily as a systematic presentation of known facts. It is unusual, in a paper covering such a vast and established field, not to find a single reference to previous work of other investigators. Indeed, the only references given relate to texts in the field of pure mathematics, concerning the analytical tools used in the derivations.

The origin of the analysis of columns beyond the Euler critical load goes back to Bernoulli and Euler, in the first half of the eighteenth century. Complete treatments of this problem of the so-called "Elastica" are found in such standard texts as A. E. H. Love's "Mathematical Theory of Elasticity" and R. V. Southwell's "Introduction to Theory of Elasticity." In the latter work Professor Southwell presented material which is not only identical in substance and mathematical method with the author's treatment,[11] but he includes a chart [12] that gives all the configuration shown by Mr. Ryder in Table 2. Furthermore, the information in Table 1 is given by Professor Southwell with some data added.[13] To be sure, there are differences of emphasis and detail, but none in substance and method.

In his discussion of practical columns and beam columns by the small deflection theory (differential Eq. 33), the author offers no information that cannot be found in generally available publications. In particular, Eq. 34 merely represents a superposition of customary solutions of beam columns as presented by S. Timoshenko,[14] D. H. Young[15] and others. The derivation of the Euler load from a beam-column analysis, Eq. 36, can be found in any standard textbook.

Numerical methods of integration applicable to columns and beam columns have been developed by N. M. Newmark, M. ASCE (among others). Professor Newmark indicates[16] how his method can be extended into the large deflection range; although, in view of the purely academic interest of this problem, he omits its elaboration. These numerical procedures are identical in substance, although not necessarily in detail, with those used by the author.

It is not implied in this review of the literature that the author's material is not new in some of its details and elaborations and that it was not independent work that led him to his findings. However, the fundamental content of this paper and its methods, as well as its conclusions, have been part and parcel of established knowledge for a considerable time.

With regard to its practical implications, it should be noted that the major part of this paper deals with phenomena beyond the Euler critical load. In the first sentence of section 5, however, the author himself notes that "Columns loaded above the critical point, of course, would never be used as structural members." This substantial part of the paper, therefore, is of no practical help to the designing engineer. As far as columns loaded below the critical point are concerned, Fig. 6 is misleading; because practical columns do not behave in the way assumed for this figure, as is firmly established by numerous experimental and analytical investigations. Initial imperfections as well as nonelastic behavior for shorter columns make this graph inapplicable. On the other hand, the methods of dealing with practical columns as proposed by the author in section 4 (beginning at Eq. 32) have long been used in practical design.

[13] *Ibid.*, pp. 434-435, Tables 1 and 2.

[14] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1936, Chapter I.

[15] *Transactions*, ASCE, Vol. 101, 1936, p. 422.

[16] *Ibid.*, Vol. 108, 1943, p. 1187.

The fact that in this approach "there is no critical point for an actual column" is again part and parcel of these methods.

It is generally realized that the field of column analysis and design is in an unsatisfactory state. This situation, however, is not due to lack of analytical knowledge on the behavior of isolated columns in the elastic range. Indeed, the details of this topic have been worked out in the most exhaustive manner; and the author's paper, dealing exclusively with such isolated, elastic columns, adds no new evidence of value in the practical column range.

The real and substantial problems in column design, on the solution of which further progress depends, are (*a*) the behavior of isolated columns beyond the elastic range, and (*b*) the analysis of columns as component parts of structures (trusses, frames, bents) both in and beyond the elastic range. It is hoped that future investigators will turn their attention to these topics, which are of fundamental importance for the development of more accurate and rational structural column design.

ROBERT M. MAINS,[17] ASSOC. M. ASCE.—In consideration of the voluminous literature on column behavior, a new paper on the subject should perform one of two functions: Set forth solutions for problems hitherto unsolved, or present more convenient methods for applying existing solutions to the practical column. The author's work on theoretical columns is interesting in that it restates, with some changes in notation, problem solutions which are readily available in such books as "Theory of Elastic Stability" by S. Timoshenko.[18] Indeed, many of these solutions date back to the Euler-Bernoulli correspondence concerning problems of the "elastica" about 1740.

In studying this paper, the writer hoped that it would contain forms of solution which would permit more convenient computations of practical columns. However, the methods used in the section dealing with practical columns seem to be much more cumbersome than existing methods. For example, the results of Col. 13, Table 5, which give deflections for Fig. 8, were checked with a brief half page of computation by the use of the numerical procedure of N. M. Newmark, M. ASCE, combined with the relation:[19]

$$w_a = \frac{w_i}{\frac{P_c}{P} - 1} \qquad (54)$$

in which w_a is the additional deflection due to load P; w_i is the sum of the initial deflection and the deflection due to lateral load; P_c is the critical buckling load; and P is the applied end load. The results obtained from this computation agreed with those of the author within 1%, which is certainly adequate for practical purposes. A similar saving in the labor of computation, although not so marked, may be made by the application of the same technique to the problem in Fig. 9.

---

[17] Asst. Prof., Civ. Eng., Cornell Univ., Ithaca, N. Y.

[18] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1936.

[19] *Transactions*, ASCE, Vol. 108, 1943, p. 1181, Eq. 4.

Although the author's equations for the calculation of deflections are adequately tied in with computations of stress, it is not made clear just how buckling loads are to be determined for the practical column which fails by elastic buckling instead of by yielding. The relationship between deflections and buckling loads is emphasized in Professor Newmark's method, and the buckling load is obtained conveniently in the process of solution.

Since there are practical problems (although not necessarily in bridges and buildings) in which elastic buckling occurs before yielding of the column, the writer fails to see any advantage in clarity of theory or simplicity of application for the author's methods over "step-by-step" processes already available.

CHI-TEH WANG,[20] ESQ.—Although the nonlinear theory of column buckling in the elastic range was first developed by G. Kirchhoff[21] almost ninety years ago, a recapitulation for the average practical engineer still appears to be praiseworthy. Mr. Ryder's paper presents an excellent résumé of the theory, together with an enlightening discussion relating to the stability of the columns. Several points, however, are in need of further clarification.

In conclusion (3), Section 3, it was concluded that "(3) At values of P/A close to the critical, the deflection is indeterminate, and may assume any fairly small value." This was supposedly proved by showing that the curves of $\frac{M_i}{A\,L}$ and $\frac{M_e}{A\,L}$ have the same slope or are tangent to each other at $\frac{\delta}{L} = 0$. It is a simple matter to show that when two curves are tangent to each other they need not necessarily meet at more than one point. Of course, they may. To prove that there is actually only one point at which these two curves meet, reference is made to Eq. 13, in which $k^2 = \frac{P}{E\,I}$ and $q^2 = \left(\frac{k\,\delta}{2}\right)^2 = \frac{P\,\delta^2}{4\,E\,I}$. When $P = P_c = \frac{\pi^2\,E\,I}{L^2}$, $k^2 = \frac{\pi^2}{L^2}$, and $q^2 = \frac{\pi^2\,\delta^2}{4\,L^2}$. The left-hand side of Eq. 13 is then equal to $\frac{\pi}{2}$. The elliptical integral on the right-hand side will be equal to $\frac{\pi}{2}$ only if q^2 is zero. Since $q^2 = \frac{\pi^2\,\delta^2}{4\,L^2}$, it is zero only if $\delta = 0$; that is, at the critical load the deflection is zero, and at any other load close to the critical value the deflection, however small, has a definite value and can be calculated from Eq. 13. When this is proved, Eqs. 29*a* and 29*b* are equal only at the point $\delta = 0$ and not at any other point or points close to $\delta = 0$, and the original conclusion (3) is therefore incorrect.

Mr. Ryder mentions in the "Synopsis" that he is merely re-emphasizing the well-known fact that at the critical point the deflection is indeterminate. The so-called "well-known" fact is accepted as such because most writers in strength of materials deal only with the linear theory and, therefore, reach that erroneous conclusion. Actually, from the nonlinear theory, it is clear that the so-called "buckling load" is the load at which the straight form of the ideal column begins to be unstable. At any load greater than the critical load, the column has two possible forms of equilibrium, the straight form, which is unstable, and the bent form, which is stable. For any load which is less than, or equal to, the critical value, the ideal column has only one form of equilibrium, namely, the straight form. Accepting the result obtained from the linear theory, some writers consider the equilibrium at the critical load as neutral equilibrium since the deflection then seems to be indeterminate. It is evident that such terminology is not correct in the strict sense.

[21] "Ueber das Gleichgewicht und die Bewegung eines unendlich dünnen elastischen Stabes," by G. Kirchhoff, *Journal für reine und angewandte Math.*, Vol. 56, 1859.

Another objection may be raised with respect to Fig. 5, in which Euler's column formula has been extended to the yield point of the material. It should be noted that Mr. Ryder's theoretical discussion does not hold true if the stress exceeds the elastic limit of the material, namely, the proportional limit. For some alloy steels the proportional limit is approximately 90% of the yield stress. Perhaps in these cases, if a large factor of safety is used, diagrams such as Fig. 5 could be accepted for design purposes, as is the usual practice of civil engineers. For aeronautical engineers, who have to deal with aluminum alloys most of the time, this practice has long been found to be unsatisfactory because the proportional limit in some cases is only about 50% of the yield stress.

Since the author is interested in the "rational" explanation of column behavior, the writer feels that this is a point worth mentioning. The most accurate experiments on columns, up to the present time, probably were those made in the Berlin-Dahlem material testing laboratory by using a very elaborate construction for the end supports of the columns.[22] For structural steel columns with a yield stress of 45,000 lb per sq in., the test results show that there is a marked deviation from the Euler curve above $\frac{P_c}{A} = 39{,}000$ lb per sq in.[23] Theoretically, the use of Euler's column formula for stress beyond the proportional limit cannot be considered to be correct. Between the proportional limit and the yield stress one should use the tangent modulus formula, which recently has been verified theoretically by F. R. Shanley. Fig. 5 should then be modified as in Fig. 10 in which $\frac{P_t}{A} = \frac{\pi^2 E_t}{(L/r)^2}$, and E_t is the tangent modulus of the material and is defined as the slope of the compressive stress-strain curve at the stress corresponding to $\frac{P_t}{A}$. The same objection can be applied to Fig. 6.

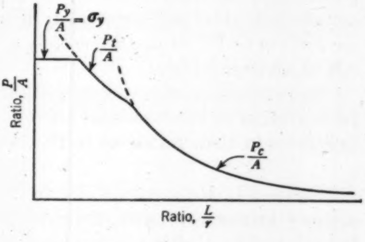

FIG. 10

---

[22] "Neuere experimentelle Beiträge zur Frage der Knickfestigkeit," by K. Memmler, *Proceedings*, 2d International Cong. for Applied Mechanics, Zürich, 1926, pp. 357–363.

[23] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1936, p. 174, Fig. 109.

In the "Summary," it is emphasized that in a strict sense there is no critical point for an actual column. This statement is indeed very true. If one uses the linear theory, the load versus deflection curve of an actual column in compression is approximately a rectangular hyperbola with asymptotes $P \rightarrow P_c$ when $\delta \rightarrow \infty$. This condition, originally discussed by R. V. Southwell,[24] is interesting, because from the tests of actual columns the buckling load of a corresponding ideal column can be approximately determined. Thus, a relation between the theoretical discussion of ideal columns and the testing of actual columns can be obtained. It is obvious that when δ is not small the nonlinear equation must be used; the theoretical discussion of actual columns will yield no result concerning the buckling load.

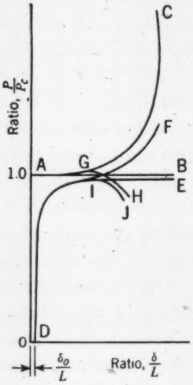

FIG. 11

The behavior of ideal and actual columns as obtained from various rational theories can be summarized in Fig. 11. Suppose that the column is slender and that the material can sustain the compressive stress $\frac{P}{A}$ without failure of elasticity. The loading of an ideal column will follow the curve OAB according to the linear theory and OAC according to the nonlinear theory. At some point G on curve OAC, the deflection δ is so large that the sum of direct compressive stress and bending stress due to the bending moment $P\,\delta$ is sufficient to produce elastic breakdown. Beyond this point the actual curve AGH will begin to drop away from AC, since the material can now sustain less stress than before. For an actual column with an initial deflection of δ_0, the loading of the column will follow the curve DE according to the linear theory, and the curve DF according to the nonlinear theory. At point I, the maximum stress in the column reaches the elastic limit and then the actual curve DIJ will drop away from DF. It should be noted that the upper part of curve DE is approximately a rectangular hyperbola which approaches AB as an asymptote.

In conclusion, the writer wishes to congratulate Mr. Ryder on his clear presentation of the nonlinear theory which will clarify for many engineers the questions in their minds as to the behavior of columns.

ERNEST L. ROBINSON,[25] Assoc. M. ASCE.—As any devotee of the sport of archery knows very well, there is nothing uncertain or mysterious about the behavior of an elastic column beyond the Euler length. In 1915, and in 1916, the writer published two analyses of the curve whose ordinate is everywhere proportional to the curvature. The first gave[26] equations for a deflecting column connecting load and deflection both with the original length and the deflected length, and presented graphic solutions of these equations, as well as charts for the required elliptic integrals. The second paper presented charts[27] for the hydraulic catenary connecting the middle depth with the tension, area, wetted perimeter, and mean hydraulic radius as well as a fairly large diagram showing the actual shape of the curve.

[26] "Curves for Strength and Deflection of Very Long Columns," *Engineering News*, June 10, 1915, pp. 1108–1109.

FREDERICK L. RYDER,[28] ESQ.—It is stated in the discussions, particularly by Professors Winter and Mains, that a good part of the material in the paper is to be found elsewhere in the literature. In view of this criticism, the writer wishes to clarify the purpose and scope of the paper, as follows:

It is well known that various aspects of the analytical treatment of the column problem have been investigated previously. Although these treatments have no doubt been adequate for those scholars who were able to integrate them into a comprehensive theory, the writer felt that in no case did they present to the average engineer a unified, cohesive theory of column behavior. As taught in the schools, for example, column behavior is discussed largely in terms of empirical results, presumably because there is no paper that presents a reasonably simple but well-rounded analytical treatment. The result is that most engineers do not understand the rationale of column mechanics.

To remedy this situation, the writer has attempted to develop, from the beginning, a logical and sequential column theory, geared to the needs of the modern engineer. Because of the analytic and self-developing nature of the work, it was unnecessary to use the methods and results of previous investigators, and in fact they were not used.

Aside from what he hopes is a more meaningful and useful organization of certain known results, the writer believes that certain parts of the paper are essentially new—for instance, the discussion of column stability in Section 3, which is essential to an understanding of column mechanics. Also, the essence of the step-by-step method appears to be entirely new, at least as applied to columns. In this connection, the writer wishes to point out a basic feature—namely, that his method is not one of successive approximations, and consequently does not require a good guess as a first approximation. This procedure is in contrast with previous methods, such as that of N. M. Newmark,[29] M. ASCE. The difference would seem to be important in the case of complicated columns, as, for example, a cargo boom, which often consists of pipes of different sizes joined at their ends, with multiple hoisting blocks applying both lateral and eccentric axial loads at different points near the end of the boom.

The writer had also hoped that Fig. 3, which presents a convenient solution of slender columns loaded above the critical point, was new. However, it turns out that curves of a similar nature have been published by Mr. Robinson. The writer extends his apologies.

With regard to specific ideas presented in certain discussions, the writer wishes to reply as follows:

To Mr. Rowe he wishes to extend his thanks for the interesting historical notes.

[28] Development Engr., Shirgun Corp., New York, N. Y.

[29] "Numerical Procedure for Computing Deflections, Moments, and Buckling Loads," by N. M. Newmark, *Transactions*, ASCE, Vol. 108, 1943, p. 1161.

Professor Winter states that a discussion of columns loaded above the critical point is of no practical value. The writer believes that a study of such columns is necessary to obtain a proper insight into the behavior of the more usual columns. Furthermore, such columns are often used as machine and instrument parts. This use, to be sure, is of interest to mechanical engineers rather than to civil engineers.

As Professor Mains declares, the writer did not extend his analysis to include the determination of the buckling load for columns of other than the ideal shape. The reason is simply mathematical complexity, for it would have led to the solution of Eq. 3 with the parameter I a function of x, and not necessarily continuous. Quite often columns of nonideal shape have nonideal loading, in which case they may be completely analyzed, both as to stress and as to deflection, by the step-by-step method.

Professor Wang indicates that, at values of P/A close to the critical, the deflection of an ideal column is a determinate problem, contrary to the writer's statement in Section 3, conclusion (3), and may be evaluated from Eq. 13. The writer believes nevertheless that his original statement is correct. A numerical investigation of Eq. 13 in the vicinity of $q = 0$ will show that, as q is varied, K varies by a lesser order of magnitude. This demonstration constitutes the mathematical and physical definition of indeterminateness of q, and hence of deflection.

Professor Wang's clarification of the behavior of the column between the proportional limit and the yield point is most enlightening from a rational point of view, and would seem to be of definite value in close design.

FOREWORD

Under terms of the basic act and subsequent legislation, the Tennessee Valley Authority (TVA) has designed and constructed sixteen major hydroelectric projects to control and utilize the water of the Tennessee River and its tributaries, thus providing for navigation, flood control, and the generation of electric power. These major projects (see Fig. 1) are located at the most feasible sites to insure the unified development of this river and its tributaries consistent with the economical adaptation of structures to the geology, topography, and hydraulic conditions.

The geology of these sites is interesting. The local formations involved are the Knox dolomite, Chickamauga limestone, and some subordinate shale members. In general, both the Knox dolomite and the Chickamauga limestone are fairly soluble when considered over geologic intervals of time, and for this reason numerous seams and cavities abound in the region.

FIG. 1.—DAMS OF THE TENNESSEE VALLEY AUTHORITY

In the construction of these major hydroelectric structures for the development of the valley, an important by-product, especially for the civil engineering profession, has been the mass of technical data made available as a result of the many problems encountered and overcome. A record of the foundation treatment required in the construction of these projects provides one type of technical data which, by its nature, is of particular value to civil engineers. Prior to this Symposium, two groups of papers published in the Society's *Transactions* have described the foundation treatment at Norris, Guntersville, Chickamauga,[1] Kentucky, and Hales Bar[2] dams. The material included in these papers concerned either the geology or the treatment required at the dam site. The two papers presented herewith serve to complete this special series.

Foundation treatment at the Douglas and Fort Loudoun dams has followed the general procedure developed since 1936 for TVA dams founded on limestone. The success of the treatment illustrates that gravity type dams may be founded on limestone satisfactorily provided that proper methods of excavation, cavity filling, and grouting are employed.

At the beginning of construction the late Theodore B. Parker, M. ASCE, was chief engineer. He was succeeded on July 1, 1943, by C. E. Blee, M. ASCE. Arthur L. Pauls, M. ASCE, was chief construction engineer. E. C. Eckel, Affiliate, ASCE, was chief geologist until his death in November, 1941, when he was succeeded by Berlen C. Moneymaker, Assoc. M. ASCE.

At Fort Loudoun Dam, J. K. Black, M. ASCE, was project manager; and J. F. Partridge, M. ASCE, construction engineer. E. C. McClenagan was construction superintendent.

On Douglas Dam, Lee G. Warren, M. ASCE, was project construction manager; T. F. Taylor, Assoc. M. ASCE, construction engineer and later acting project manager; and James S. Lewis, Jr., M. ASCE, construction superintendent.

Appreciation is expressed to A. H. Weber, civil engineer, for assistance given in the preparation of the first paper in this Symposium.

FORT LOUDOUN DAM

BY ARTHUR L. PAULS,[8] M. ASCE

SYNOPSIS

Undoubtedly, the most distinctive feature of the foundation at Fort Loudoun Dam was the presence of solution cavities at unprecedented depths below the water table. Solution occurred at depths as great as 300 ft below the original ground surface and 260 ft below the water table. Experience with this foundation has demonstrated that structural deformational features rather than rock solubility often control the depth and extent of weathering. Established grouting procedures and practices are described only briefly to permit a more complete discussion of the deep mining operations in the large bedding cavities both for consolidation and for the construction of an effective cutoff. In the north core wall, cavities were mined to a depth of 220 ft under the most difficult working conditions.

INTRODUCTION

Fort Loudoun Dam is the ninth and final dam, on the Tennessee River, necessary for extending the navigable channel to Knoxville, Tenn.—a distance 650 miles upstream from the confluence of the Tennessee and Ohio rivers at Paducah, Ky. (see Fig. 1). The structure is located about 1 mile from Lenoir City, in Loudon County, Tenn.; 602.3 miles above the mouth of the river; 1.2 miles above the confluence of the Little Tennessee River; and 47.7 miles downstream (or 26 miles by highway) from Knoxville.

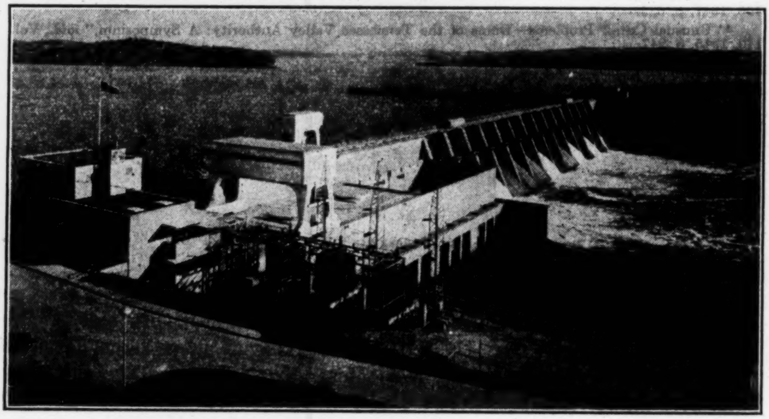

FIG. 2.—FORT LOUDOUN DAM VIEWED FROM THE NORTH BANK OF THE RIVER

---

[8] Alhambra, Calif.; formerly Chf. Constr. Engr., TVA, Knoxville, Tenn.

The over-all length of the combined earth and concrete dam (see Fig. 2) is 4,185 ft; and the structure is 95 ft higher than the original river bed or 165 ft from the lowest excavation. The south embankment is a rolled earth fill dam 2,600 ft long between the lock and the south abutment. The navigation lock between this earth embankment and the spillway has a chamber 360 ft long and 60 ft wide with a maximum single lift of 80 ft. The spillway section has fourteen bays, each 40 ft wide closed with Tainter gates 32 ft high. The powerhouse and intake span the original main river channel and have an over-all length of 280 ft in four bays. The service bay is stepped into the north bank and a core wall extends about 300 ft into the north abutment. A saddle dam on the north rim, 2,283 ft upstream from the main dam, is a rolled fill structure 525 ft long.

Selection of Site

As early as 1927, geologic studies were made by the Army Engineers in the vicinity of Fort Loudoun Dam to determine the availability of a suitable dam site. Investigations were continued by the TVA, and many sites were explored within the 10-mile to 12-mile reach of the river defined by the operating level of Watts Bar Dam downstream and by the cost of dredging the upper reaches of the Watts Bar pool as balanced against the cost of a higher dam. The occurrence of major faults and other geologic disturbances in the area limited the number of usable sites both topographically and geologically. Furthermore, the underlying rock of the entire area is more or less calcareous and therefore subject to weathering and solution.

Seven sites were studied, and four of these were explored by diamond core drilling. The Belle Canton Island site at mile 602.3 was finally selected; and, although this site was obviously not the best topographically, it did appear to be geologically preferable to any of the other sites available (with two exceptions, both of which had other disadvantages that offset the more suitable foundation). Enough drilling was completed at the Belle Canton Island site to disclose that the weaknesses could be corrected although the magnitude of the problem, as shown by the drilling, grouting, and concreting quantities in Table 1, was fully recognized when treatment was begun.

TABLE 1.—Drilling and Grouting Quantities

Feature	Drilling (Lin Ft)			Grout (cu ft)	Concrete (cu yd)
	Diamond	Wagon	Calyx

GEOLOGY

The topography of the Fort Loudoun dam site was not as favorable as that at the other sites because the alluvial valley is unusually wide—more than 2,800 ft (see Fig. 3). The river channel, approximately 1,800 ft from bank to bank, was originally divided by three alluvial islands into four separate channels from 100 ft to 300 ft wide. At the north abutment of the dam, the main channel was cut into the base of the ridge that formed the right bank of the river along the apex of a broad meander beginning just upstream. In the process of cutting into the right bank, this meander receded from the higher ground leaving a clay-covered terrace slope which forms the south abutment of the dam. The topography ranges from El. 730 in the river bed to El. 900 on the crest of the flanking ridges.

The only bedrock exposed at the dam site was that in the bluff on the north abutment ridge. Elsewhere the rock was covered by overburden varying in thickness as much as 40 ft and consisting of both alluvial and residual deposits, although the alluvial material capped most of the area where outcrops were not present. Stratigraphically, the underlying rock belongs to the Ordovician period of east Tennessee. Of the belt of rocks in the vicinity, only the Tellico and Sevier formations are actually involved in the dam foundation.

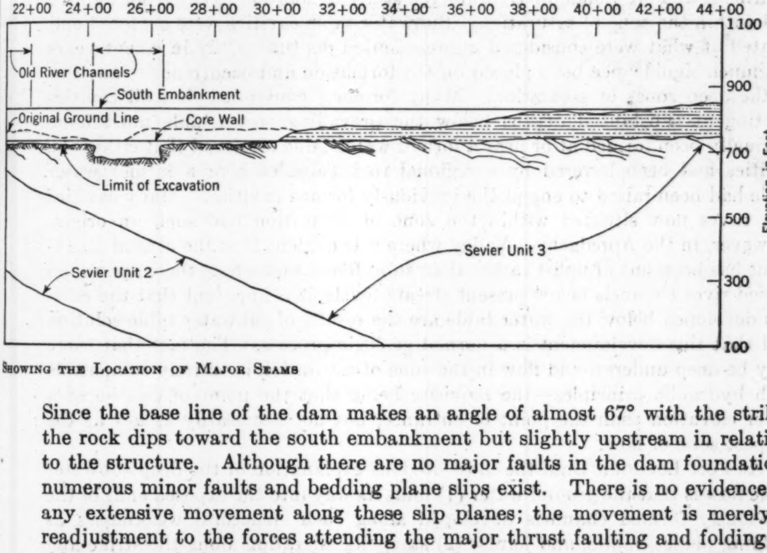
FIG. 3.—GENERALIZED GEOLOGIC SECTION

The Tellico formation is generally regarded as sandstone, but in this belt it is an arenaceous limestone; and, in spite of the siliceous character of the formation, it is nevertheless soluble. Because of the irregularity of the bedding and the presence of less soluble wavy stylolitic bands, cavities are not readily formed along the bedding planes. A distinctive feature of this formation at Fort Loudoun is the presence of an intraformational disconformity approximately 100 ft below the contact of the Sevier formation. There was an old erosion surface along the bedding at this position on which from 3 ft to 5 ft of shaly and fossiliferous limestone were deposited. This old erosion surface had been further attacked by solution, and a cavity was present along it.

The Sevier formation as a whole is quite diversified—ranging from a coarsely crystalline marble, through limestone and shaly limestone, to a dense blue-gray calcareous shale. It has been found practicable to divide this formation into three units (see Fig. 3), each with a predominant lithologic type. Unit 1, or the lower 225 ft, is predominantly limestone. Near the top of this unit the amount of shale becomes progressively more abundant and grades into the part designated as unit 2. As a whole, this unit is more soluble than the remaining part of the Sevier formation; hence, the cavities are usually larger and are either filled or partly filled with a clay residue. Unit 3 is mostly a gray calcareous shale; but, as in the other two units, there is a certain amount of interbedded shaly limestone varying in thickness from 20 ft to 100 ft. As this unit is less resistant structurally than the lower units, it has suffered considerable deformational effects and consequently is deeply weathered.

The geologic structure at the site is typical of the regional structure with a strike of north 40° to 45° east and an average dip of from 30° to 35° southeast.



SHOWING THE LOCATION OF MAJOR SEAMS

Since the base line of the dam makes an angle of almost 67° with the strike, the rock dips toward the south embankment but slightly upstream in relation to the structure. Although there are no major faults in the dam foundation, numerous minor faults and bedding plane slips exist. There is no evidence of any extensive movement along these slip planes; the movement is merely a readjustment to the forces attending the major thrust faulting and folding in this region. A thrust fault in the Tellico formation is unique in that it is the only thrust fault of any magnitude at the site that was not developed along the bedding. However, the movement is not considered extensive although a cavity has been formed along this weakness. Almost without exception, the many solution cavities developed in the foundation were controlled by solution along geologic structures—faults, joints, and bedding planes. At the intersection of these fractures, the larger and more continuous cavities and seams were developed. Solution followed intricate patterns with channels and cross channels predominating, separated at irregular intervals by rock pillars. The presence of these pillars greatly augmented the bearing strength of the formation, but a certain amount of consolidation grouting was considered necessary. Contrary to the normal conception that relatively more cavities are to be expected in the purer limestone, the cavities in this area were primarily controlled by structural features rather than by the purity of the rock. Also, founding a dam on impure, less soluble, limestone does not necessarily insure a better foundation than one on a pure, more soluble limestone—provided the latter is free of deformational features.

For convenience in the field but of no regional geologic significance, the master cavities or weathered bedding seams were designated from lower to upper as the Tellico, disconformity, No. 1, No. 2, No. 612, adit, and R13. These seams and their positions relative to the dam are shown in Fig. 3.

FORMATION AND CHARACTER OF CAVITIES

An excellent opportunity was presented during foundation excavation and treatment at Fort Loudoun Dam for the study of solution cavities both above and within the zone of saturation. Subwater table cavities were explored and treated at what were considered unprecedented depths. Only in recent years has much significance been placed on the formation and occurrence of cavities in the deep zones of saturation. Many formerly contended that all cavities existing at substantial depths below the prevailing water table must have originally been formed at or near a former water table level and that either the cavities had been lowered by a regional rock subsidence or a former water table had been raised to engulf the previously formed cavities. Many cavities and caves now situated within the zone of saturation had such an origin. However, in the Appalachian Valley where it is evident that the crustal movement has been one of uplift rather than subsidence, and where there are no old buried river channels below present stream levels, it is apparent that the cavities developed below the water table are the results of subwater table solution and that this development is a normal geologic process. The fact that there may be deep underground flow in the zone of saturation is entirely compatible with hydraulic principles—the requisite being that the point of exit be at a lower elevation than the point of entrance, but not necessarily as low as the deepest zone of flow.

At Fort Loudoun Dam the most obvious explanation of the deep subwater table flow is that the ground water (1) finds its way into the exposed ends of the previously formed channels developed along such structural weaknesses as bedding planes, faults, and joints; (2) starts its migration along the strike and down the dip of these conducting channels in irregular circuitous paths to a depth determined by the hydraulic head, by the solubility of the rock, and by the structural weaknesses; and (3) resurges upward to the point of discharge. The flow and resulting creation of cavities proceed downward until an upward or lateral movement is less resistant than continued downward flow. Thus, a system of both vertical siphons and low-angle inverted siphons develops, one group below the other, the depth dependent primarily on the differential head. Often, the watercourses are clogged with insoluble residue that causes the water to seek deeper levels as solution continues. The existence of an inverted siphon flow was actually observed during excavation and was further attested by the presence of cold-water springs or boils in the river bed. Dye injected into holes upstream from the cofferdam showed in the boils encountered in the upper few feet of excavation more than 1,000 ft away.

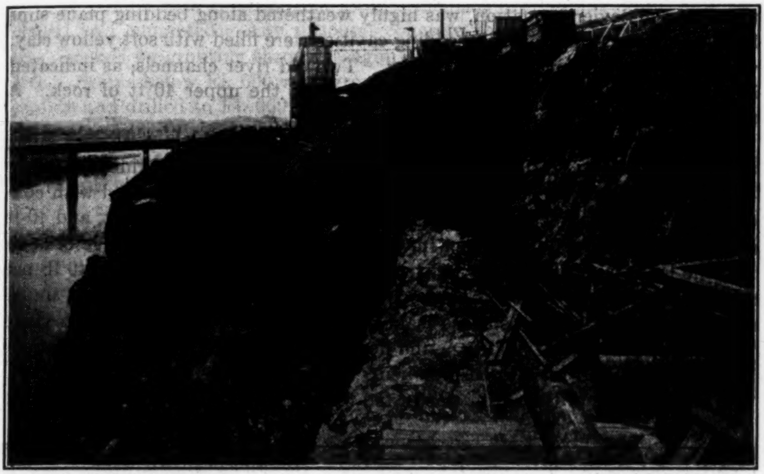


FIG. 4.—NORTH ABUTMENT, SHOWING TYPICAL ROCK PINNACLES

In the north abutment, solution has resulted in the formation of a series of deep troughs separated by intervening pinnacles (see Fig. 4). This formation, occupying a ridge with a steep bluff at the encroaching meander of the river, demonstrated an interesting point—namely, that the presence of a steep and apparently sound limestone rock bluff is not a guarantee that sound rock extends backward into the bluff; it may be nothing more than a false front with deep weathering just behind it.

FOUNDATION INVESTIGATION

For purposes of exploration the pattern of core drilling consisted of holes on lines parallel to the old preliminary drill ranges to enable the utilization of holes previously drilled. Holes were spaced on 50-ft centers with some intermediate check holes. Ordinarily, 3-in. diamond drill bits were used. The depth of holes depended on the geologic structure and ranged from 33 ft to 198 ft below the original rock surface.

For the lock location, ten ranges were drilled from upstream to downstream—a total of ninety-one holes and 8,580 lin ft. In addition, one 36-in. calyx drill hole 75 ft deep was sunk for visual inspection of the rock in place. Exploratory holes were drilled concurrently with construction, and each section was drilled in advance of excavation to determine the problems involved. A total of 58,193 lin ft of diamond drilling and 365 lin ft of calyx drilling was completed for the exploration of the dam foundation. (A general description of calyx drilling has been presented elsewhere by Mr. Lewis.[4])

SOUTH EMBANKMENT

The bedrock of the south embankment, predominantly calcareous shale of unit 3 of the Sevier formation, was highly weathered along bedding plane slips from El. 730 to El. 690. The bedding cavities were filled with soft yellow clay, which was the residuum of weathering. Two old river channels, as indicated in Fig. 3, were extremely cavernous throughout the upper 40 ft of rock. A typical weathered section is shown in Fig. 5.

A trench was excavated to fairly sound rock from the lock southward along the line of cutoff to Station 29+63. It was approximately 3 ft wide; and, after 4-in. vertical pipes were set on 2-ft centers, the trench was backfilled with concrete to a depth of 5 ft. Wagon drill holes were drilled in 20-ft, 30-ft, and 40-ft stages on 2-ft centers using the 4-in. pipe for casing. After each stage of drilling, the holes were thoroughly washed using pressures of 20, 30, and 40 lb per sq in., respectively, for each of the three stages, followed by grouting under similar pressures. Some surface leakage of grout occurred during each stage but it appeared farther upstream and downstream for each subsequent stage—a good indication that a cutoff was being obtained as the holes were deepened. The effectiveness of the cutoff was tested by grouting 60-ft diamond drill holes on 10-ft centers. Very little additional grout was accepted by these holes, and the cores recovered indicated excellent grout penetration along the weathered shale beds.

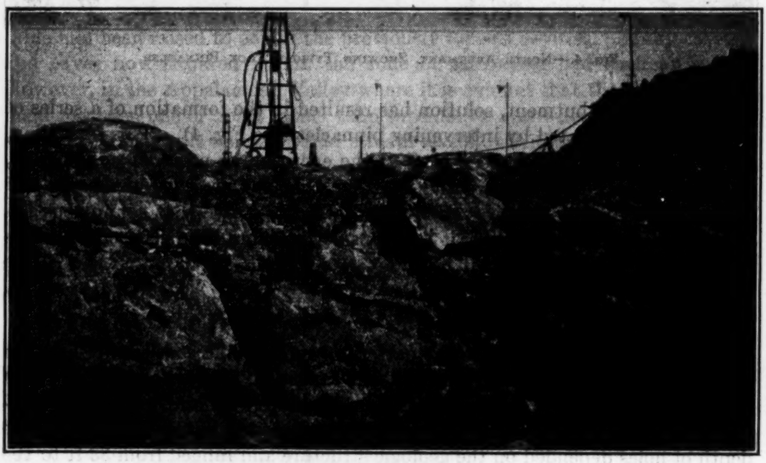

FIG. 5.—WEATHERED ROCK IN THE OLD RIVER CHANNELS; SOUTH EMBANKMENT

---

[4] "Large Core Drills Aid Construction at Chickamauga Dam," by James S. Lewis, Jr., *Transactions* ASCE, Vol. 105, 1940, p. 850.

Rather than attempt to treat the intersection of the cutoff with the old river channels in a similar manner, a positive cutoff was secured by backfilling the 38-in. calyx drill holes with concrete. Originally, these holes were drilled to El. 690 on 5-ft centers with the intervening unsound rock being removed. Because the practice proved both expensive and dangerous, the holes were backfilled with concrete and an intermediate overlapping 38-in. hole was drilled and concreted. Any unsound concrete that might have been placed was checked by grouting through wagon drill holes in the center of each 38-in. hole. Seams below El. 690 were grouted through diamond drill holes on 10-ft centers and drilled to El. 660. Where mining between the 38-in. holes on 5-ft centers was possible, wagon drill holes on 2-ft centers were grouted to form the intervening cutoff and to consolidate any unsound concrete. While this cutoff was being constructed, sufficient water entered the holes to prohibit drilling until the entire area was encircled with diamond drill holes on about 5-ft centers 20 ft upstream and downstream, and grouted using neat cement with calcium chloride added to accelerate the set.

Permeability and porosity tests indicated that the overburden south of the core wall was essentially impervious and that a satisfactory cutoff could be obtained by stage grouting. Holes were first drilled 20° from the vertical to intersect any strike joints present; but, since there was a relatively small grout acceptance, the remaining holes, for economy, were drilled vertically on 6.25-ft centers and grouted in 10-ft stages to El. 680 with deeper check holes to El. 640 every 50 ft. The first stage was grouted at a pressure of 0.5 lb per foot of overburden and each successive stage at an additional 5 lb per foot of overburden until the last stage, which was grouted at a pressure of 50 lb per sq in.

Lock

In most of the rock underlying the lock river wall and the downstream half of the land wall, closely spaced weathered seams and cavities were present in depths from 30 ft to 40 ft. Below this zone the cavities were separated by from 20 ft to 50 ft of intervening sound rock that possessed considerable bearing strength in the form of irregularly spaced rock pillars. As the major cavities in the lock foundation—those along the bedding plane slips—were inclined to the southeast with an upstream pitch, they became progressively nearer the rock surface toward the downstream end of the lock.

Obviously, with so many deep cavities and seams existing under the lock area, it was not practicable to excavate the entire zone of cavitation. If a stratum of sound rock were deep enough, although superimposed on defective material, it could support the lock structures through arch action; and, as a precautionary measure, the entire lock area was subjected to consolidation grouting prior to cutoff treatment—in most instances, before concreting operations. Even with this program of foundation treatment, excavation to depths as great as 60 ft was necessary for the river wall foundation.

The depth and spacing of the consolidation holes were contingent on rock conditions and foundation requirements. Both first-stage holes 20 ft deep and second-stage holes 40 ft deep were sunk with wagon drills on 10-ft and 5-ft centers in parallel lines from 10 ft to 12 ft apart. Stage one was usually grouted at a pressure of 20 lb per sq in.; and stage two, at a pressure of 40 lb per sq in. The program was supplemented with diamond drill check holes, and grout pipes were calked into any open seams for grouting after concrete was poured, as shown in Fig. 6. Under the river wall and lower miter sill, the grouting program was supplemented by mining through calyx drill holes wherever necessary to secure a cutoff and to augment bearing strength.

Fig. 6.—Pipes Set in Lock Foundation for Consolidation Grouting After Placing Concrete

The cutoff across the lock consisted essentially of a shallow curtain of wagon drill holes 40 ft deep grouted at low pressure and a deeper curtain of diamond drill holes from 100 ft to 150 ft deep grouted at high pressure. The low-pressure curtain was designed primarily to reduce, to a minimum, the percolation under the structure through small cracks and joints in the rock surface. Stage one of the low-pressure holes was drilled 20 ft deep on 2-ft centers and grouted at a pressure of 20 lb per sq in. The holes were redrilled to 30 ft, washed, and then grouted at a pressure of 30 lb per sq in. They were finally drilled to 40 ft, washed and grouted at a pressure of 40 lb per sq in. Diamond drill holes for the high-pressure curtain followed the same line as those for the low-pressure curtain and varied in spacing and depth to satisfy structural and geological conditions. In highly weathered areas, grouting alone was not considered adequate and 36-in. calyx drill holes were spaced on such centers that it was possible to mine out unsound material between the holes and to backfill the holes with concrete. Because of the soundness of the near-surface rock under the upper miter still, the low-pressure grout curtain was eliminated and the high-pressure curtain was utilized to grout the deep bedding seams.

Spillway and Powerhouse

Limestone of Sevier unit 2 underlies the spillway from its intersection with the lock to the 9–10 block line where it grades into unit 1 for the remainder of the spillway area to the 1–2 block line. At this line a gradational contact with the Tellico formation underlying the powerhouse takes place, see Fig. 3. Exploratory drilling had shown the rock of the spillway to be intricately dissected by weathered seams and cavities from the top of rock at El. 730 to El. 700. Below this zone of weathering, the rock was essentially sound except for the presence of several master bedding cavities that were remarkably continuous and extended to great depths.

The No. 1 seam, the No. 2 seam, the No. 612 seam, and the adit seam (Fig. 3) were the structural features that controlled the spillway excavation pattern. Other structural weaknesses were comparatively tight except at or near the intersection of bedding cavities and faults. As in the lock, some compromise had to be made between open excavation and a program of foundation treatment. Excavation was generally carried to El. 700 (El. 712 for the apron), and the additional rock was excavated down the dip of these major bedding seams to a point where mining and grouting were more economical than was the process of making a further open cut. The resulting spillway excavation had the appearance of a level rock surface modified by the removal of large wedge-shaped blocks at the outcrop of the major bedding planes.

Except for the disconformity seam which underlies practically the entire powerhouse area and several minor strike joint cavities, the foundation rock of the powerhouse was only slightly weathered and little excavation beyond design requirements was necessary. The intake section was excavated to El. 715 with additional rock removal along the weathered bedding planes in intakes 2 and 3 and with removal of weathered rock at the outcrop of the No. 1 seam in intake 4. Excavation for the draft tubes was governed by design with the exception of a wedge-shaped block along the outcrop of the disconformity seam in Sevier unit 1.

Consolidation grout holes were drilled throughout the entire spillway area to augment the bearing strength of any unsound rock. Consolidation consisted not only of grouting through wagon drill holes and diamond drill holes, but also of mining large seams and cavities through calyx drill holes and backfilling these mined zones with concrete. The most extensive mining operation for consolidation was along the adit seam under spillway block 15. The full width of the block, upstream and downstream, was excavated by undermining; and, because of the overburden, the operation was accomplished in stages. A section 10 ft wide was first excavated and a concrete pillar was placed for support. This procedure (Fig. 7) was then repeated until the entire area had been mined out and backfilled with concrete.

Consolidation grouting of the intake sections was a simple procedure compared with the extensive and intricate program necessary under most of the spillway blocks. Excavation left only the deep disconformity seam to be treated, and this was accomplished through a uniform pattern of diamond drill holes on 10-ft centers grouted at a pressure of 50 lb per sq in. Occasionally, holes were taken to the deeper Tellico seam but it was found to be essentially tight.

All areas of unsound rock which might be potential aquifers for leakage under the spillway and powerhouse were treated by constructing a cutoff curtain extending the full length of the structure along the upstream face. The method of treatment varied to meet the conditions as they were encountered. It consisted of stage grouting through diamond drill holes and wagon drill holes, and of mining and backfilling with concrete through calyx drill holes—in those areas in which grouting alone was not sufficient. Mining involved the removal of a part of the unweathered rock immediately surrounding the actual seam to provide a tunnel large enough for a man to work. Most of these cutoff tunnels were about 4 ft high and from 4 ft to 5 ft wide. On completion of the mining program, the tunnel was backfilled with concrete and the calyx drill holes were filled with concrete to the surface to secure a hydrostatic head on the tunnel concrete that greatly reduced the possibility of voids and air pockets.

FIG. 7.—MINING ADIT SEAM UNDER SPILLWAY BLOCK 15

Exploratory drilling had shown the No. 612 seam (Fig. 3) to be badly weathered throughout most of the spillway section. Eight calyx drill shafts were started in spillway blocks 10, 11, and 12, but their completion was prevented by a prohibitive amount of water that could not be controlled successfully by pumping. An auxiliary cutoff was grouted across block 10 along the strike to prevent this leakage and to form a barrier against which a cutoff could be grouted. Holes were drilled and grouted first on 16-ft centers, followed by holes on 8-ft centers and 4-ft centers, and finally on 2-ft centers throughout blocks 10 to 14. The entire procedure was repeated in three stages—drilling and grouting the same holes first on 8-ft centers, then on 4-ft centers, and finally on 2-ft centers. On completion of this work, the calyx drill holes and mining operations were completed without further water problems.

Low-pressure grouting, through wagon drill holes, was applied to spillway blocks 12, 13, and 14 only. The remainder of the spillway was subjected to closely spaced deeper diamond drill holes grouted in stages at a pressure of

100 lb per sq in. Final spacing of holes was usually 2 ft on centers; and, in the powerhouse area, holes were spaced on 4-ft centers. Fig. 8 shows the pattern of cutoff treatment across the spillway area and Fig. 9 shows similar treatment given to the powerhouse foundation.

FIG. 9.—SECTION ALONG POWERHOUSE AND SERVICE BAY CUTOFF SHOWING TREATMENT OF LARGE BEDDING CAVITIES AND STRIKE JOINTS

Although it was not part of foundation treatment, an extensive grouting program undertaken for sealing leakage under the cofferdam was largely responsible for controlling the flow of water into the river bed construction area.

The first-stage cofferdam enclosing the lock and the ten adjoining spillway blocks was essentially tight; but, as excavation progressed below the overburden, several boils developed along the outcrop of the weathered bedding seams and from the diamond drill holes that penetrated deeper cavities. As further leakage was anticipated with deeper excavation, the entire perimeter of the cofferdam was subjected to grouting—first through holes on 20-ft centers and then through holes on 10-ft centers with some holes on 5-ft and 2.5-ft centers. Initial grouting was done with neat cement; but, since large quantities were consumed in the first holes, clay-cement grout was substituted for the major part of the work. For the more persistent leakage, asphalt was used successfully to stop the flow of water.

A similar grouting program was developed for the second-stage cofferdam comprising the remainder of the spillway and powerhouse area, but grouting of this stage was completed prior to unwatering. Although the second-stage cofferdam was tighter than the first-stage cofferdam and presented practically no water problems, its imperviousness was not completely ascribed to the grouting of the cofferdam before unwatering. The large quantities of clay-cement and asphalt injected into the first-stage cofferdam had considerable effect on the tightness of the second-stage cofferdam as was revealed by the excavation. Drilling and grouting quantities for the cofferdams are listed in Table 2.

NORTH ABUTMENT

Exploration of the north abutment revealed that the depth of excavation required to reach sound rock would necessitate a nonoverflow gravity type of dam between the service bay and the north core wall. In a manner typical of the entire north abutment area, the Tellico formation underlying the proposed nonoverflow section and service bay was dissected by a complex series of vertical joints along which weathering had taken place to great depth, leaving high pinnacles of comparatively sound rock separated by deep troughs filled with a sandy clay residuum (see Fig. 4). This condition was further aggravated by the presence of the disconformity seam (Fig. 3) which outcropped in block 3 of the nonoverflow section and necessitated a deeper excavation than was anticipated.

Under the service bay, the disconformity seam was badly weathered and the foundation was excavated to this seam over most of the service bay area. With this depth of excavation, the only consolidation necessary under the service bay consisted of grouting through diamond drill holes on 10-ft centers along ranges 20 ft apart throughout the three upstream blocks. Consolidation grouting was supplemented by driving a 4-ft tunnel along the unexcavated part of the disconformity seam and filling it with concrete, as shown in Fig. 10.

Since it was impracticable to remove the rock to the bottom of the several deep vertical joints encountered in the nonoverflow section, excavation was

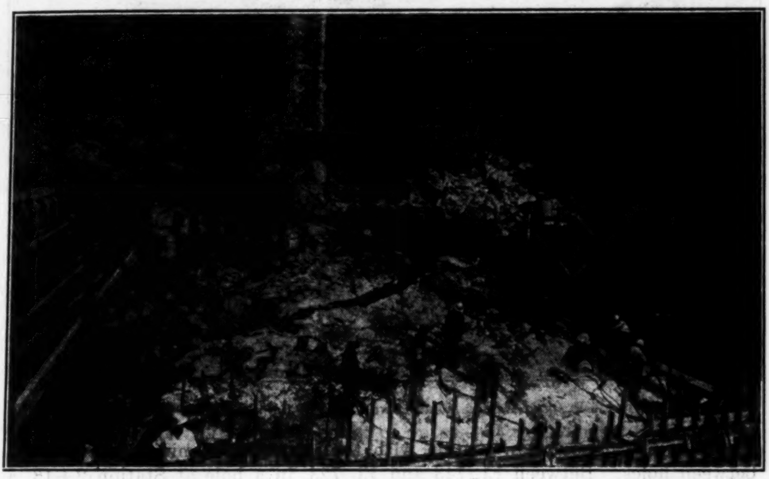

Fig. 10.—Disconformity Seam and Associated Strike Joint in the Service Bay

stopped at a depth considered adequate for bearing strength. A cutoff was constructed by mining all unsound areas through deep calyx drill holes, backfilling with concrete and subsequently grouting through closely spaced diamond drill holes. As soon as excavation in nonoverflow blocks 1 and 2 was completed, concrete was poured to El. 800 to improve working conditions and to prevent the sliding of material into the cut. Barrel forms, as shown in Fig. 11, were brought up through the pour at several points to reduce later calyx drilling.

The seams treated were of two major types—(*a*) the shallow vertical weathered joints not removed by excavation, and (*b*) the deeper continuous Tellico seam with associated strike joints. Shallow treatment in block 1 of the nonoverflow section was unnecessary as all rock below the disconformity seam was essentially sound. In block 2, several weathered joints were mined through calyx drill holes. These holes were later deepened for mining the Tellico seam. Excavation to the disconformity seam in block 3 revealed a series of shallow but closely spaced badly weathered joints; and, instead of mining between holes, 36-in. calyx drill holes were first sunk on 5-ft centers and backfilled with concrete; intermediate holes were drilled to overlap the first holes. Similar treatment was given throughout block 4 with three holes later deepened to the Tellico seam.

Treatment of the Tellico seam under the nonoverflow and service bay section saw a difficult operation. Not only did the seam occur at depths as great as 150 ft, but its treatment was complicated by the presence of weathered strike joints that required additional and deeper mining. Fig. 12 will assist the reader in the discussion to follow. Three calyx drill holes, about 5 ft apart, were drilled in the nonoverflow section with the intention of mining the cavities between holes. Between El. 743 and El. 723, in a hole at Station 2+13, a strike joint was encountered; it was thoroughly mined and a concrete plug was placed to El. 745. The plug was then drilled out and drilling was continued to the Tellico seam where excessive water entered the excavation. Concrete plugs were poured in the calyx drill holes, and a ring of six diamond drill holes grouted at high pressure, was effective in stopping the flow of water.

FIG. 12.—SECTION ALONG THE NORTH CORE WALL AND THE NONOVERFLOW SECTION CUTOFF

Preparatory to tunneling southward along the Tellico seam, the steep wedge-shaped cut, caused by mining the strike joint, was poured to El. 665 to provide a level floor from which to work. The tunnel was driven along the Tellico seam southward until it intersected a previously drilled hole at Station 2+75. A weathered strike joint at Station 2+70 was mined below the Tellico seam to El. 650 where weathering had ceased; but, to eliminate the possibility of any deeper solution along the joint, six shallow diamond drill holes were drilled from the tunnel floor along the down-dip side of the joint and grouted.

Another calyx drill hole intersected the Tellico seam at Station 3+12, and mining was started northward to intersect the first section of the tunnel. Excellent progress was made in this section despite the presence of a weathered bedding seam intersecting the Tellico seam at Station 3+12 and pinching out at Station 2+63. By using the Tellico seam as the floor and the bedding cavity as the roof of the tunnel, a cutoff was obtained along both these structures in a single operation. After the tunnels were joined, they were cleaned and backfilled with concrete.

Concrete was placed in such a manner that only a minimum of redrilling was necessary in any hole to be used for further mining. Treatment of the Tellico seam by mining north of Station 2+08 was not required; however, the unmined area was subjected to grouting. Before tunneling the Tellico seam southward under the service bay from Station 3+12, the area was subjected to a grouting pattern to check the flow of water that was indicated by exploratory drilling. Three calyx drill holes were bored to the seam. The area was found to be more badly weathered than had been anticipated; therefore, mining was continued to Station 4+72, as indicated in Fig. 9. Several strike joints in the service bay area were also intersected and treated similarly to those encountered in the nonoverflow section.

Following the mining operation, the entire nonoverflow and service bay were supplemented with grouting through diamond drill holes on 2-ft centers throughout the service bay and blocks 1 and 2 of the nonoverflow section. Blocks 3 and 4 of the nonoverflow section were treated with holes on 4-ft centers.

North Core Wall

Rock conditions under the north core wall were similar to those under the nonoverflow section. However, the deep weathering was largely confined to two major areas separated by a ridge of comparatively sound rock. The first of these areas was under blocks 5 and 6 and the second—by far the most deeply weathered part of the entire dam foundation—existed under blocks 8 and 9 (see Fig. 12). Exploratory drilling disclosed a nearly vertical oblique joint striking normal to the dam axis and weathered to the unprecedented depth of approximately 220 ft. This joint had been subjected to some lateral movement, thought to be local, but possibly with a direct bearing on the depth and degree of the solution.

An open cut excavation was first made to El. 800. Further excavation to bare the rock for deep drilling and foundation treatment was done by trenching, and heavy timbering was required to effect this operation. A trench 4 ft wide was dug to El. 745 at the south end and to El. 758 at the north end. Below these levels, weathering was restricted to the narrow vertical joints which were mined out through calyx drill holes and backfilled with concrete.

FIG. 13.—METHOD OF CALKING A CAVITY THAT INTERSECTED THE CALYX DRILL HOLE

Before drilling was begun, the bottom of the trench was filled with concrete to El. 800 and El. 796 at the north end and south end, respectively. Barrel forms were again set as required to reduce the drilling footage. Treatment under blocks 5, 6, and 7 of the core wall consisted of both shallow and deep calyx drilling. In some areas a shallow cutoff was obtained with overlapping 36-in. calyx drill holes spaced on 2.5-ft centers. Although this method was possible for shallow cutoffs, it was not feasible for treating deeper cavities because of the large amount of drilling and the difficulty, at greater depths, of obtaining the alinement necessary.

The most difficult foundation problem—not only of the north core wall but also of the entire project—was the deep vertical oblique joint under block 8. As in other parts of the foundation, calyx drill holes provided shafts for the mining operation. The first of these holes was sunk at Station 0+86.8 (see Fig. 12); and, at El. 712, the hole intersected a highly weathered area at the intersection of the oblique joint and the Tellico seam. Another hole was drilled 10 ft southward at Station 0+96.8, and the cavity was cleaned between these two holes to El. 703 and filled with concrete. The concrete plugs thus formed were redrilled, and mucking was continued to El. 695 where weathering once again was confined to the vertical joint; and the cavity was again filled with concrete. The hole at Station 0+96.8 was then no longer required and was backfilled with concrete.

The mucking, backfilling, and redrilling processes continued in 7-ft stages in the remaining hole to El. 674 where the water inflow became excessive. Another hole at Station 0+76.8 was then drilled to a slightly lower elevation and connected to the cavity with jackhammer holes. A pump was installed to handle the water, and mucking was continued. One hole in the rock was kept open for a sump, by offsetting if necessary, and the other hole was used for mucking.

At El. 635 a slide forced a temporary abandonment of the treatment until the seam-filling material was consolidated by grouting. Preparatory to grouting the seam through diamond drill holes, several minor joints intersecting the walls of the hole and the oblique joint had to be plugged to avoid loss of grout. These joints were calked by inserting a 35-in. steel casing into the calyx drill hole at the point to be treated and hand packing grout into the seam between the casing and the periphery of the hole, as shown in Fig. 13. In addition, nipples for pressure grouting were calked into the seams wherever possible. Four 1.5-in. grout pipes were driven into the seam where the slide occurred and a 4-ft concrete cap was placed. After grouting through these pipes at a pressure of 100 lb per sq in., jackhammer holes were drilled from the calyx drill hole into the seam at several elevations and grouted at high pressures. Concurrently, two ranges of diamond drill holes, one from 10 ft to 40 ft upstream at Station 0+76.8 and the other a like distance downstream at Station 0+86.8 were drilled normal to the core wall for grouting the seam. Holes were drilled on 10-ft, on 5-ft, and, in some places, on 2.5-ft centers and grouted at high pressure.

When the concrete plug was drilled out of the calyx drill hole, the sandy clay residuum had been consolidated, and the process of treating the cavity was continued to El. 593 where it pinched to a fraction of an inch. Deeper treatment was accomplished by placing 1,065 cu ft of grout into two perforated pipes driven in the seam and by injecting 105 cu ft of grout through jackhammer holes drilled into the seam from the adjacent calyx drill hole. A 4-in. pipe was encased in the concrete backfill, and a later diamond drill hole, bored into the seam to El. 478.5, was grouted with 787 cu ft of cement at a surface pressure of from 100 lb to 120 lb per sq in. as the final treatment. Supplementing the calyx drill hole procedure, diamond drill grout holes were drilled on 4-ft centers for the entire length of the cutoff to consolidate any possible concrete shrinkage in the mined areas and to treat minor cracks and joints.

North Reservoir Rim and Saddle Dam

The bearing of the ridge forming the north reservoir rim parallels the strike of the geologic structure with the dip of the rock toward the reservoir. Normally, such a structure would provide a satisfactory foundation; but the presence of a complex pattern of weathered strike and dip joints made a certain amount of rim treatment necessary to prevent leakage downstream or seepage northward through the ridge separating the reservoir from Muddy Creek Valley.

The north rim was treated by placing a grout curtain extending from the end of the core wall upstream more or less along the strike of the rock a distance of about 800 ft. Diamond drill holes, inclined 45° upstream and northeast to secure a maximum intersection with weathered dip joints, were grouted on 20-ft centers. These holes were reinforced by grouting vertical holes on 10-ft centers in the vicinity of the north core wall and on 20-ft centers farther upstream. Except for the vertical holes near the core wall (which were grouted with cement) the north reservoir rim was grouted exclusively with a clay-cement mix consisting of three parts clay to one part cement.

Drilling was discontinued whenever a cavity or group of cavities was encountered, and the hole was grouted before further drilling. The processes of drilling, grouting, and redrilling were continued throughout the length of the cutoff curtain until the final drilling of each hole showed no water loss and revealed a considerable margin of sound rock below the last cavity. For the upper 440 ft of the curtain, only two to four stages of grouting were necessary, but deeper weathering (to El. 590) toward the north core wall required grouting in as many as eight stages. Although the multiple-stage grouting procedure required a larger quantity of grout than would probably have been used with the single-stage method, the method afforded positive proof of the effectiveness of the grout curtain.

Only moderate treatment of the saddle dam was necessary because of the deep layer of overburden, the dip of the rock toward the reservoir, and the low head to which the structure was subjected. Grout holes were drilled along a zone of comparatively sound rock parallel to the axis of the saddle dam and at an angle of 45° to the south to intersect the predominant vertical joints. Holes were first drilled on 25-ft centers with intermediate holes on 12.5-ft centers. Closer spacing was necessary in some areas. The depth of grout penetration varied from El. 680 to El. 720, depending on the rock structure.

Drilling and Grouting Equipment and Materials

A maximum of sixteen diamond drills and six large-diameter calyx core drills were driven for foundation treatment in addition to several pneumatic wagon drill holes. Diamond drills were powered by four-cylinder 10-hp gasoline engines except when used in tunnel or galleries where an electric motor was substituted. Calyx core drills were driven by either 20-hp electric motors or 35-hp gasoline engines. Manufacturers' standard bortz bits were used for diamond drilling. Calyx core bits were 38 in. in diameter or smaller, and casings were made of ¼-in. steel from 54-in. to 33-in. diameters.

Seven grout mixers were used on the project, two of the type developed at Boulder Dam in Arizona and Nevada and five of the type developed at Norris Dam in Tennessee.[5] All grouting was done with 7-in. by 5-in. by 10-in., air-driven, double-acting, reciprocating pumps equipped with rubber valves and iron fluid pistons with replaceable rubber sleeves. The pumps and mixers were mounted together on skids so that they could be moved easily. The grout pumps were also used extensively for pumping water from tunnels during mining operations; and, during the treatment of the north core wall, these pumps were used successfully in a vertical position suspended in the calyx drill hole from an A-frame at the surface. In this position the pump did not require priming as the discharge line to the top of the hole remained full of water when the pump was not operating and provided a continual prime. This pump also operated satisfactorily when completely submerged in water.

---

[5] "Foundation Experiences, Tennessee Valley Authority: A Symposium," *Transactions*, ASCE, Vol. 106, 1941, p. 687.

The use of packers was limited at Fort Loudoun because of the stage-grouting methods generally required. In practically all instances where packers were used, the grout found its way through open channels and into the hole above the packers, thus grouting them in. For this reason, the use of the packers, in general, was abandoned.

For foundation grouting standard Portland cement mixed with water was used entirely, with the exception of the north reservoir rim and saddle dam as previously discussed. The water-cement ratio varied between 3.0 and 0.5 by volume. Grouting in an area was usually started with a thin grout and the water-cement ratio was gradually decreased. As pressures increased indicating possible refusal, the water-cement ratio was again increased.

SUMMARY

This paper describes the treatment of solution channels and cavities in a limestone foundation at unprecedented depths below the water table. The conditions described indicate that structural deformational features rather than rock solubility often control the depth and extent of weathering. In the Fort Loudoun limestone foundation, solution occurred down to a depth of 300 ft below the original ground surface and 260 ft below the water table. The deep mining operations both for consolidation and an effective cutoff challenged the combined efforts of the designing engineers, field engineers, geologists, and special construction personnel, all of whom contributed to the satisfactory solution of this difficult and unusual foundation problem. Contrary to the normal conception that relatively more cavities are to be expected in the purer limestone, the cavities in this area were primarily controlled by solution along geologic structures—faults, joints, and bedding planes, rather than by the purity of the rock. On this project the geologists really came into their own and to them due credit is given.

DOUGLAS DAM

BY T. F. TAYLOR,[6] ASSOC. M. ASCE

SYNOPSIS

The foundation rock beneath the concrete structure of Douglas Dam and part of the adjacent rim was dolomitic limestone of the Knox formation. Large bedding cavities existed at each abutment of the concrete dam and the rock in the original river bed was highly cavernous. That part of the rim which was formed by shale was relatively tight.

The procedure used to prepare the foundation for the concrete dam consisted of excavating the highly cavernous rock, and mining, cleaning, and backfilling with concrete the large bedding cavities that were overlain with sound rock. These operations were supplemented with an intensive grouting program over the entire foundation for the concrete dam.

The reservoir rim adjacent to the dam was grouted principally where the outcropping rocks were limestones. Very little foundation treatment was needed in the shale rim. An analysis of final grout consumptions in all areas treated show that a satisfactory foundation was obtained. Observations made more than six months after the reservoir had been filled to maximum pool level indicated that seepage from the reservoir did not exist.

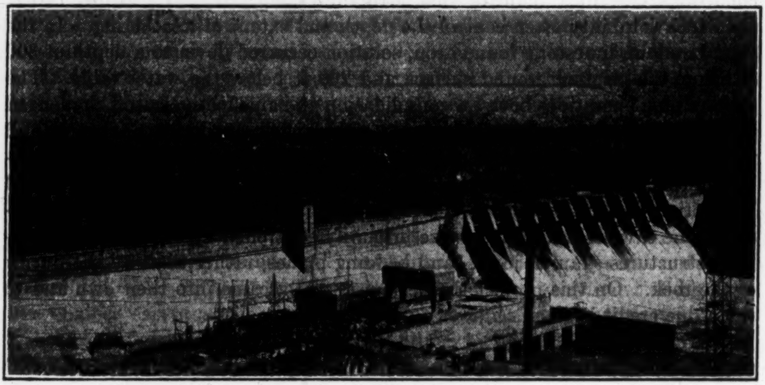

FIG. 14.—DOUGLAS DAM

INTRODUCTION

Douglas Dam is in Sevier County, Tennessee, on the French Broad River approximately 32 miles above its mouth (see Fig. 1). The site was located at a convergence in an otherwise broad valley. The original river channel at that point was about 500 ft wide at normal flow, with the bottom at approximately El. 868, and flanked on each side by a relatively narrow alluvial flood plain, on the average at El. 880. The south bank of the river was an almost vertical rock bluff. The north bank sloped away in the form of a steep sodded hill.

---

[6] Supt., Tennessee Eastman Corp., Oak Ridge Tenn.; formerly Constr. Engr., TVA, Douglas Dam, Dandridge, Tenn.

The concrete dam is approximately 200 ft high above the lowest point of the foundation and is 1,682 ft long at the crest. The main dam and powerhouse contain about 542,000 cu yd of concrete. Fig. 14 is a view of the completed dam, and Fig. 15 shows the plan of the structure and the geologic profile along the axis.

The topography of the reservoir rim, extending approximately 5 miles from the south end of the concrete dam, required the construction of eight earth dams in existing low saddles. The largest of these earth saddle dams contains 474,000 cu yd of compacted clay, and the total of all the earth saddle dams was 532,000 cu yd.

The foundation for the concrete dam is composed of dolomitic limestone of the Knox formation. The dolomite extends southward along the reservoir rim for a distance of 1,500 ft to Station 35+00. At this point, a relatively narrow band of limestone of the Lenoir formation begins and continues to a contact with the Athens shale on the south. The contact between the Lenoir limestone and the Athens shale is under the north end of the first and largest of the saddle dams. The remaining saddle dams are constructed on shale.

Preliminary exploratory borings at the dam site consisted of diamond core drill holes on three parallel ranges. The range lines were spaced 100 ft apart and were approximately parallel to the proposed axis of the dam. Holes were drilled on these ranges at 100-ft intervals, except at the south abutment where a few holes were drilled at 50-ft intervals. The holes penetrated from 100 ft to 250 ft into bedrock.

The exploratory drilling completed prior to the start of construction gave a general picture of the foundation, including the approximate elevation of sound, unweathered rock. It also indicated that, in the river bed, deep solution and weathering caused the formation of an extensive honeycomb of cavities and fissures. The weathering and solution apparently had not developed into any regular cavernous system.

In addition to the preliminary borings, considerable exploratory drilling was done during actual construction operations to develop accurate geologic sections. These sections were used for determining final excavation grades and for planning the general program of foundation treatment. Exploratory work was done with diamond core drills supplemented by a number of large-size, 42-in., shot drill holes to check questionable areas. The shot drill holes were planned to become a part of a tentative method of foundation treatment. A general section of the foundation along the axis of the dam is shown in Fig. 15(*b*).

Under the north abutment it was noticed that air was passing continuously in and out of some of the exploratory holes. These "blowing" holes indicated the presence of an extensive cavity in the foundation rock strata. It was

anticipated that this cave would have to be explored, and would receive special treatment.

At the south abutment a large bedding-joint cave was encountered which extended for some distance into the reservoir rim beyond the south end of the concrete dam. Drill holes in the rim indicated that no special foundation problem existed beyond the limits of the cave.

The anticipated program for foundation treatment consisted mainly of a general procedure for the concrete dam, plus a special treatment of the cavities existing at the north and south abutments and some curtain grouting in the reservoir rim areas.

NORTH ABUTMENT

The natural slope of the north riverbank at the dam site was nearly parallel to the dip of the foundation rock. Weathering in the upper strata of bedrock was fairly uniform and averaged from 8 ft deep to 10 ft deep over most of the area. The weathered rock was removed by open cut methods to expose good foundation rock.

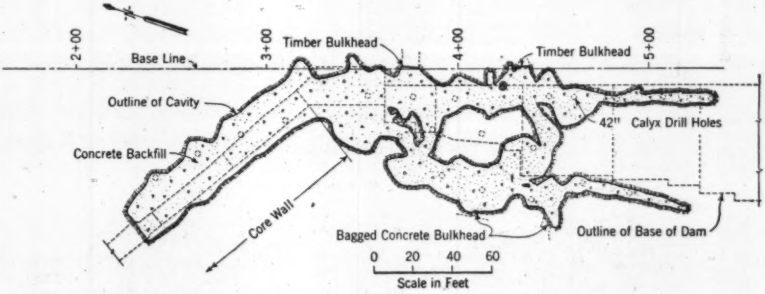

FIG. 16.—BEDDING-JOINT CAVITY UNDER NORTH NONOVERFLOW SECTION

The area in which the original exploratory drilling had indicated that an extensive cave developed along a bedding plane was further checked with 42-in. calyx drill holes. It was found that the cave extended under most of the area occupied by the north nonoverflow section of the dam and also under the north core wall. The location of the cave is given in Fig. 16, with the outline of the base of the dam shown superimposed on the plan of the cavity.

The bedding-joint cave was partly filled with clay, and it was intercepted by several strike joint cavities running normal to the axis of the dam. These strike joint cavities formed enlargements in the main cave, which made the maximum height of the cave approximately 5½ ft. About 40 ft of sound rock existed above the roof of the cave after the foundation for the dam had been excavated to final grades. The removal of this sound rock above the cave was not considered practicable or desirable. To provide adequate bearing and watertightness, it was decided to mine out and fill with concrete that part of the cavity lying under the area of the concrete dam and core wall.

To accomplish the mining and concreting operations, 42-in. calyx drill holes were drilled from rock surface to the roof of the cave on approximately 25-ft centers. Small hoists were set up over the drill holes to remove the muck and excavated material from the cave. After the cavity was mined out, it was thoroughly washed and cleaned with compressed air and water. Fig. 17 shows a section through the cave and gives the position of the large calyx drill holes.

Near the south end the height decreased so that it was necessary to enlarge the cave to provide working room for cleaning and washing. At the point where mining methods were stopped, the cave was approximately 0.6 ft thick.

Fig. 17.—Details of Treatment for the North Bedding Cavity

As shown in Fig. 16, there were comparatively few solid rock pillars supporting the roof of the cave.

Large quantities of water were used in the washing operations; but it was not necessary to install pumps in the cavity. The cave extended upstream and downstream far enough so that the water drained freely by gravity.

At the north end of the core wall, the rock was extensively weathered above the roof of the cave. Therefore, it was necessary to excavate by open cut methods until the core wall could be extended to the floor of the cavity. This is shown in Fig. 17. In all cases it was found that the floor of the cave was formed by a thin shaly bed which retarded the weathering below it.

Formwork was necessary in some cases to confine the limits of the concrete backfill and to establish construction joints. The original 42-in. calyx drill holes for mucking purposes were also used to place concrete. Filling was started from the calyx drill holes at the south end of the cavity and advanced northward. The floor of the cave received a thick bed of sand-cement mortar placed immediately in advance of the concrete—and as speedily as possible, to provide a hydrostatic head of fluid concrete. This method proved satisfactory; by filling the calyx drill holes with concrete, sufficient head was created to provide a relatively tight fill against the roof of the cave.

A total of 1,298 cu yd of concrete with ¾-in. (maximum size) aggregate was used to backfill the cave. The average mix had a water-cement ratio of 0.55 by weight and contained 1.83 bbl of cement, 0.79 tons of sand, and 0.74 tons of coarse aggregate per cubic yard of concrete.

After the cave had been completely backfilled, it was further treated by consolidation and curtain grouting with neat cement. The grout holes were extended through the cave from the foundation of the dam.

RIVER BED

The upper 20 ft to 60 ft of bedrock in the original river channel were extremely cavernous. This section formed the foundation for the spillway and a part of the powerhouse and intake section of the dam. Large cavities were found along many beds and were interconnected by cavities extending along both strike and dip joints. Some of the cavities were large enough to be termed caves and were continuous for long distances, principally along the strike of the rock. Solution was intensified because the strike of the rock was approximately parallel to the flow of the river. The cavities were partly filled with clay, sand, and gravel, and some of the foundation was so greatly weathered that it presented the appearance of clay and gravel in which nested huge floating boulders. Fig. 18 shows this condition.

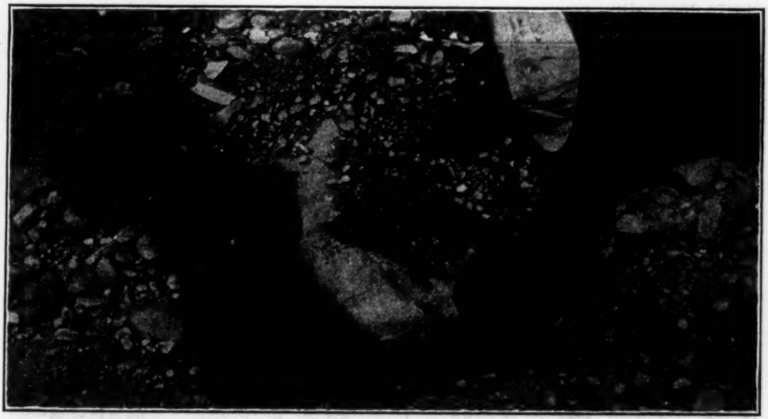

FIG. 18.—TYPICAL VIEW OF ROCK CONDITIONS IN THE RIVER BED FOUNDATION PRIOR TO FINAL EXCAVATION

The excavation of this cavernous rock presented an extremely difficult construction problem because of the large flow of water coming into the cofferdam area from the various cavities. When the first-stage cofferdam was unwatered, large leaks or boils occurred in the river bed which threatened the entire excavation program.

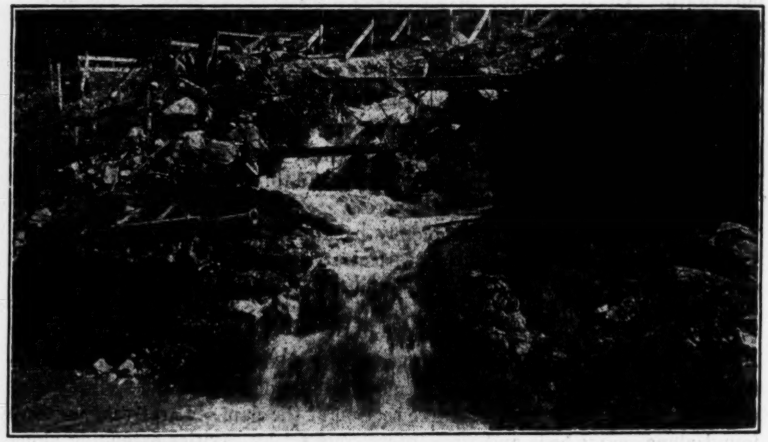

Fig. 19.—Cavernous Rock and Leakage Under the Upstream Cofferdam

Fig. 20.—Water Boil in the Excavation Area

To continue excavation, extensive grouting with asphalt, clay, and cement mixtures and with other materials was tried in an effort to cut off the flow of water coming in the work area. This was supplemented by large-scale clay blanketing in the river bed both upstream and downstream from the cofferdam.

In asphalt grouting, care was exercised to prevent asphalt from entering the foundation rock lying under the area of the dam below the final excavation grades. Although these efforts succeeded in cutting off a large part of the inflow of water, leakage was still a major problem during excavation operations. For a considerable period, thirty pumps discharging 100,000 gal per min were in constant operation to keep the cofferdam area dewatered sufficiently to permit excavation to progress. Fig. 19 shows the cavernous rock beneath the upstream arm of the first-stage cofferdam. One of the many large leaks is shown and asphalt may be noticed where it had been used in cofferdam grouting. Fig. 20 shows one of the many boils of water in the middle of the excavation area. Although the construction difficulties and the cofferdam grouting are not part of the foundation treatment program, they are mentioned to indicate the scope of the foundation problem in the river bed.

As the weathered and cavernous rock was removed and excavation progressed in depth, the leakage was confined to the sides of the excavated area. Despite construction difficulties, all foundations were excavated to sound, principally unweathered rock; and, by isolating small areas, concrete for the dam was placed on a dry foundation. A few relatively minor seams remained below the final excavation grades. These were treated with consolidation and curtain grouting.

South Abutment

The alluvial flood plain on the south side of the river at the dam site ended at a vertical rock bluff approximately 75 ft high. Beyond the top of the bluff was a gently sloping upland. From the top of the rock bluff southward for a distance of 327 ft, the rock formed the foundation for the south nonoverflow section of the concrete dam. Early exploration indicated that extensive excavation would probably be required in this abutment. Prominent deeply weathered strike joint solution channels extended through the foundation normal to the axis of the dam. In addition to these solution channels, there were less pronounced bedding cavities. Terrace clay and gravel were present in the overburden as well as in the cavities.

The program followed in the south abutment area consisted of excavating by open cut methods to a well-defined bedding cavity. Below this cavity the vertical fissures were mined out and backfilled with concrete. Fig. 21 shows the excavation in the south abutment and one of the major strike joint solution channels. The area was excavated 134 ft below the original ground surface, 115 ft being rock.

The exploratory drilling also revealed the presence of a large bedding cavity beginning at the end of the south nonoverflow section of the concrete dam and extending into the rim. The cave was partly filled, and at some points tightly filled with clay, sand, and terrace gravel, with the terrace gravel normally in lenses. Exploratory drilling indicated the presence of the cave for approximately 700 ft between Stations 20+0 (El. 963) and 27+0 (El. 790).

Enlargements of the cave existed at strike joint solution cavities. The cave was excavated by drift mining supplemented by 42-in. shot drill holes on 50-ft centers extending vertically from the ground surface to the floor of the cave. A drift was excavated following the cavity down the dip from a portal near the end of the concrete dam. Fig. 22 shows a section through the cave and gives the position of the shot drill holes. Mining operations were extended for a distance of 410 ft from El. 963 at Station 20+0 to El. 860 at Station 24+10. The height of the cavity ranged from 3 ft to 10 ft except for one section 50 ft long, which was 25 ft high. In some instances, it was necessary to excavate rock to obtain sufficient working room in the cavity. During the mining operations no difficulty was experienced with ground water until the cavity reached El. 873, which was river level. Below this elevation, periodic pumping was necessary to allow excavation to proceed.

FIG. 21.—STRIKE JOINT SOLUTION CHANNEL IN SOUTH ABUTMENT

To prevent leakage, a concrete cutoff wall or plug was designed and placed in the cavity as a water stop. The concrete plug extended from the floor to the roof of the cavity. The cavity was cleaned and the concrete was placed by using the large-diameter shot drill holes. Concrete filling was begun at the low end of the cave and proceeded up the dip; and wood forms were used to maintain construction joints and the proper width of the plug. Care was exercised at the south end of the plug to obtain a solid tie into rock, at which point the plug was widened considerably. The plug contained 2,458 cu yd of concrete using a maximum size of aggregate of 1½ in.

After the concrete had contracted, the joint between the roof of the cave and the top of the concrete plug was grouted. Where necessary, openings be-

tween the roof of the cavity and the concrete plug were calked to prevent grout leaks, and the grout was supplied through nipples previously placed on approximately 20-ft centers along the roof of the cavity. The detail of these grout outlets and of the concrete plug is shown in Fig. 22. As an added precaution, clay was placed to fill the cavity both upstream and downstream from the concrete plug.

An extensive program of cement grouting followed the completion of the concrete plug, with the drill holes extending from the ground surface through the concrete filled seam. This procedure made the concrete plug a part of the grout curtain extending from the dam into the rim area.

South Reservoir Rim

Beyond the south end of the concrete dam, the rim is formed by Knox dolomite for a distance of 0.4 mile. A limestone of the Lenoir formation begins at this point and continues for a short distance to a contact with the shale of the Athens and Sevier formations. The shale ridge extends southward with an average width of 1,000 ft, at a maximum reservoir elevation of 1002. The highest point of the ridge is approximately at El. 1240, and the shale ridge drops below a design crest of El. 1019 at seven saddles. At each of these saddles an earth dam was required in addition to a large saddle dam at the contact of the limestone and shale.

The part of the rim underlain by the Knox dolomite is covered by a blanket of terrace clay and gravel which averages 43 ft in thickness. Most of the Lenoir limestone rock comes to the surface, and there are many exposed ledges and pinnacles of limestone.

Except for the one cave at the end of the concrete dam, there was little evidence of solution and weathering in the rocks of the south rim. Weathering had not affected the Athens shale except for a few minor beds. It was found that the unweathered shale was not absolutely impervious as core drilling encountered streams of water at relatively low levels. The beds in the Sevier shale were folded and faulted. The shales were somewhat calcareous and contained a few interbedded layers of shaly limestone. The entire formation was essentially insoluble and without cavities or deep weathering.

North Reservoir Rim

The alluvial flood plain on the north bank of the river at the dam site ends in a steeply sloped sodded bank which rises to El. 1200 approximately 0.3 mile from the north end of the concrete dam. The underlying rock is the Knox dolomite formation.

Preliminary borings in the short section of the north rim revealed well-defined cavities which in general followed bedding planes. This drilling showed the water table at a relatively low elevation—indicating the probability of open cavernous rock. The north rim was treated with an extensive high-pressure grout curtain to prevent leakage around the end of the dam.

Grouting of the Concrete Dam Foundation

Consolidation Grouting.—The entire foundation beneath the concrete dam and powerhouse, with the exception of the spillway apron, was consolidated with neat cement grout for a depth of approximately 40 ft. The drilling and grouting progressed in stages with the holes on a regular pattern. The first-stage holes were placed on 20-ft centers parallel and perpendicular to the base line of the dam. Second-stage holes were placed midway between first-stage holes, third-stage holes midway between second-stage holes, etc. The drilling and grouting of a stage in an isolated area were completed before the next stage was begun. The quantity of grout consumption in a hole in one stage determined whether an additional stage hole was required. The strict theoretical pattern of holes was varied in some places. In general, wagon drills were used for all the consolidation holes. In some cases where the total depth of hole exceeded 40 ft, diamond core drills were used. All holes were vertical except that, in places where known vertical solution channels existed, some angle drilling was done to obtain most effective grouting.

The consolidation holes and the seams intercepted by them were washed with air and water under pressure through nipples grouted into the drill holes at the foundation surface. No attempt was made to wash or to grout individual seams in the consolidation holes. The holes, however, were water tested to determine the proper consistency of neat cement grout with which to start the grouting treatment.

The area that formed the foundation for the north nonoverflow section of the dam was given special treatment because of the cavernous area beneath. The consolidation holes were extended through the concrete backfilled cave, and every effort was made to secure a tight seal between the top of the concrete and the roof of the cave.

When consolidation grouting was first begun in the north abutment it was noticed that the grout traveled several hundred feet downstream from the limits of the dam. To prevent the grout from traveling into areas where it was not needed, the limits of the foundation of the dam were outlined with drill holes 40 ft deep spaced on 5-ft centers. These holes were grouted with a thick cement grout fed by gravity to form a curtain to confine the consolidation grout. This method probably eliminated a large percentage of grout waste.

For all consolidation grouting, a maximum pressure of 40 lb per sq in., measured at the surface of the hole, was used. In general, most of the grouting was completed prior to placing concrete in the base pours of the dam. Uplift gages were installed at intervals for checking any possible uplift in the foundation rock. The grout used was composed of neat cement and water and varied from 0.6 to 2.0 parts of water to one part of Portland cement by volume.

Low-Pressure Curtain Grouting.—A grout curtain to form a water cutoff in the foundation beneath the dam was extended in a line just downstream from, and parallel to, the upstream face of the concrete dam. This curtain was formed by grouting shallow holes, in general averaging about 50 ft in depth. Pressures not exceeding 40 lb per sq in. were used. The low-pressure curtain was drilled and grouted in conjunction with the consolidation grouting. The treatment given these holes was similar to the consolidation program, except that the low-pressure curtain holes were treated more intensively and were drilled mainly with diamond core drills.

Drilling and grouting were done in stages with the first-stage holes on 24-ft centers; the second-stage holes reduced the spacing to 12 ft; the third-stage holes reduced the spacing to 6 ft; etc. The resulting minimum spacing at any one place on the low-pressure curtain was 1.5 ft; and the maximum spacing, 12 ft. Water testing was used to determine the initial grout consistency and grout mixes and pressures were identical to those used in consolidation grouting.

High-Pressure Grout Curtain.—The relatively low elevation of the water table at the dam site, together with known information regarding seams and cavities, indicated the need of a deep high-pressure grout curtain along the upstream face of the dam. To determine the depth of this curtain, a number of deep check holes were drilled, water tested, and grouted. The results obtained in the check drilling and grouting of these holes indicated that the curtain should extend to a maximum depth of 200 ft. A number of small seams were encountered between 100 ft and 200 ft below the surface of the foundation.

The high-pressure curtain followed the line of the low-pressure grout curtain. Fig. 15(*b*) shows the relative position of the grout curtain. The drilling and grouting were done in stages with the first-stage holes placed on 18-ft centers. Successive stages reduced the hole spacings by one half, and the number of stages required for an area was determined by the grout consumption of the preceding holes. The minimum spacing of holes at any one point in the final curtain was 1.4 ft; and the maximum spacing, 9 ft. The depth of drilling was decreased where the grout consumption of previously drilled holes indicated a satisfactory curtain at lower levels. The minimum depth of holes was maintained at 100 ft.

The normal procedure was to wash and grout the lowest known seam or cavity. The packers were then raised and the operation repeated with each seam until all had been grouted. This procedure allowed each seam to be washed and grouted prior to the beginning of the washing of the overlying seam. Ample time was allowed between grouting and washing operations to permit the grout to harden. This process was accomplished by providing sufficient flexibility in plant equipment to allow either washing or grouting to be conducted at other locations.

Almost all the drilling and grouting were done from the lower drainage gallery after the bulk of the concrete had been placed. Thus, additional protection was afforded against uplift when using the higher grouting pressures. The maximum grouting pressure was 200 lb per sq in. measured at the top of the hole, and was in excess of the hydrostatic pressure on any seam, but less than the unit weight of the overlying rock and concrete. A neat cement grout, varying from 0.6 to 5.0 parts of water to 1 part of cement by volume, was used.

The results of the high-pressure curtain grouting as accomplished by successive stages are illustrated in Fig. 23(*a*). This curve shows the grout consumption per foot of depth of hole for each successive stage of grouting.

Rim Grouting

South Rim Grout Curtain.—A grout curtain was provided extending from the south end of the concrete dam along the reservoir rim. Tied into the end of the high-pressure grout curtain beneath the concrete dam, this curtain extended to the south end of the first saddle dam. Extensive drilling and grouting operations were employed in the area between Station 20+50 and Station 27+00 to check, tighten, and provide a water stop around the south end of the concrete dam. These operations also completely checked the cave that had been mined out and backfilled with a concrete plug.

The drilling and grouting were done in stages—as many as were necessary to check any area of high grout consumption—with the first-stage holes on 100-ft centers. In some cases, five stages were used, resulting in hole spacing of 6.25 ft. All holes were driven with diamond core drills to El. 860 or lower—slightly lower than the elevation of the original river bed.

No seam washing was attempted in the rim grouting. Neat cement grout with calcium chloride added to accelerate the setting time was used.

The neat cement grout varied from 0.6 to 2.0 parts of water to 1 part of Portland cement by volume, with 3% of calcium chloride ($CaCl_2$) by weight of cement added. The effect of the rim tightening by successive grouting stages is indicated in Fig. 23(*b*), which shows the grout consumption per foot of depth of hole for each stage.

Check drilling and grouting indicated that no other intensive grouting program was necessary in other parts of the south rim except at saddle dam No. 1, where considerable grout was injected, particularly at the contact between the Lenoir lime-

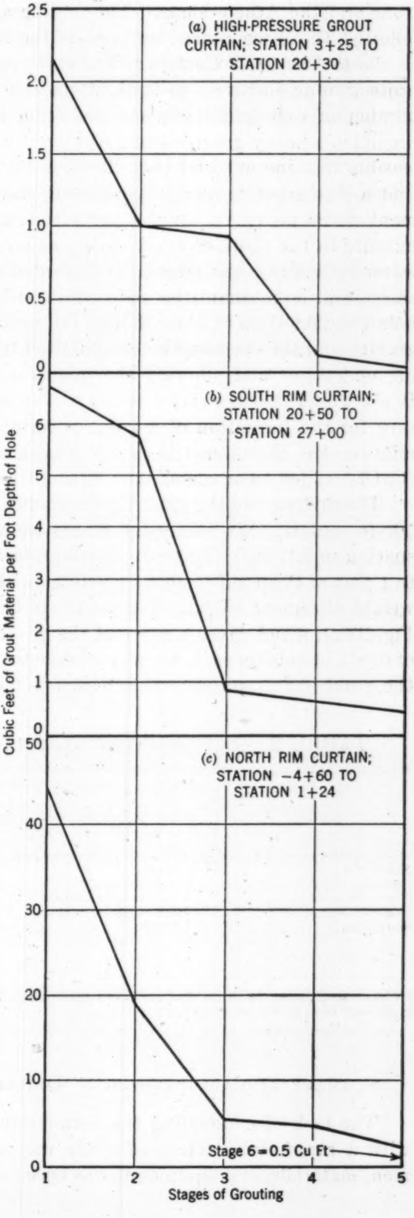

FIG. 23.—RATE OF GROUTING CONSUMPTION

stone and the Athens shale. The drilling and grouting under this saddle dam followed the same procedure used in the rim area south of the concrete dam.

North Rim Grout Curtain.—The north reservoir rim possessed some natural protection against seepage in the form of a long earth blanket. However, the number of well-defined dip cavities lying along the line of the grout curtain predicted a heavy grout consumption. It was considered neither necessary nor feasible to mine out and backfill these cavities with concrete; but it was felt that a clay grout or a grout containing clay in a prescription mixture with cement would provide a satisfactory cutoff against seepage. A clay and cement mixture in the proportion of 1 part cement to 4½ parts of clay and 6 parts of water by volume was tried. The grout was pumped into the drill holes as a slurry and large quantities were consumed. The maximum consumption per hole was 20,905 cu ft, even though the pressures used were only slightly above gravity and the consumption was limited to 500 cu ft before suspending grouting operations and allowing the mixtures to set for a period of three days. It was found that the clay mixture was spreading much farther than was necessary for the formation of a grout curtain; and, accordingly, the clay-cement mixture was abandoned in favor of neat cement grout with calcium chloride ($CaCl_2$) added to accelerate the setting time.

The drilling and the grouting were done in stages with the first-stage holes on 100-ft centers. Six successive stages were required, which reduced the hole spacing to 3.12 ft. The neat cement grout varied from 0.6 to 2.0 parts of water to 1 part of Portland cement by volume with 3% of calcium chloride ($CaCl_2$) by weight of cement added. The results of the north rim tightening are shown in Fig. 23(*c*), which gives a curve of the grout consumption in cubic feet per foot of depth of hole for each successive stage to stage five. At stage six (not shown) the grout consumption had decreased to 0.5 cu ft.

SUMMARY AND COMPARISON OF DRILLING AND GROUTING QUANTITIES

The task of conducting the foundation treatment program in conjunction with a rapid construction schedule was difficult. A judicious disposition of men, materials, and equipment was necessary to obtain satisfactory results and costs. Approximately three hundred men were utilized on the drilling and grouting program. Table 3 shows the linear feet of drilling for the various features and the quantities are separated to show wagon drilling and diamond drilling as well as the quantities of grout consumption. An interesting comparison of the results of the grouting may be obtained from the three curves in Fig. 23.

The rock conditions were different for each case as demonstrated by the rate of grout consumption per foot of depth of hole in stage one of grouting. The north rim having large cavities took 45 cu ft per foot of depth; and the concrete dam where rock was good, and also preconsolidated, took only 2.2 cu ft. On the south rim where the rock was reasonably tight and a concrete plug was constructed, the first-stage rate was 6.7 cu ft per foot of depth. A satisfactory tightening was obtained by the use of successive stages of grouting and by intensive treatment. The rate of grout consumption in the final stage was 1 cu ft or less per foot of depth of hole in all cases.

Drilling and Grouting Equipment

Standard equipment was used for drilling and grouting. Two-compartment, mechanically-agitated, mixers were used, and the grout was pumped by 7 by 5 air-driven duplex reciprocating pumps. Standard manufacturers' set bortz bits were used on the diamond core drills and the core drills were both air driven and gasoline motor driven. Two types of packers were used in the grout holes—a simple mechanical packer and an expanding rubber packer.[1]

During peak operations on the job, thirty wagon drills, fourteen diamond drills, eight grout mixers, and three large-diameter shot drills were employed.

Ground-Water Investigations and Foundation Drainage

Ground-Water Investigations.—The areas adjacent to the concrete dam and strategic points in the reservoir rim were watched carefully for seepage during the period of reservoir filling. A program of ground-water wells was laid out, and wells were drilled for ground-water measurements. All holes were driven below river bed to approximately El. 868.

Observations were made of these wells regularly and also of any additional existing farm wells. Hydrographs of the ground-water table were plotted. A gradual rise and an adjustment in the water table were noted as the reservoir rose, but in no case was there any drastic change or any sign that would indicate leakage from the reservoir.

Foundation Drainage.—Foundation relief drains were drilled beneath the concrete dam just downstream from the high-pressure grout curtain. Fig. 24 shows the position of the drain holes. These holes were drilled 30 ft deep into foundation rock and were placed on 8-ft centers. The relief of the holes was in the lower drainage gallery. All the foundation drain holes were drilled after the foundation grouting program was completed. When the reservoir had filled to within 2 ft of the maximum pool level, the foundation drains had a flow of only 56 gal per min.

A regular pattern of holes was also drilled over the area under the spillway apron. These holes were drilled 10 ft into foundation rock and extended through the concrete slab of the apron to provide relief from uplift pressures.

SUMMARY

Sufficient geologic information made possible advance planning and scheduling. This information was augmented by additional exploration during the construction period. Careful coordination of excavation and concreting with foundation treatment was essential, because of an extremely fast construction program. Substituting concrete for grout wherever feasible, as well as confining grout mixtures within required limits, minimized the waste of cement. Large-diameter core holes used in connection with mining and placing concrete plugs allowed visual subsurface examination and assured a positive cutoff.

DISCUSSION

Berlen C. Moneymaker,[7] Assoc. M. ASCE.—The two papers in this Symposium illustrate the magnitude of problems encountered in the construction of dams on limestone foundations in a region that has been humid for a long time, geologically. The rocks of the Tennessee Valley have been exposed to the relentless attacks of the agents of weathering for millions of years. Siliceous rocks have decayed to great depth and the carbonate rocks (limestone, marble, dolomite, and calcareous shale) have weathered by solution. Soluble rocks not only have been "worn down" to their present elevation largely by solution, but they are also "honeycombed" by caves and smaller solution channels to considerable depths. Cavities are largest and most numerous in the upper part of the bedrock, becoming smaller and less numerous with increasing depth.

Of the sixteen dams completed by the Tennessee Valley Authority (TVA) to date, nine are founded entirely or partly on limestones. Three additional dams in the area, built before the creation of the Authority, are also founded on limestone foundations. Although some of these sites were much better than others, all of them were to some degree cavernous.

Mr. Pauls' paper on Fort Loudoun Dam is a fairly complete record of difficulties met during the construction period. The first geologic problem involving this project was the selection of a dam site. A preliminary geologic investigation of that section of the Tennessee River in which Fort Loudoun was to be located, undertaken in May, 1935, soon revealed that no really good dam sites were to be found. To locate the best site available, a detailed study was made of the river from mile 576 to mile 609. The geology of this 33-mile stretch of the river was carefully mapped and fourteen potential dam sites were selected for investigation.

Some of these sites (see Table 4(*a*)) had been considered by the U. S. Army Engineers; others had not. A few holes drilled by the engineers at the Marble Bluff site showed the rock to be cavernous. The numerous sinks at both Marble Bluff and Bogart Island indicated extensive bedrock solution. At the Loudon sites, foundation conditions were thought to be fairly good but the reservoir rim was low, thin, and cavernous. The Rock Quarry Bar sites were considered the best dam sites in the entire 33-mile stretch of the river; but they were also ruled out because of the low, thin, and cavernous reservoir rim. The Bussell Shoals sites and the Coulter Shoals site were soon found to be on deeply cavernous rock.

When the operating level of Watts Bar Dam was established at El. 745, several of these sites were automatically dropped from consideration and the search for the Fort Loudoun site was thus limited to a 12-mile stretch of the river. Exploratory drilling at four sites which had not been ruled out because of geologic or engineering reasons revealed that the Belle Canton Island was the best site available. This site was therefore selected as the site for Fort Loudoun Dam.

---

[7] Chf. Geologist, TVA, Knoxville, Tenn.

The rock involved in the foundation of Fort Loudoun is nonuniform in character. It ranges from the coarsely crystalline sandy limestone of the Tellico formation, through coarsely crystalline pure limestone, finely crystalline impure and shaly limestone, to calcareous shale in the Sevier formation. Structurally, the strata of both formations have an average strike of about N 42° E and dip southeastward at angles of from 30° to 35°. The limestones of both formations are cut by numerous steep to vertical joints and the shaly members of the Sevier are somewhat folded (see Fig. 3) but less extensively jointed. In both formations, the limestones have been dissolved away along all structures sufficiently open to permit the movement of ground water. The shales of the Sevier formation are not soluble; but in many places the soluble calcium carbonate has been leached from them, leaving seams of soft mud. Although such mud seams are not cavities, they are actually little different from mud-filled solution cavities as foundation defects.

From the beginning it was recognized that the Fort Loudoun site contained serious defects of considerable magnitude. Even while the dam site was under exploration, the chief geologist, the late Edwin C. Eckel, Affiliate ASCE, appraised it in the following words: "The Belle Canton Island [Fort Loudoun] dam site is much worse than Chickamauga." The correctness of this appraisal was verified by the Authority's Board of Consultants, whose report of June 18, 1942, stated that "No site of the whole Tennessee Valley System has shown so many weaknesses."

Mr. Pauls' paper is a detailed account of the nature of these numerous defects and the methods by which they were overcome to afford excellent foundation conditions for Fort Loudoun Dam.

Mr. Taylor's paper on Douglas Dam deals with a project in which the problems presented by a limestone foundation were entirely different from those at Fort Loudoun. The only point of similarity between the two projects was that the problems at both were the result of solution of the bedrock.

The selection of a site for Douglas Dam was a comparatively simple matter. Before the final choice was made, a 30-mile stretch of the river was considered. Many localities were easily ruled out on basis of topography and the general poorness of foundation conditions, but four sites were considered in some detail. These sites are listed in Table 4(*b*).

Preliminary geologic field studies revealed that the rock at all these dam sites was cavernous, but the Douglas site appeared to be much better than the other three. It met the engineering requirements somewhat better than the other sites and was selected as the site for Douglas Dam.

Douglas Dam is located on a rather narrow belt of Knox dolomite, which is exposed along the northwest limb of a broad, relatively flat syncline. At the dam site, the strata strike from N 40° to 60° E and dip southeastward at angles of from 15° to 20°. The Knox dolomite consists mainly of cherty dolomite and limestone, although there are some sandy beds in the formation. Except for the sandy layers and the chert, the formation is of fairly uniform solubility throughout.

The preliminary drilling proved that the upper 20 ft to 60 ft of bedrock was extremely cavernous, especially in the original channel and flood plain areas, and that a sizable open cavity existed in each abutment. Subsequent excavation revealed that the cavities were developed along joints and bedding planes. The two large abutment caves and many of the smaller cavities were developed along both joints and bedding planes, but some of the smaller openings were restricted to one structure or the other.

The bedding-joint cave in the right abutment was a "blowing cave." It was intercepted by a drill hole in the early stages of exploration and the "blowing" phenomenon was noticed by the drillers. Two other holes in the same general area exhibited like behavior. In the summer, these holes became "sucking" holes. The "blowing and sucking" behavior of the drill holes suggested that the cave was extensive and proved that somewhere it had a natural opening, although such an opening was never found. The principal problem presented by the two abutment caves was that of watertightness; however, there was no definite assurance that the 40 ft of sound rock overlying the right abutment cave afforded adequate support for the end of the dam. Although these caves required a considerable amount of painstaking work under none too pleasant working conditions, their treatment did not involve any difficult or unusual problems. They were cleaned out and then plugged with concrete. The cave in the south abutment, in some places, was a rather crooked channel, and it was found to be more economical to mine out enough rock to provide for a straight cutoff plug instead of following the meander-like bends of the natural opening.

As indicated in Mr. Taylor's paper, the greatest problem presented by the cavernous rock at Douglas was that of controlling the water in the cofferdams. The strike of the strata was essentially parallel to the river channel. Solution cavities developed along bedding planes and strike joints served as conduits to pipe water into the cofferdams. All attempts to shut the water out of the cofferdams were ineffective, and excavation progressed with difficulty, block by block. Pumps in constant operation discharged 100,000 gal per min for some time, the maximum discharge being about 105,000 gal per min.

In spite of the tremendous problem of controlling water, an excellent watertight foundation was prepared. The transition between highly cavernous rock and tight, noncavernous rock was nearly everywhere sharp. The depth to which solution had progressed varied from place to place but there was no relation between the depth of solution and the lithologic character of the rock.

The two papers form a valuable record of the geologic problems, and their solution at dam sites in limestones. Mr. Taylor's paper on Douglas Dam is especially interesting as a record of a hard-fought and desperate struggle between engineer and river under the handicap of a short construction schedule. At times the outlook was dark for the engineer, who finally won by dint of his sound experience with limestone foundations in general and his very thorough knowledge of the geologic conditions at Douglas Dam in particular.

C. E. **Blee**,[8] M. ASCE.—The paper dealing with the Fort Loudoun Dam is of particular interest to the writer since he was directly in charge of the construction of this dam as project manager for the first eighteen months, being succeeded by J. K. Black, M. ASCE, who had been construction engineer on the project. It is a very comprehensive and well-presented account of the complex foundation conditions encountered and of the procedures employed to overcome these difficulties.

Perhaps the most significant feature of the foundation conditions at the Fort Loudoun site was the comparatively great depth to which the solution channels extended. This is stressed in the paper as is also the fact that structural deformation was often the determining factor which controlled the depth and extent of disintegration rather than the solubility of the rock. This latter effect was readily discernible on the ground from the crisscrossed lines of disintegration following bedding planes, joints, and faults and always having an enlarged zone of disintegration at the intersection of these features. In the case of a flowing stream where differences in head are available, there is, of course, no reason, from the standpoint of hydraulics, why water should not find its way through open cracks or fissures thus producing solution at considerable depths. At some dam sites there are geological conditions which definitely limit the depth to which solution can go. For instance, at the site of the Chickamauga Dam, there is a stratum of bentonite which effectively stopped the penetration of water and so afforded a horizon below which it was known that foundation treatment need not be carried.

At Fort Loudoun one of the chief difficulties from the construction standpoint was in cutting off the flow of water into the excavation areas. Nearly 700,000 cu ft of grout, including neat cement, clay cement, and asphalt, were required to control the flow through the rock into the first-stage cofferdam. In sinking the calyx holes within the cofferdam area, it was often necessary to encircle the hole with a line of supplementary grout holes to cut off the flow of water through seams encountered at greater depth.

Only by the utilization of the experience gained and of devices developed during comparatively recent years could a major dam and lock structure be successfully constructed on a foundation as bad as that which existed at the Fort Loudoun site. At Fort Loudoun the engineers of the Tennessee Valley Authority (TVA) had the benefit of previous experience and of the devices developed at the comparatively large number of dams, including Norris, Chickamauga, Guntersville, Kentucky, and Hales Bar, which had been built on difficult limestone foundations—as well as the experiences of other organizations recorded in the technical literature. By the publication of this Symposium together with those previously published in the *Transactions* of the Society, the experience gained by TVA is made available to the profession as a whole.

---

[8] Chf. Engr., TVA, Knoxville, Tenn.

Effectiveness of the cutoff and grouting operations at Fort Loudoun is demonstrated by the low rate of seepage past the dam site. Holes 3 in. in diameter were drilled just downstream from the cutoff on approximately 11-ft centers throughout the spillway section. These open drainage holes extend from 30 ft to 80 ft into the rock beyond the excavated surface and so can be expected largely to intercept any seepage through the foundation rock under the concrete structure. The seepage, as measured by the discharge from the total of these holes, amounts to less than 10 gal per min with a full reservoir. Careful records have been kept of the ground-water levels in both abutments of the dam and these indicate that there is very little seepage through the abutments.

As stated by Mr. Pauls in the "Summary," the operations for consolidation and for an effective cutoff challenged the combined efforts of the designing engineers, field engineers, geologists, and construction personnel. The close cooperation that existed between the engineers, geologists, and construction personnel was an outstanding feature of the Fort Loudoun job; that the challenge presented by the difficult foundation conditions was successfully met is attested by the results achieved.

A complete and explicit account of the methods and operations used in foundation treatment at Douglas Dam is given by Mr. Taylor. The information thus made available should be useful to anyone having a similar foundation problem.

Cavities encountered in the foundation rock at Douglas Dam were, in general, larger and more continuous than those at Fort Loudoun but were not as complex nor did they extend to such great depths. At Douglas, blowouts and leakage through cavities into the cofferdam areas presented particularly severe problems because of the extremely fast construction schedule for the job—calling for completion in less than fourteen months after work was started. Use of large-diameter calyx drill holes as construction devices to give working access to disintegrated seams or cavities underlying sound rock, and to afford a means of depositing concrete in these seams after being cleaned out, is well illustrated in the work described. Another and rather unusual device was the use of a grout curtain to confine, to the desired area, the grout used for consolidation.

As in the case of Fort Loudoun, the measurements of foundation drainage and the ground-water investigations at Douglas Dam demonstrate the effectiveness of the foundation treatment.

ROBERT A. LAURENCE,[9] ESQ.—Not only is the value of close, continuous cooperation between engineers and geologists emphasized in this Symposium, but also the changed and increased duties and responsibilities of the geologist since the late 1920's on such construction projects are illustrated. The changes result chiefly from the exhaustion of excellent sites and the emphasis on multipurpose projects. The discovery of ideal sites is becoming almost impossible; but, as the Douglas and Fort Loudoun examples show, detailed preliminary investigations and geologic study can result in the rejection of the most unsatisfactory sites, and a thorough knowledge of the subsurface conditions is necessary to insure proper treatment of the foundation finally selected. The Fort Loudoun site was selected after investigation of fourteen alternate sites, and the Douglas site was one of four originally considered. Furthermore, drilling for grouting the Douglas cofferdam revealed that, had the axis of the dam been located more than 100 ft upstream or downstream, an additional 10 ft to 20 ft of highly cavernous rock would have been encountered in the spillway and powerhouse foundations.

---

[9] Regional Geologist, U. S. Geological Survey, Jefferson City, Tenn.; formerly Geologist, TVA, Douglas Dam, Tennessee.

These examples also illustrate the effect of seemingly insignificant lithologic or structural features in determining the course and extent of solution and weathering. The north abutment cave at Douglas Dam was caused by the presence of a shaly layer less than 1 in. thick, which had deflected the ground water along the 20° dip of the beds, thus concentrating the solution. Although (see Fig. 17) the cave was large enough for mining and backfilling only to Station 5 + 32 (El. 891), weathering and small cavities were present along this bed as far as Station 13 + 0 (El. 679). The thin insoluble bed, which caused development of the south abutment cave for a total distance of more than 700 ft down the dip, was even less conspicuous.

The extent and continuity of cavities along bedding planes and strike joints are further shown by the fact that dye placed in the river, more than 1,000 ft upstream and downstream from the cofferdam, appeared in the same leak in the excavation area within from 30 min to 45 min.

No description of the Douglas foundation is complete without mention of the unusual filled sink on the south abutment between Stations 18 + 90 and 19 + 53. This sink was developed before the deposition of the Lenoir limestone, and was filled with 65 ft of extremely fine-grained volcanic ash and 55 ft of thin-bedded dolomite. It extended to El. 847; but, since the lower 40 ft of the volcanic ash was fresh, compact, and insoluble, excavation was "bot-

TABLE 5.—RESULTS OF PRELIMINARY CORE DRILLING AT BELLE CANTON SITE, FORT LOUDOUN DAM

tomed" at El. 881. Many core drill holes were put through the bottom of this filled sink but no outlet was found. Deep solution on the strike joint channel shown in Fig. 22 was closely related to this sink hole.

Under the heading, "Geology," Mr. Pauls states that:

> "Contrary to the normal conception that relatively more cavities are to be expected in the purer limestone, the cavities in this area were primarily controlled by structural features rather than by the purity of the rock."

This statement is misleading. Although it is true that the shape, extent, and localization of the cavities were controlled by structural or sedimentary features, nevertheless all the major cavities at Fort Loudoun, as shown in Fig. 3, were in the Tellico, Sevier unit 1, and the lower part of Sevier unit 2. Although unit 3 and the upper section of unit 2 also suffered intense deformation, the rocks were much more shaly, and so suffered less from solution. The distribution of cavities in the various rock types is also demonstrated by Table 5, summarizing results of the exploratory drilling.

JAMES B. WARD,[10] JUN. ASCE.—To those concerned with the investigation, preparation, and treatment of foundations, the experiences set forth in this Symposium are invaluable. Since dams are built to serve a variety of purposes, it is no longer practicable or possible to locate the sites only in areas where good foundations are available. It is often necessary to locate these structures where they will best serve the purpose for which they were intended, and to improvise methods and procedures to meet the foundation conditions as they are. Such was the case in the selection of the Fort Loudoun Dam and Douglas Dam sites, the cleaning and foundation grouting of which are so ably presented by Mr. Pauls and Mr. Taylor. Moreover, the authors of this Symposium have demonstrated the utility of adequate geologic information in the planning and again in the construction of dams.

To appreciate the magnitude of exploration and foundation treatment required for the successful completion of the Fort Loudoun Dam, one has merely to examine the drilling, mining, and grouting quantities. The fact that more than 800,000 lin ft of drilling (including 584,000 lin ft of diamond core drilling, 16,000 lin ft of large-diameter calyx drilling, about 10,000 cu yd of concrete to backfill cavities and mined-out seams, and approximately 2,000,000 cu ft of cement and cement-admixture grouting) was necessary, testifies to the enormity of the undertaking. Seldom, if ever, have the ingenuity and combined efforts of engineers, geologists, and construction specialists been so challenged.

Undoubtedly, the most striking feature of the Fort Loudoun foundation is the fact that subwater table cavities and weaknesses were explored and treated at what are thought to be unprecedented depths, below any previous water table level. The method by which this was accomplished was well covered in the Symposium. The formation of such deep-lying cavities has been the subject of much discussion. Observations made almost daily during the construction of Fort Loudoun Dam support the explanation postulated in Mr. Pauls' paper. It may be emphasized that the clogging or damming up of subterranean channels by the insoluble residue from the solution of the impure carbonate rock appears to play an important role in the formation and rerouting of cavities and channels to deeper levels as solution continues. This may well explain the scarcity of cavities at great depths in the purer or more soluble carbonate rocks, such as those encountered at Douglas Dam. Moreover, the statement that the formation of cavities may be more dependent on structural deformation than on the relative solubility of the rock also deserves emphasis.

---

[10] Dist. Geologist, Soils and Geology Section, U. S. Engr. Office, Mobile, Ala.; formerly Resident Geologist, TVA, Fort Loudoun Dam, Lenoir City, Tenn.

Of considerable interest and importance to those engaged in the selection and investigation of dam and quarry sites in limestone and related rock formations is the condition encountered in the north abutment ridge. What appeared as a steep and apparently sound limestone bluff developed into nothing more than a false front with extensive weathering and solution just behind it, causing a series of deep troughs separated by intervening pinnacles. This condition may be found where steep bluffs have been formed by encroaching meanders and may be due to the fact that overburden is not able to form on a steep bluff that has been or is being cut back or undercut and, hence, rain and surface water drain away immediately. In the case of ridges behind bluffs, it is possible for the overburden to accumulate, forming a catchment for the rain water. The water, in turn, seeps downward to, and finds access along, joints or other areas of structural weakness in the rock. The ground water is thus recharged in a manner that permits continuous solution. In the exploration and treatment of a formation of this nature, horizontal and low-angle core drill holes may be used most advantageously.

It was apparent at the outset of foundation exploration that detailed and reliable geologic information, properly portrayed and prepared well in advance of construction, was mandatory for the effective and economical preparation and treatment of this highly defective dam foundation. Thus, a staff of geologists consisting of a resident geologist, with from two to three assistants (an organization larger than is usually required on a project of this nature), was in residence during most of the construction period; but, to re-emphasize the magnitude of the geologic and foundation work involved—at the peak of construction as many as sixteen diamond core drills and six calyx shot drills were in continuous operation—three shifts, seven days each week. During the course of the project several hundred geologic drawings, including sections, sketches, plans, and models were prepared which portrayed the foundation condition and aided in the determination of the required excavation, as well as the type and probable extent of foundation treatment. The exploratory drill pattern was such that geologic sections could be prepared not only along ranges parallel and normal to the axis of the dam structures, but also, by interpolation, along any other direction desired. With a myriad of such sections, they were difficult to use unless they were studied in their relationship with one another. For this reason, what are thought to be novel methods of displaying subsurface conditions were devised. After considering peg, glass, and cardboard models, it was evident that some type of transparent or sectional model would be best suited for the visualization or interpretation between the various related sections. Hence, after experimentation, it was found that a transparent model could be constructed most economically by using rigid celluloid film positives, developed from photographic negatives of the geologic sections. These film positives were assembled in an upright position on a rectangular wood base, on which an outline of the particular dam structure had been superimposed. The transparent sections were properly oriented by dovetailing, and were correctly arranged on, and attached to, the wood base by fastening them through metal eyelets to piano wire that was suspended along the top and bottom of four upright steel rods securely anchored at each corner of the rectangular base. The completed model enabled at a glance the visualization of the foundation conditions in an accurate three-dimensional manner.

Another type of model used to advantage may best be described as a hollow, sectional model of plywood construction. It consists simply of mounting a front and reverse print of a geologic section on the front and back of a piece of thin plywood of similar dimensions, and arranging a series of related sections so mounted on a wooden base as to correspond with their location to each other and to the dam structure being represented. The sections are arranged and held securely on the base in an upright position by the slit grooves provided in the sides of a 3-in. upright board wall built around the base. Both longitudinal and transverse sections were dovetailed together in the manner of the transparent model described herein; and the sections were cut with a band saw along the line of the proposed excavation indicated thereon, thus enabling one, simply by removing the upper part of a section, to study the foundation conditions that existed before, and those that would exist after, excavation. This model was invaluable both in the planning for the removal of a maximum of the required excavation with mechanical equipment and in the determination of the method and probable extent of foundation treatment required.

That the difficult foundation conditions at Fort Loudoun were successfully overcome is attested by the fact that seepage through the foundation at full reservoir is inconsequential. Thus, it is indeed gratifying that the contributions of the geologists on this project have been so generously acknowledged in Mr. Pauls' paper. Assisting the writer at intervals during the construction of this project were the following geologists: Earl C. Van Horn, William V. Conn, Coy L. Watson, and Chilton E. Prouty.

J. C. NOWELL,[11] M. ASCE.—In considering Mr. Taylor's able paper on the extensive cleaning and grouting operations required at Douglas Dam, it may be of interest to connect it with the study of the original, preliminary drilling records and with the selection of the position of the axis of the dam. Early drilling had disclosed numerous cavities, but restrictions on the authorized scope of the preliminary program had prevented drilling sufficient intermediate holes to determine the extent or the interrelation of the numerous major cavern areas which were encountered later. The Douglas project was suddenly authorized for immediate construction about two months after the Japanese attack on Pearl Harbor, Hawaii, with the unprecedented schedule of closure set at fourteen months, to provide additional power for expanding aluminum production.

---

[11] Asst. Mgr., Eng. Dept., Gen. Electric Realty Corp., Schenectady, N. Y.; formerly Project Engr., Design Dept., TVA, Knoxville, Tenn.

It was essential to locate the dam axis immediately and to begin construction without awaiting the results of additional exploratory drilling. In the interests of speed it was perhaps fortunate that the topography closely limited the location of the axis, especially at the bluff on the left abutment. Brief study was given to swinging the right end of the axis slightly to the west in an effort to place the north abutment farther downstream from the creek just above the dam. This creek had cut somewhat of a gash into the sloping north bank, indicating a possible area of fractured rock with increased subsurface weathering.

On the other hand, such a shift in the north abutment would have resulted in obvious disadvantages in the layout of the structures. It was decided, therefore, to proceed full speed on the preferred basis of a straight alinement at right angles to the stream bed. Subsequent drilling indicated such lack of improvement in the condition of the rock downstream as to have resulted in no major reduction in the cleaning and grouting operations for foundation treatment. However, in limestone and dolomite areas especially, it seems advisable to emphasize that a preliminary drilling pattern on 100-ft squares (as mentioned in Mr. Taylor's paper) is insufficient to assure any definite opinions as to the expense or time required for the construction of a major dam. It was fortunate that the foundation conditions actually encountered did not materially delay the completion of the project as a whole. However, this should be credited to the resourceful methods of the construction personnel, rather than to any adequate exploratory program, which had been impossible due to the lack of authorization for extensive investigations.

Mr. Taylor has well described the rather wide variety of methods used in the foundation treatment for the Douglas project. It is interesting to review the principal factors considered in determining the specific treatment to be applied to any particular part of the foundation. In addition to the usual requirements, such as adequacy, permanency, and cost of treatment, special emphasis was placed on speed to meet the unusually fast schedule for closure of the dam in the spring of 1943. With wartime demands on the aluminum company's operations and on the atom bomb project at near-by Oak Ridge, Tenn., the question of speed, rather than that of cost, was given primary consideration. In general, therefore, mass excavation and other mechanical methods were selected, rather than alternatives requiring more handwork and extended periods of time for the foundation treatment. For example, when a difficult cavernous condition was disclosed under the north half of the spillway apron, a redesign was determined on dropping the apron grade in this area. Thus, a heavy general shovel cut, excavated to an elevation below the weathered rock, was decided upon rather than the filling of the cavities below the cap rock. The latter measure would have been especially slow because of cofferdam leakage conditions described in Mr. Taylor's paper.

Similar need for the speed of mass excavation and concreting was one of the prime considerations in deciding to carry the left abutment blocks in the vicinity of Station 19 down to the level of a bedding cavity which was followed down the dip to about El. 890 (see Fig. 15). Brief consideration was given to an alternative scheme based on treating and leaving in place the partly fractured and somewhat weathered rock above the bedding cavity, with the load on the foundation then reduced by the adoption of a concrete core wall embedded in a rolled fill section, rather than the standard concrete gravity dam section. Such a scheme indicated a possible saving in expense, but would have affected completion dates adversely, especially as it would have been necessary to place the rolled fill in winter. It was again obvious, therefore, that the removal of the questionable rock not only would result in a more conventional and conservative design, but would be essential to meet required completion dates since mass excavation and concreting would eliminate much tedious drilling, grouting, and other "dental" work in treating cavities, which would have delayed the project.

As Mr. Taylor has stated, the heights of the caves on both the right and left abutments were increased by drift mining to permit better access for men and equipment in placing the concrete plugs. This also assisted in the bonding and keying of the concrete to the sound rock. It was particularly required for the left abutment where heavy sound rock, both above and below the cave, permitted the use of a narrow concrete plug designed to take the upstream headwater load by shear into the roof and floor of the cave.

It would be of interest to have available even an approximate estimate of the total extra cost of mass methods used in the interests of speed to reduce cleaning and grouting operations. In considering such problems, the large quantities of extra excavation and concrete involved are likely to appear inordinately expensive as compared with the estimate usually prepared for cavern filling, grouting, and other similar measures. On the other hand, the large quantities in themselves tend to reduce unit cost. Also, such mass measures eliminate the uncertainty of difficult "dental" work and questionable cavern grouting; and they provide a conservative design with little chance for the development of trouble from future leakage. Especially with wartime and postwar shortages of labor, there are obvious advantages in substituting machine operations for handwork. It seems probable, therefore, that little if any actual extra expense was encountered on the Douglas project, in lowering mass excavation grades, as compared with the expense of the extra and especially difficult foundation treatment that would have been necessary if the original tentative excavation grades had been held.

In spite of continuous wartime pressure to keep the job on schedule, regardless of the foundation difficulties encountered, it would appear that the project manager (Lee G. Warren, M. ASCE), Mr. Taylor, and others not only maintained a conservative point of view, which assured a thoroughly safe foundation, but also simultaneously used a wide variety of resourceful methods in the cleaning and grouting of the foundations for the Douglas project.

John F. Partridge,[12] M. ASCE.—The profession is indebted to Mr. Pauls for his fine exposition on the treatment of the foundation for the Fort Loudoun Dam on the Tennessee River. This paper, together with previous papers convering other Tennessee Valley Authority (TVA) projects,[1,2,13,14] provides a strong background for a technique for handling foundation problems, which problems a few years ago would have been the cause for rejection of otherwise highly advantageous dam sites. This is of great import to the national economy, since before the rivers of the United States are completely controlled there will be an increasing scarcity of ideal dam sites.

---

[12] Constr. Engr., TVA, Fort Loudoun Dam, Lenoir City, Tenn.

Great strides have been made by the construction industry, in the development of methods and machinery for applying principles of modern foundation treatment, but much remains to be done in this field. The continued cooperation of geolgists, design engineers, construction personnel, and the supervisory field engineers is essential to progress in this work.

Standard TVA practice dictated that geologic data of an exploratory nature be furnished continuously to the design section, and preliminary designs be referred back to the construction forces for criticism on their suitability to current construction procedure. Both final designs and construction schedules incorporated the suggestions and recommendations of the field forces. In certain instances the field geologists were granted the supervision of construction activities, under the general supervision of the field engineers. This procedure was facilitated by the organizational setup which placed all construction activities pertaining to grouting and foundation treatment under an associate engineer, reporting directly to the construction superintendent, and nominally under the technical direction of the construction engineer.

The human equation, involving the vigilance of the staff of geologists, the core drillers and core drill inspectors, and the supervisory engineering forces, is the largest single factor in the successful treatment of foundation rock which has been weathered to the degree encountered at Fort Loudoun Dam. Each linear foot of the cutoff curtain is a potential hazard. The repeated thinning and swelling of the area of decomposition, as well as the weathering along the bedding seams and along the intersecting planes of fractures, require an alert and constantly repeated inspection, to insure the continuity of the plane of the cutoff curtain. Seams and intersecting joints in the plane of the curtain must be mined out, cleaned, and washed, until a "live-rock" contact, a "concrete-to-live-rock" contact, or a "grout-to-live-rock" contact is secured. Every step in the work (including both drilling and grouting) must be described accurately and conscientiously. Each step must be recorded and evaluated—including the logging of the drill holes, the plotting of drill holes to show all joints and fractures in the rock formation, and the recording, by stages, of all grout quantities. Effectiveness is often a matter of relative values. When there is doubt, intermediate check holes should be drilled. A liberal drilling program in the exploratory stages of the work, will result in economies in the entire program.

In all phases of the work at Fort Loudoun Dam, the resident geologist and and the grouting superintendent had "their hands full." The great footage of

[14] "Large Core Drills Aid Construction at Chickamauga Dam," by James S. Lewis, Jr., *ibid.*, Vol. 105, 1940, p. 850.

cores from all core drilling operations meant many hours of examination and logging. Drilling and grouting were continuous operations. It was from the records of these operations that the picture of the weaknesses in the foundation rock was built up. Actual core losses, where present, painted a clear picture. In other instances it was only possible to piece together a clear view of the situation, by observing the "relative density" of lines of fracture (dip, strike, and oblique joints), revealed by plotting the logs of drill holes on cross-section paper, as profiles of each respective range. Except for this method of detection, much time would have been lost and much grout wasted, because to stop persistent leakage it would have been necessary to make a general coverage of an area, instead of proceeding first with a selective coverage of suspicious areas, revealed by the multiplicity of minor fractures detected in the recovered cores.

The drilling and grouting program at Fort Loudoun Dam involved the following total quantities (see Table 1):

Description	Quantity
Diamond drilling, in linear feet	445,839
Wagon drilling, in linear feet	197,226
Calyx drilling, in linear feet	15,007
Grout, in cubic feet	1,067,387
Concrete, in cubic yards	9,816

Construction was started in July, 1940, and power was delivered over the transmission lines in the autumn of 1943. It is obvious that the drilling and grouting program had to be pressed to completion throughout all stages of the construction work.

The general scheme of foundation treatment was formulated during the exploratory stages of the work with a pattern of holes on 50-ft, 60-ft, and 100-ft centers. The detail was developed and expanded as intermediate and supplementary drill holes supplied additional information. The logging of all holes drilled required the presence of a large force of geologists and inspectors. All cores were preserved until the information could be plotted and coordinated, formations were proved, and the data and findings were checked by the local staff and the board of consultants. Exploratory holes were subsequently augmented by intermediate holes, reducing the spacing at each drilling by one half. Each set of holes was grouted before redrilling and grouting, unless washing between holes was done to increase the efficacy of the grouting or to trace any interconnection of cavities and seams. Packers in various holes, and a liberal use of dye introduced into the wash water, aided in the latter operation.

Drilling and grouting were continued through all stages of evacuation. When concreting was started, pipe casing was carried up through the concrete, to facilitate subsequent drilling operations. There were some exceptions to this procedure when drilling through the concrete proved necessary. In the case of the grout curtain for the spillway, powerhouse intake, and the service-bay sections, the heel of the dam at the upstream face, at ground level, was poured as an integral part of the dam structure, in a projection upstream. This provided a base for setting up the diamond and the calyx drills, and permitted the drills to be in continuous operation without interference with concreting operations as the various blocks of the dam were raised above. All grout holes and calyx drill shafts in these areas were drilled through this projecting lip, and thus afforded a positive connection between the grout curtain and the monolithic structure of the dam proper. The concrete backfill, in the mined-out sections and the large cavities along the line of the cutoff, was placed under pressure, induced by pouring upgrade, through successive vertical shafts (36-in. calyx drill holes). These areas were drained of trapped air and subsequently grouted through grout pipes placed before the concrete was poured. Further consolidation was insured by the regular pattern of curtain drilling and grouting, done after the completion of mining and concreting operations.

Reference is made by Mr. Pauls to the formation and the character of the cavities, particularly in the zone of saturation. This deep weathering and the formation of cavities below the water table caused no small annoyance, before the significance of the process of their formation was recognized. Water was fed into the subwater table strata, over a wide area outside the cofferdam, wherever bedrock (with or without an overburden of gravel) was in contact with the waters of the river channel. Percolating to great depth, by direct or indirect paths, the waters emerged within the cofferdam area, either as seepage over a wide area, or as flow in quantity at points of weakness in the rock formation. Emergence usually occurred along dip joints or weathered bedding seams, particularly at the trace of their intersection. Leakage along the strike joints usually was more direct and in greater quantity, but at lesser depth.

The resultant characteristics of the area inconvenienced the work, through the difficulty of tracing the source of the leakage, (*a*) in the control of the water for construction purposes, and (*b*) in the determination of the foundation treatment, and the probable extent of such treatment. Once the principle of deep percolation was recognized, it was evident that control of the leakage was possible only by interception, since control of the rock surface outside the cofferdam was obviously impractical.

Interception was possible by stage drilling and grouting, (1) on the riverbank, immediately outside the cofferdam, (2) through the base of the cofferdam, (3) at any point between the cofferdam and the area of excavation for the dam, (4) along the upstream or downstream face of the foundation excavation, or (5) within the area of the excavation proper. Grouting with asphalt, a mixture of cement and clay, and neat cement grout were all used successfully. Asphalt proved to be much better than coal-tar pitch. The latter is slower to melt, more likely to chill and plug the hole, and it emits fumes of brownish hue which create dangerous as well as disagreeable working conditions. An asphalt with melting point of 165° F to 175° F, proved to give the best results. Experiments with clay-cement mixes showed best results with 9 cu ft of clay (absolute volume) to 3 ft of water. Lesser amounts of cement were unsatisfactory and showed considerable shrinkage. In holes showing very large "takes," a 9:2 mix was used, completing with a 9:3 mix at refusal. In the 9:3 mix actually 12 cu ft of clay were used instead of 9 cu ft, because of the loose measure. Although the water content never exceeded 7.5.cu ft per batch, it was varied below this amount, in accordance with the desired fluidity. The clay was obtained from borrow pits in the vicinity of the dam. It was red in color, nonplastic, free of sand, but given to crumbling on drying. It was screened through half-inch hardware cloth, to remove large lumps, vegetation, or other large objects that might cause damage to the pumps or clog the lines. Central station grout mixing was used successfully throughout all grouting operations. Mixes were pumped with facility, and at times the varying distances exceeded 1,000 ft.

In general, asphalt grouting was used in the more open formations, particularly along the outcropping of badly weathered seams, or where the joints being treated carried water in quantity sufficient to carry away the cement and cement-clay mixes as fast as pumped in. Sandbags were placed over surface leaks as they developed, thus allowing the asphalt to cool and harden sufficiently to prevent further loss of asphalt. Cement-clay mixes were used when large takes were experienced, particularly in cofferdam grouting, in the treatment of the north reservoir rim, and in the grouting of the saddle dam. For the cutoff and curtain grouting under the lock and the concrete sections of the dam, neat cement grout was used. Cement grout was used similarly in the treatment of the south embankment and the north core wall (including the north abutment rim immediately upstream from the core wall).

Seepage from deep penetration was stopped by consolidation grouting in a pattern over the entire area of excavation. Interception of heavy leakage required a concentration of effort to provide grout in quantity at a point a sufficient distance down the dip of the rock to permit hardening and so to offset excessive leakage. A range of grout holes, parallel to the strike of the rock, gave a curtain at right angles to the intersecting dip or oblique joints and tapped the weathered bedding seams. Such a condition in block 10 of the spillway section is described by Mr. Pauls. There the asphalt grouting proved most effective in the open weathered formation along the outcrop of the bedding seams, and was secured by subsequent grouting with cement below (down the dip) and in back of the asphalt curtain.

The drilling and grouting program for the south embankment started in the early stages of construction, and was pushed constantly in order to complete the work before beginning to place the earth fill embankment. The magnitude of the task was not understimated and the job was completed with a minimum of interference with construction operations. Interference resulted chiefly from a lack of proper facilities for the disposal of wash water from washing operations preceding the grouting. In preparing for the cutoff trench (which was excavated southward from the lock to a point well beyond the old river channels), the first step was the excavation of the overburden of silt, clay, sand, and gravel. This was done for a sufficient width upstream and downstream from the line of the proposed concrete core wall, to give space for the use of power scrapers and rollers during the placing and compaction of the earth fill in the embankment. The removal of the overburden probably increased the lateral leakage during the grouting, but an even greater advantage resulted from then being able to observe directly the results of the stage drilling and grouting.

In describing the treatment of the foundation rock where the core wall of the south embankment crossed the old river channels, it probably would have been more informative to have stated that sufficient water to require control thereof by grouting entered the area from upstream along the strike of the rock formation. The leakage was traced by dye, placed in seepage ponds which formed in borrow pits at the inner toe of the upstream cofferdam embankment, several hundred feet distant. A line of diamond drill holes, on 5-ft centers, drilled parallel to, and some 20 ft upstream from, the cutoff trench and a similar line with fewer holes 20 ft downstream virtually encircled the area. The grouting consolidated the enclosed area, intercepting from upstream the direct seepage or flow into the area and from downstream the backflow of subsurface water from within the cofferdam enclosure.

During the planning stage preceding construction, it had been suggested in anticipation of leakage under the cofferdam, that a line of grout holes be drilled and grouted, at intervals, along the entire length of the cofferdam. The alternative was to begin stripping and excavation, for the dam, and, as leakage developed within the area of excavation, to drill and grout to the extent necessary. The first would have greatly increased the scope of what was estimated to be a large and expensive drilling and grouting program. The second presented the disadvantage that if grouting of the cofferdam later proved necessary, in order to reduce the leakage within the area of the excavation, it might be difficult to prevent excessive loss of grout where the overburden had been removed by stripping and excavation. The decision was to proceed with the excavation and to follow with the grouting to control the leakage as it developed. No question was ever raised as to the soundness of this decision. Leakage under the cofferdam was serious in a few areas only. Some of these areas required intensive treatment; others required no treatment.

Permeability and porosity tests, in the area of the south abutment of the dam, indicated that the overburden to the south of the zone in which a core wall was considered necessary was essentially impervious, and that a satisfactory cutoff could be obtained through stage grouting without resorting to an open trench and concrete core wall. However, the provision in the scope of the project for a future canal and flood channel from the Little Tennessee River resulted in the necessity of reinforcing the overburden on the upstream face of the south embankment at the extreme south end. At that point the excavation for the proposed channel would be flooded by the impounded waters. The cut exposed certain lenses of gravel extending toward the axis of the dam and well under the body of the embankment. The reinforcement of the overburden consisted of removing the exposed gravel, to a depth depending upon its texture and its position, and its replacement with embankment material rolled in place.

With respect to the lock, the spillway, and the powerhouse sections, Mr. Pauls' paper, complete with illustrations, appropriate sections, and photographs, gives an excellent picture of the problem, and little can be added without needless repetition.

At the north abutment it should be visualized that the vertical oblique joints, transverse of the line of the north core wall, were continuous for an unknown distance upstream and downstream from the line of the cutoff curtain; and that they existed as open cavities from the rock surface to depths exceeding 200 ft, although no evidence of their presence appeared on the surface of the hillside. They were irregular in outline, with branching arms funneling into the main trunk; at times they exceeded 5 ft in width; for the most part they were filled with a residuum of arenaceous material saturated with water below the water table, to form a quicksand.

The presence of some such cavities was partly expected, because large sinks and open cavities were observed immediately following the first rains, and subsequent to stripping the overburden along the ridge above the north abutment for the construction of access roads and a storage area for concrete aggregate. At a later date, when work was started on the north core wall, the significance of these earlier sinks was recognized; and further disturbance of the natural ground surface along the north rim in the vicinity of the north abutment was avoided.

In the construction of a watertight cutoff in the area, it was appreciated that any core wall, or curtain, constructed by backfilling with concrete after all weathered material and residuum had been removed by mining operations, must be functional in design to withstand the development of a pressure head against the wall with reservoir full. To prevent rupture of the wall, and any movement of the ruptured section in a downstream direction, the concrete backfill was wedged against such movement, by cutting into the side walls of the joint cavity. Steel reinforcing bars were also placed to insure a monolithic structure with adequate support by the rock formation in place. This reinforcement was kept clear of known locations of intended calyx drill holes; although, if an occasional bar became displaced, there was no complication because the calyx drill would cut both steel and concrete with equal facility. In the treatment through the deep holes at Stations 0+86.8 and 0+96.8 (Fig. 12), the 7-ft stages mentioned could not always be maintained because of the varying degree of consolidation of the residual material filling the cavity. The safety of the men was the primary consideration fixing the depth of material removed at any one time. Stages of excavation actually varied from 4 ft to 10 ft.

Because of the nature of the material filling the cavity along these vertical joints, consolidation by grouting at the prevailing depths was variable in its effectiveness. Apparently the external pressure balanced the grouting pressure (external, relative to the grouting system, and internal, relative to the quicksand or filling medium), and the displacement, by grout, of the ground-table water in the quicksand was extremely local in its effect. The writer suggests that the grouting of such a medium, be selected as a problem for research in the field of soil mechanics. The displacement of the water of saturation, in a quicksand or in a sandy clay residuum under pressure, with slow or quick setting chemical grouts or neat cement grout, has not been reported, to the writer's knowledge, in current engineering literature.

A mechanical difficulty encountered was the difficulty in maintaining the intended spacing of the grout holes for their full depth. The drill holes were deflected in the drilling, or were divergent because of inaccuracies in the leveling up of the drills themselves. This resulted in both unequal spacing at depth and in divergence from the plane of the drill curtain. Often the holes failed to strike the cavity, resulting in a loss of the hole and of the time consumed in drilling the hole. In drilling to depths of 200 ft this time loss was serious.

The time consumed in stage drilling and grouting, compared with the time of step procedure in drilling, mining, concreting, and redrilling with calyx drill holes, was a continually disputed point. In the writer's opinion, a more efficient operation would have resulted from a more extended grouting program.

Reference to Fig. 12 reveals a badly weathered area just beyond the end (block 9) of the north core wall. This region was thoroughly explored, and was deemed to be a critical area. Because of its depth, laterally, from the impounded waters in the reservoir, it was believed to be safe against the action of percolating waters. To insure against such lateral percolation, the rim treatment upstream from the north abutment grouting was definitely tied into the north core wall.

During the entire treatment of the north core wall area, and the north rim as far as the saddle dam, a check was maintained of the general effectiveness of the grouting program. This was done through a pattern of drilled wellholes, covering the area of the hillside extending from the future water line of the reservoir, up over the crest of the ridge and down the opposite slope away from the reservoir, to the base of the hill at Muddy Creek. Water-level readings were made twice daily and plotted as water-level contours. Changes in water-table elevations were thus detected and, with due allowance for the effects of wash water, were used in the grouting operations, as a means of detecting the efficiency of the grouting operations.

Portland P. Fox,[15] Assoc. M. ASCE.—Few, if any, dams in the world have received such thorough and extensive foundation exploration and treatment as those described by Messrs. Pauls and Taylor. The authors are to be commended for an excellent presentation of much data of interest to engineering geologists.

Of the nine dams constructed on the main stem of the Tennessee River, only one was constructed on noncarbonate rocks. Watts Bar Dam is constructed on interbedded, fissile shale and sandstones of variable hardness. At the other eight main dams founded on carbonate rocks, open and filled cavities and channels, of various sizes and shapes, were found along bedding planes, faults, unconformities, and joints. The conditions at each site are quite different from the others because of the geology of the area. When confronted with numerous and different problems at each site, the geologist found the particular site at a given time a little worse than any others.

It is difficult to state that any one site is worse than another, but the foundation at Fort Loudoun Dam offered about the most varied types of cavities. The persistent steep dips and the variable physical character of the limestones and shales were chiefly responsible. Kentucky Dam was noted for both small and large persistent cavities parallel to bedding planes from El. 300 above sea level to El. 30 below sea level. Large, and nearly vertical, solution channels developed along joints to a depth of 200 ft below the top of rock. The foundations of Chickamauga and Guntersville dams ably demonstrated the effectiveness and the influence on solution in limestone by thin interbedded layers of shale or bentonite. Hales Bar Dam foundation demonstrated concentrated honeycomb cavities developed along, and adjacent to, two minor thrust faults in a thick-bedded, relatively pure limestone. Fort Loudoun Dam foundation demonstrated the great depth to which solution takes place in steeply inclined limestones in a warm humid climate and the control of the geologic structures on solution of the limestones.

---

[15] Regional Geologist, U. S. Bureau of Reclamation, Billings, Mont.

The papers form valuable records for other engineers, but they would be even more valuable if the authors would give the unit cost of the excavation, the average unit cost of the diamond, wagon, and large-diameter calyx drill holes, and the unit cost of the two types of groutings used.

The success in the rapid and efficient treatment of these most difficult foundation problems during World War II was due to the availability of highly trained construction personnel.

The writer has had the opportunity to explore a number of dam sites on the upper Missouri River and its tributaries. Several of these sites are located on limestones as soluble as any in the Tennessee Valley Authority (TVA) region. There is a marked contrast in the degree of cavitation in limestones in this cold dry climate as compared with conditions in the TVA region. Relatively pure limestones comprise the foundation rock at the Yellowtail Dam in south central Montana on the Big Horn River. Recent core drilling has proved that cavitation is limited.

STABILITY OF SOIL SLOPES

By Ek-Khoo Tan,[1] Jun. ASCE

With Discussion by Messrs. Paul Baumann, Gregory P. Tschebotarioff, Jacob Feld, Earl M. Buckingham, K. B. Hirashima, Donald M. Burmister, and Ek-Khoo Tan.

Synopsis

All cohesionless soils assume an angle of repose. On the other hand, when the soil possesses some cohesion the natural slope can be made steeper. A study of the phenomena and mechanics involved in the failure of earth slopes is reported in this paper. In the model studies of sand slopes used to investigate the slide phenomenon, the angle of repose of cohesionless soil was found to be an entirely superficial phenomenon and independent of the height of the slope. However, the inclination and the height of a bank of cohesive soil were found to depend upon cohesion. A technique to create an equivalent cohesion in a cohesionless soil was developed to reproduce actual sliding failures on a small-scale model. These laboratory failures were found to be remarkably similar to those observed in nature; and they proved ideal for studying the mechanics of failure.

Photoelastic studies were made on gelatin models to investigate the distribution of stresses, and their relative order of magnitude. There was a remarkable resemblance between the pattern of shearing stress and the pattern of shearing strain obtained by means of the sand model. It appears that failure is initiated in a plastic region near the top of the slope.

An approximate mathematical solution of the slope problem based on the theory of plasticity was developed to determine the possible position of the sliding curve and the stress conditions leading to failure. The theory shows the slip lines to be arcs of circles. A sliding failure is imminent whenever the height and inclination of slope, and the shearing properties of soil, bear such a relation to each other that a plastic region develops and tends to enlarge progressively.

Introduction

One of the most important, and at the same time most interesting, problems in the field of soil mechanics is the investigation and analysis of the stability of

soil slopes. Whenever a natural bank of cohesive soil is exposed and left unsupported laterally, experience has shown that there are certain critical height-to-slope relations necessary for stability. When these conditions are exceeded, a failure by sliding is inevitable. This slide phenomenon has been observed extensively by engineers, and has been found to follow typical forms of failure.

The most complete analysis of landslide phenomena was conducted by the Swedish Geotechnic Commission, whose investigations were prompted by the failure of a quay wall in Göteborg in 1915. Subsequently, the commission made a complete study of slides in railway cuts, and found that the shape of the sliding curve in cohesive materials showed a decided curvature that could be approximated by an arc of a circle. The expression of the fundamental principles of the "Swedish circular arc methods" are credited to K. E. Petterson[2] and S. Hultin.[2] In 1927 W. Fellenius[3] and H. Krey[4] perfected the method for practical application. Subsequently, contributions were added by Karl Terzaghi,[5] M. ASCE, J. Jaky,[6] and D. W. Taylor,[7] Assoc. M. ASCE.

Part I of this paper concerns the phenomenon of slides and the mechanics of failure, which were investigated by means of small-scale model slopes of soil. Part II concerns the photoelastic investigations made on gelatin models in order to obtain a clearer concept of the distribution, and of the relative order of magnitude, of the shearing stresses within a slope as the failure condition is approached. Part III is devoted to the development of an approximate mathematical solution of the slope problem based on the theory of plasticity, which permits the determination of the possible position and form of the sliding curve and of the approximate stress conditions leading to failure.

I. Investigation of Soil Slopes by Models

Model tests of soil slopes were made to study the mechanics of failure in cases where the slide phenomenon is controlled by gravitational influences only. In cohesionless sand the angle of repose represents a limiting condition when the soil assumes a natural stable slope. When the soil possesses some cohesion, on the other hand, it is capable of standing at a considerably steeper slope than that of a cohesionless material. The maximum inclination and height to which a stable earth slope can be constructed depend primarily on the character and physical properties of the earth in the slope, and on the moisture conditions.

The apparatus used for the model investigation on sand (see Fig. 1) consisted of a galvanized iron box with tight joints and an open end. This box, placed on a firm support, was provided with a device for tilting it to any desired angle. The angle of slope of soil was measured by a clinometer. A "coarse to fine" sand was used throughout the investigation.

1. Angle of Repose Phenomenon for Dry Cohesionless Materials.—A series of tests was made with the sand deposited in two density states, loose and dense. In each case the slope was formed to its natural angle of repose of 33°, which was determined by a clinometer. A very loose state was obtained by spreading sand in thin layers with a large funnel, the thickness of the layer being controlled by the height of a funnel tip above the sand. Quite a dense state was obtained by using a vibrating device which compacted the sand to the desired density. The technique of placing the sand was developed so as to obtain reproducible consistent results. The apparatus was then tilted slowly until the first visible movement of the sand was observed. The angle of repose of dry sand used in these tests was found to vary between two limiting values—a maximum of 36° just before a slide, and a minimum of 33° just after a slide. The lower angle, which occurs after a slide, is created by the momentum of the material as it slides down the slope in an effort to seek a stable position. Failure was observed to begin at the top of the slope and was confined entirely to the surface layers of the slope. Because of the superficial nature of the slide phenomenon, the angle of repose of dry material is independent of the height of the slope; the slope always tending to flatten itself by superficial slides to the angle of repose. The results in Table 1 for a series of tests on the given material, compacted at different densities, show that the angle of repose is practically independent of the density of the material.

FIG. 1.—MODEL APPARATUS FOR INVESTIGATING THE STABILITY OF SAND SLOPES

TABLE 1.—ANGLE OF REPOSE ϕ, IN DEGREES; AVERAGE OF A SERIES OF TESTS FOR EACH MATERIAL

Material	Void ratio e	Maximum ϕ	Minimum ϕ
Sand:			
Loose	0.73	36	33
Compacted	0.65	36	33.5
Loose Gravel:			
⅜-in.	...	36.5	31
¾-in.	...	42.5	27

To determine the effect of the coarseness of the material on the angle of repose, tests were made on gravels separated into ⅜-in. and ¾-in. sizes. The maximum angle of repose for a ⅜-in. material (36.5°) is only slightly larger than sand, whereas for the ¾-in. material the angle of repose (42.5°) is noticeably larger. This is due to the greater interlocking effect as the particle size increases. Angles of repose of 45° are a frequent occurrence in talus slopes of coarse fragments. The angle of repose of 31° after a slide, for the ⅜-in. material, is noticeably smaller than that for the sand; and for the ¾-in. material the angle of repose (27°) is still smaller, the momentum effect being more pronounced for the larger particles in flattening the slope.

2. Phenomenon of Slides in Slopes of Cohesive Soils.—When a slide occurs in a cohesive soil, it is a deep-seated rather than superficial phenomenon involving the rupture and the breaking away of a large mass of earth from the slope. The maximum inclination and height to which a stable slope of cohesive soils can be constructed are definitely limited, and depend primarily on the magnitude of the cohesion that the soil possesses.

The cohesion in natural soil deposits is the result of an internal system of forces: (1) Capillary forces arising from capillary moisture films at the grain contact; and (2) intermolecular attractions between the finer soil grains.

According to the usual concept of model analysis there should first be a geometric similarity between model and prototype, and the forces controlling the phenomenon should have a constant ratio. These requirements cannot be satisfied readily, because if the particle size of the soil is reduced in accordance with the scale ratio, the properties of the soil are altered materially. Gravitational and molecular forces cannot be altered. Capillary forces are difficult to control in the laboratory in a small-scale test. This means that every model test is really full scale. However, in a small-scale model, if a slide phenomenon can be produced similar to slides observed in nature, then it can be stated that the performance of the model is similar to nature.

In order to reproduce this phenomenon in the small-scale model it was necessary to develop a special technique which, because cohesion is the important factor, involved creating an equivalent cohesion in a cohesionless material that could be controlled so as to satisfy model requirements and reproduce a slide failure in the laboratory. However, it must be remembered that the influence of the mass of the soil involved in a failure cannot be learned from a small-scale model; but the model does afford a good insight into the mechanics of failure.

Cohesion is essentially an intergranular stress phenomenon created in one case by capillary forces arising from the capillary moisture film at the grain contact or by molecular forces between the finer soil grains, which resist shearing displacements of the grains. Thus, natural cohesion is the product of an internal force times the tangent of the angle of friction between grains. In the technique described herein an identical situation can be created by substituting a uniform system of external force for these natural internal systems of forces which are the source of natural cohesion.

The equivalent cohesion in the model soil slope was obtained by covering the cohesionless sand slope by a rubber membrane. This was stretched loosely over the slope but was tightly clamped to the sides of the apparatus, as shown in Fig. 1, so that the air in the soil mass could be evacuated. The soil was thus subjected to a uniform external pressure which could be maintained constant and be easily controlled or varied at will. This uniform external pressure produced an essentially uniform intergranular stress throughout the soil mass. The most important advantage was that the cohesion could be made sufficiently small so that a failure by a slide could actually take place.

Model slopes were formed: (1) With sand placed in a very loose state, and (2) with sand placed in a medium dense state. The sand was then transformed to a soil possessing an equivalent cohesion. The applied uniform system of external forces was determined by measuring the vacuum within the soil mass by means of three water manometers in Fig. 1, placed at intervals along the slope. The fact that they gave equal readings showed that the pressure was practically uniform over the slope. The apparatus was then tilted until a failure occurred. The angle of slope was measured; the form of failure was observed after the rubber membrane was removed. A new slope was built for each test. Fig. 2 shows the relations between the equivalent cohesion and the resulting angle of the slope at failure for the loose and dense states. It is important to note that: (*a*) The angle of slope at failure increases linearly with the equivalent cohesion except for very small value where the restraining influence of the rubber membrane itself is appreciable compared with the air pressure; and (*b*) the density of the sand has a very marked effect on the angle of slope at failure, because of the important increase in the angle of friction with increase in density.

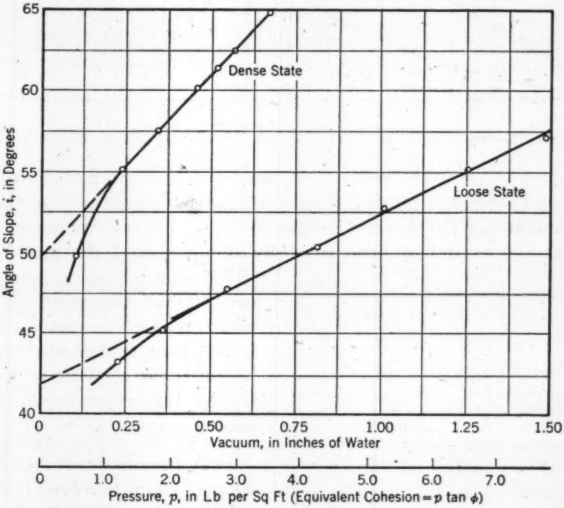

Fig. 2.—Relation Between the Angle of Slope at Failure and the Magnitude of the Equivalent Cohesion

3. Model Investigations of the Deformations Within the Soil Slope and the Location and Form of the Rupture Surface.—A procedure was devised to obtain a record of the deformation within the soil slopes, and the locations and forms of the rupture surface. A piece of glass, which was cut to the shape of the sand slopes and carefully ruled with vertical lines of lampblack and oil, about 1/16 in. wide (Fig. 3), was placed within the soil mass. After the glass had been placed against the side of the apparatus, the sand was carefully deposited against it,

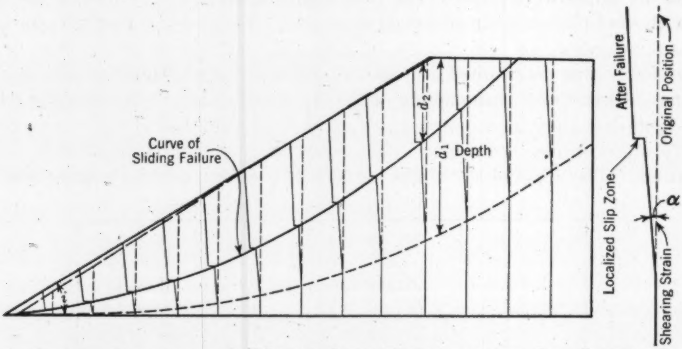

FIG. 3.—SHEARING DEFORMATIONS AND SLIDING CURVE DEVELOPED IN THE SAND SLOPE AT FAILURE

and the slope was formed as before. When any deformation or sliding occurred within the soil mass, the movement of the sand was registered on the glass by the displacements of the vertical lampblack lines. These movements were observed after the sand had been carefully removed and the glass plate was withdrawn. Displacements of about one fifth of the width of the line could readily be detected. Fig. 3 illustrates a typical curve of failure. These investigations reveal the following important facts, which are shown graphically in Fig. 4:

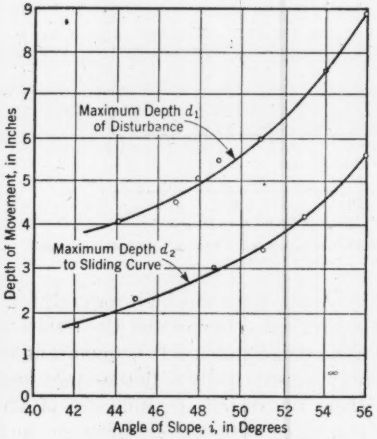

FIG. 4.—RELATION OF THE DEPTH OF MOVEMENT TO THE SLOPE ANGLE i AT FAILURE

(1) As cohesion increases, a larger mass of soil is involved in the failure and the principal failure curve recedes deeper from the surface of the slope;

(2) In all cases the zone of disturbance extends a considerable distance below the final sliding curve; and

(3) An appreciable volume change was observed in the soil slope as evidenced by the vertical movements of the surface of the slope. A subsidence occurred in the case of loose sand, and an expansion in the case of dense sand.

The angular displacements of the lines, or shearing strains, as shown in Fig. 3, reached a maximum value of about 7°. This represents a shearing strain of 0.1225 in. per in.

A study of the displacements within the soil slope was made at different stages prior to failure. These measurements establish the fact quite clearly that failure occurs in a soil slope after the strain exceeds a certain rather well-defined maximum value.

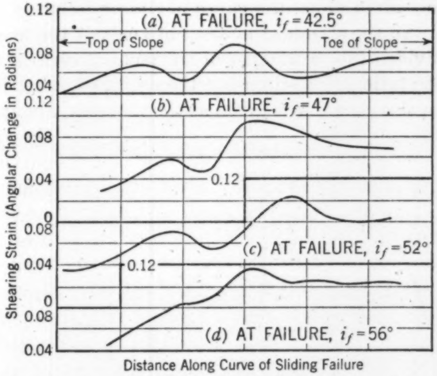

FIG. 5.—DISTRIBUTION PATTERN, SHEARING STRAINS ALONG THE ADJUSTED CURVE OF SLIDING FAILURE, FOR VARIOUS ANGLES OF THE SLOPE i_f AT FAILURE

This maximum strain, which is associated with first evidence of an incipient failure by a slide, seems independent of the angle of slope and occurs at or near the middle of the sliding curve. The curves of Fig. 5 show the distribution of shearing strains along the sliding curve at impending failure. The wave pattern is quite consistent in all tests, with a maximum at or near the middle of the sliding curve. This peculiar wave propagation, or development of shearing strains, in the soil slope at impending failure bears a close resemblance to the variation of maximum shearing stress obtained in the photoelastic studies on gelatin models shown subsequently in Fig. 9.

4. Investigation of the Failure of Model Vertical Banks.—It is a well-known phenomenon in nature that cohesive soils can stand up in a laterally unsupported vertical bank. In these tests the initial equivalent cohesion was made much greater than required for the stability of the bank of the given height. The cohesion was then decreased slowly until the bank failed.

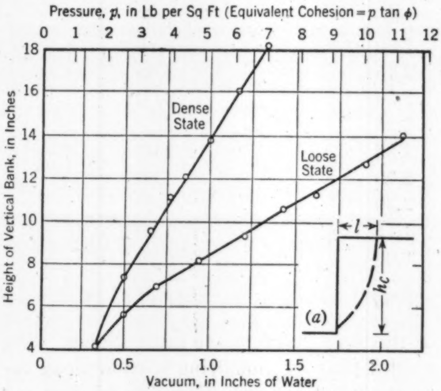

FIG. 6.—RELATION BETWEEN THE CRITICAL HEIGHT OF A VERTICAL BANK AND THE MAGNITUDE OF EQUIVALENT COHESION

The results of the investigation (see Fig. 6) show that the critical height at which the laterally unsupported embankment will stand vertically is a linear function of the cohesion. When failure occurred, the break at the surface of the embankment was found to be approximately 37.3% of the critical height of the embankment. This agrees quite closely with actual failures observed in nature where breaks occur at 0.4 h_c to 0.5 h_c (see critical height h_c of bank in Fig. 6(*a*)).

5. Analysis of the Curves of Failure by the Swedish Circular Arc Method.—A series of the observed curves of failure was analyzed by the usual Swedish circular arc method. The principles of this method are based on the following assumptions: (1) The problem is a two-dimensional one; (2) failure takes place along an arc of a circle; (3) the mass of soil above the failure curve tends to rotate about some center of rotation; and (4) the shearing resistance is fully mobilized along the curve of sliding failure.

In the standard method of analysis the mass of soil above a sliding curve is divided into a number of elementary vertical sections and the usual principles of static equilibrium are then applied; that is, $\Sigma M=0$; $\Sigma H=0$; and $\Sigma V=0$. In this case ΣM is taken as the moment, about the center of the circular arc, of the resisting forces along the sliding curve which moment, for stability, must balance the moment of the forces causing sliding. The lateral earth-pressure forces acting against the vertical side of each element are considered as conjugate stresses and the resultant is zero. The weight of the soil element acts through the centroid of the element and is resolved into its tangential and normal components, W_t and W_n, respectively, on the sliding curve. In Fig. 7 let the material above the critical slide plane be divided into sections 1 to 9, exerting forces or weights W_1, W_2, etc. Denote the respective components of weight by W_n (normal) and W_t (tangential), with numerical values as follows:

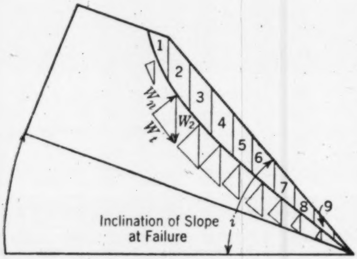

FIG. 7.—SWEDISH CIRCULAR ARC ANALYSIS

Section	W_n	W_t
1	1.00	1.75
2	2.75	3.00
3	3.50	3.00
4	3.25	2.20
5	2.80	2.00
6	2.70	1.60
7	2.20	1.50
8	1.75	1.20
9	1.00	0.70
	20.95	16.95

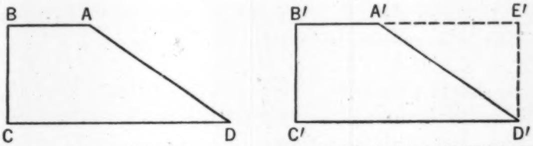
The tangential component W_t is the force that tends to cause sliding. The normal component W_n tends to resist sliding by mobilizing friction along the sliding surface, which, according to the usual concepts of sliding friction, can become equal to $W_n \tan \phi$ as a limiting value. The ratio of the forces resisting sliding to those causing the sliding is usually defined as the factor of safety. According to this concept this factor of safety should decrease to unity at impending failure.

The observed curves of failure, obtained from the tests on cohesive soil slopes, were analyzed and the results showed that, the angle of internal friction

ϕ being 33°, the factor of safety at failure was $\frac{\Sigma W_n}{\Sigma W_t}\tan\phi = \frac{20.95 \times 0.649}{16.95} = 0.80$; that is, somewhat less than unity. The significance of a factor of safety less than unity at failure is not fully understood. The real mechanics of failure are evidently not fully taken into account by the simplified Swedish circular arc method. The circular arc method assumes an average condition along the entire length of arc. The actual stresses set up in the soil slopes probably bear very little resemblance to those assumed in the circular arc method.

II. Photoelastic Studies of Gelatin Models

Photoelastic studies were made on gelatin models of slopes to obtain a clearer picture of the distribution, and the relative order of magnitude, of the shearing stresses set up within a slope. Such studies offer great possibilities for investigating the distribution of shear stresses and the stability conditions of soil embankments. Since the problem was to determine the stresses, in the soil slope, created by gravity forces, it was necessary to use a photoelastic material sensitive enough to show the stresses set up by its own weight. Gelatin seems to be quite satisfactory material for this purpose. The technique of making gelatin models has been fairly well developed.[8,9,10] Gelatin, glycerin, and water were mixed in the proportion 12:14:76. Glycerin was added to produce a tougher and more elastic gel. The higher the concentration of the gelatin, the more sensitive the gel becomes. The properties one should look for in a gel are a high degree of translucency, optical sensitivity, and elasticity. It was found that a few drops of hydrochloric acid added to the mixture would yield a more translucent model.



(a) MODEL SLOPE (b) BEFORE REMOVAL OF TEMPLATE

Fig. 8.—Similitude Relations in a Gelatin Model

A glass flume, 17 in. by 10 in. by 3⅝ in., with 3/16-in., removable, plate-glass front walls and back walls (see Fig. 8) served as a container for the gelatin model. A perforated templet A′ D′, made of galvanized iron and shaped to simulate the desired slope, was placed in the container. The perforations in the templet permitted the gelatin to be poured so that a continuous medium with a level upper surface was formed while the gelatin was cooling and setting. The gelatin model slope could then readily be cut to shape after the gelatin had set.

---

[8] "Gelatin Models for Photoelastic Analysis of Stress in Earth Masses," by F. B. Farquharson and R. G. Hennes, *Civil Engineering*, April, 1940, p. 211.

[9] "Gelatin Models," by T. R. Cuykendall, Eastern Photoelasticity Conference, May, 1939.

[10] "The Application of Photoelasticity to Soil Mechanics," by R. G. Hennes, 1st Northwestern Photoelasticity Conference, March, 1940.

With this perforated templet in place, and before the upper part A′ E′ D′ above the templet had been removed, the stress distribution in the gelatin solution was evidently hydrostatic. The distribution remains practically unchanged when the gelatin sets, as shown by the fact that there was no double refraction when the gelatin block was put into the polariscope.

To prevent the gelatin model from sticking to the glass side of the flume, and to eliminate friction, cellophane was attached to the glass side by a thin layer of vaseline. It was found necessary to allow the gelatin to cool to the same temperature as the flume before it was poured, to prevent the cellophane from wrinkling and to avoid disfiguring the surface of the model.

After the solution was poured into the flume, it was then allowed to set for a period of at least 30 hr, but not more than 48 hr, the period in which the shrinkage of the gel becomes excessive. The flume was placed on its side, the glass plates were removed carefully, and the cellophane was peeled off. The material above the templet was discarded and the templet itself was severed carefully from the model. The gelatin and the inner face of each glass plate were lubricated with thick mineral oil and the glass plate was replaced. This procedure was followed meticulously on both sides of the model. When the model, now shaped to the desired slope, was returned to its vertical position, the body forces came into play, causing the gelatin to deform.

1. Similitude Relations of Gelatin Models.—In making gelatin models certain conditions should be satisfied: (1) Surfaces AB and AD in Fig. 8 must be free of stress for the natural slope; and (2) the stresses in the slope should be confined to those caused by gravitational forces only.

In the gelatin model the surfaces BC and CD, while simulating conditions in the model sand slope, introduce a rigid boundary which does not exist in natural slopes. However, at failure, when a plastic state exists within the region of failure, the effect of the rigid boundaries may become less important. To reproduce the desired boundary conditions in the gelatin an ideal procedure would require that the gravitational force be applied and released alternately. However, since this is not possible, the aforementioned experimental procedure, involving the templet, was used. Before the perforated templet (A′ D′ in Fig. 8) was removed, the block of gelatin A′B′C′D′ was under a hydrostatic stress distribution. When the templet and wedge A′E′D′ are removed, the free boundary condition along plane A′D′ is satisfied, the free boundary condition along A′B′ is unchanged, and the gravitational body force in the volume A′B′C′D′ is brought into play.

2. Distribution of Maximum Shearing Stresses; Isochromatics.—If a transparent model of gelatin is stressed in its plane, and, if linearly polarized light is sent through the stressed body by means of Nicol prism, interference phenomena and colored fringes called isochromatics are produced which can be observed on a screen by the use of a second Nicol prism. On the screen these isochromatic lines will appear in repetition, each color corresponding to a certain principal stress difference:

$$(\sigma_1 - \sigma_2) = \text{constant} = 2\,\tau_{max} \dots\dots\dots\dots\dots\dots (1)$$

in which σ is the unit principal stress; and τ is the shear stress. The isochromatics gave a clear picture of the distribution and the order of magnitude of the maximum shearing stress throughout the slope in the gelatin model. The outside surface of one glass plate was divided into 3-in. squares, because the lenses of the polariscope allowed only a field of 5 in. in diameter to be observed. When the entire field for one position of the model had been mapped, the angle of tilt was increased and the isochromatic pattern was again mapped. The tilting caused a slight variation in the configuration and intensity of the maximum shearing stresses.

Two gelatin models were made and showed identical patterns of isochromatics. A calibration of the gelatin was made by cutting off a right prism 3 in. by 3 in. by 6 in., and the fringes resulting from its own weight were measured. It was found that the calibration constant for the fringe order corresponded to 84% of height, *h*, of the prism. This calibration permits an approximate quantitative study of the maximum shearing stresses. The values of the maximum shearing stresses, as determined on the gelatin model, were transformed to the corresponding values in the sand model by multiplying the calibration constant for the maximum shearing stress values obtained on the gelatin model by a scale ratio:

$$\frac{\gamma_s}{\gamma_g} \times \frac{L_p}{L_m} = \gamma_r \, L_r \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which γ_r is the scale ratio of the unit weight of soil (γ_s) to the unit weight of gelatin (γ_g) and L_r is the linear scale ratio of the sand phototype (L_p) to the gelatin model (L_m).

To study the possible conditions with respect to the boundary BC and CD, Fig. 8, which are likely to exist in the sand model or in the prototype slope, photoelastic model studies were made for two conditions—with an adhering and a lubricated base. By separating the gelatin along boundary BC the tension in the material was eliminated at this boundary. When the model adheres to the base, there is a concentration of stress at the toe of the slope; but, when the base is separated and lubricated, the stress concentration at the toe disappears and there is also a general decrease in stress throughout the model as shown in Fig. 9(*a*). The separation of the gelatin from the boundary BC decreased the stresses in the vicinity of this boundary, but increased the stresses near the toe of the slope. These represent possible limiting conditions. Judging from the stress and strain patterns, where one fringe order $= 0.84\,h = (\sigma_1 - \sigma_2) = 2\,\tau$, it is probable that the actual stress condition in the sand lies somewhere between these two limiting conditions, since the shearing stresses along the rigid boundary at the toe of the sand slope, where the height is small, must also be relatively small.

The gelatin model was formed to an initial slope of 29°. The distribution of shearing stresses formed a regular pattern within the slope and increased in intensity as the angle of slope was increased by tilting successively to 34°, 39°, 44°, and 49°, as shown in Fig. 9. To interpret these stress conditions in terms of mechanics of failure in the sand slope, contours of equal shearing strength have been superimposed on the isochromatic patterns in Fig. 9. The positions of these lines were determined by means of the scale ratio of Eq. 2. The calibration constant (0.84% of height, *h*, of gelatin for one fringe order) is substituted in Eq. 2. The lines are always parallel to the surfaces of the slope.

It is important to note that the wave pattern of shearing stress bears a close resemblance to the pattern of shearing strains in Fig. 5 obtained in the model investigations on slopes of sand possessing equivalent cohesion. The significance of the wave pattern in Fig. 5 is now made clear. In the same general region where the shear-stress contour lies above the corresponding contour of shearing strength, the shearing strains are a maximum, and the material has reached a plastic state. Physically the shearing stress cannot exceed the shearing strength; but the excess stress must be transferred to the adjacent regions where there is a reserve of strength. Thus the plastic state encroaches on the elastic region and spreads progressively until, finally, a rupture surface develops and the slope fails by a slide.

Fig. 9.—Isochromatic Patterns for Difference Values of the Slope *i*

It is now evident that, at 29°, a sand slope is stable. As the slope is tilted to the angle of repose or slightly greater (34°) a plastic region develops only near the surface of the slope, which accounts for the superficial nature of the angle-of-repose phenomenon.

When the angle of slope is to be increased, the equivalent cohesion must be increased, accordingly, to some higher value in order to maintain a stable slope. The uniform cohesion, in effect, raises the line of constant shearing strength with respect to the line of constant shearing stress so that the regions of reserve of strength slightly exceed the plastic regions. For this given value of cohesion, when the slope is tilted slightly above the critical value, the plastic region encroaches on the region of reserve of strength and the sliding curve finally develops.

III. Theoretical Plasticity Analysis

Part III concerns the development of an approximate mathematical theory for the plastic failure of a soil slope due to its own mass, which would permit the determination of the possible position and form of the sliding curve and of the approximate stress conditions leading to failure. A theoretical investigation was made based on the assumption that a wedge is formed by two intersecting planes (OD and Oy in Fig. 10), within which the state of stress has progressed from an elastic to a plastic state.

(a) EXTERNAL BOUNDARY LOADING CONDITIONS. SLOPE OF SAND. (b) EQUILIBRIUM CONDITIONS

Fig. 10.—Hypothetical Wedge of Plastic Material

The general principles of the plasticity theory developed by A. Nádai[11] were used to study the phenomenon of failure of slopes. Fig. 10(*a*) represents the model of a sand slope governed by the following conditions:

(1) A uniform normal external pressure is applied on surfaces AB and AD equal to that creating the equivalent cohesion in the sand model;

(2) Surfaces AB and AD are free from shearing stresses; and

(3) Since the wedge is symmetrical about Oy, the lateral displacement of surface BC is zero.

According to the theory of plasticity the stress in the plastic region is independent of the plastic deformation. The solution of the problem is approximate because it is necessary to assume the entire wedge to be in plastic state, whereas in nature only the region above the rupture surface is in a plastic state.

---

[11] *Zeitschrift für Physik*, Berlin, 1924, p. 106.

In nature, no rigid boundaries exist which would influence somewhat the stress condition within the plastic zone. In the laboratory, this problem is complicated by the fact that body forces are acting, that the boundary conditions cannot be satisfied readily, and that the solution of nonlinear differential equations is required. Therefore, it was decided to investigate only a certain class of solutions to develop one that would represent the physical phenomenon reasonably well. The theoretical investigation is concerned with determining the plasticity equations, which would define approximately the stress conditions for the plastic state and would permit drawing the potential slip planes in the slope.

In his presentation of the theory of elasticity, S. Timoshenko[12] states the two differential equations of equilibrium required for defining the stresses in the elastic region. For the two-dimensional case, using polar coordinates and the body forces shown in Fig. 10(*b*):

$$\sigma_r + r\frac{\partial \sigma_r}{\partial r} + \frac{\partial \tau_{r\theta}}{\partial \theta} - \sigma_\theta + r\,\gamma\cos\theta = 0 \ldots\ldots\ldots\ldots (3a)$$

and

$$\frac{\partial \sigma_\theta}{\partial \theta} + r\frac{\partial \tau_{r\theta}}{\partial r} + 2\,\tau_{r\theta} - r\,\gamma\sin\theta = 0 \ldots\ldots\ldots\ldots (3b)$$

In the plastic region it is necessary to introduce an additional equation, which expresses the fact that, in the plastic state, the stresses are in equilibrium; thus:

$$\left(\frac{\sigma_r + \sigma_\theta}{2}\right)\sin\phi + c\cos\phi = \sqrt{\frac{(\sigma_r - \sigma_\theta)^2}{2} + \tau^2_{r\theta}} \ldots\ldots (4a)$$

or

$$\tau_{\max} = \sqrt{\frac{(\sigma_r - \sigma_\theta)^2}{2} + \tau^2_{r\theta}} \ldots\ldots\ldots\ldots (4b)$$

The condition of plasticity may be expressed by either Eq. 4*a* or Eq. 4*b*. Eq. 4*b* represents the common concept of the maximum shearing stress condition of failure; whereas Eq. 4*a* represents the failure condition in a cohesive soil having both an angle of friction, ϕ, and cohesion, c. Eq. 4*b* is used to obtain a solution, and to satisfy the requirement of a constant maximum shear stress throughout the plastic region. It is directly applicable to the problem represented by the gelatin model but only approximately so for a cohesive soil.

A solution of the problem consists in finding a set of functions for the stresses σ_r, σ_θ, and $\tau_{r\theta}$ which satisfies Eqs. 3 and 4*b*, and of selecting values at the boundaries reasonably consistent with the boundary conditions.

The first step is to derive a fundamental equation governing the shearing stress by eliminating σ_r and σ_θ from Eqs. 3 and 4*b*. Writing Eq. 4*b* in the form—

$$(\sigma_r - \sigma_\theta) = \pm\, 2\sqrt{\tau^2_{\max} - \tau^2_{r\theta}} \ldots\ldots\ldots\ldots (5a)$$

let the right-hand side (for simplicity) be represented by $\frac{A}{r}$, or:

$$r\,(\sigma_r - \sigma_\theta) = \pm\, A \ldots\ldots\ldots\ldots (5b)$$

---

[12] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., 1934.

Differentiating with respect to r and θ,

$$\pm \frac{\partial^2 A}{\partial r\, \partial \theta} = \frac{\partial^2}{\partial r\, \partial \theta} [r\, (\sigma_r - \sigma_\theta)] = \frac{\partial}{\partial \theta} \left[(\sigma_r - \sigma_\theta) + r \left(\frac{\partial \sigma_r}{\partial r} - \frac{\partial \sigma_\theta}{\partial r} \right) \right] \, ..(6a)$$

and

$$\pm \frac{\partial^2 A}{\partial r\, \partial \theta} = \frac{\partial \sigma_r}{\partial \theta} - \frac{\partial \sigma_\theta}{\partial \theta} + r \frac{\partial^2 \sigma_r}{\partial r\, \partial \theta} - r \frac{\partial^2 \sigma_\theta}{\partial r\, \partial \theta} \, \ldots\ldots\ldots\ldots (6b)$$

Differentiating Eq. 3*a* with respect to θ and substituting the value of $\frac{\partial \sigma_\theta}{\partial \theta}$ into Eq. 6*b*:

$$\pm \frac{\partial^2 A}{\partial r\, \partial \theta} = - \frac{\partial^2 \tau_{r\theta}}{\partial \theta^2} + r\, \gamma \sin \theta - r \frac{\partial^2 \sigma_\theta}{\partial r\, \partial \theta} \, \ldots\ldots\ldots\ldots (7a)$$

Differentiating Eq. 3*b* with respect to r, multiplying through by r, and substituting in Eq. 7*a*:

$$\pm \frac{\partial^2 A}{\partial r\, \partial \theta} = - \frac{\partial^2 \tau_{r\theta}}{\partial \theta^2} + r^2 \frac{\partial^2 \tau_{r\theta}}{\partial r^2} + 3\, r \frac{\partial\, \tau_{r\theta}}{\partial r} + r\, \gamma \sin \theta + 0 - r\, \gamma \sin \theta$$

$$= - \frac{\partial^2 \tau_{r\theta}}{\partial \theta^2} + r^2 \frac{\partial^2 \tau_{r\theta}}{\partial r^2} + 3\, r \frac{\partial \tau_{r\theta}}{\partial r} \, \ldots\ldots\ldots\ldots\ldots\ldots (7b)$$

The equation in its final form is obtained by substituting Eq. 3*a* in Eq. 7*b*, which then proves to be independent of body forces:

$$\pm \frac{\partial^2}{\partial r\, \partial \theta} \left(2\, r \sqrt{\tau^2_{\max} - \tau^2_{r\theta}}\right) = - \frac{\partial^2 \tau_{r\theta}}{\partial \theta^2} + r^2 \frac{\partial^2 \tau_{r\theta}}{\partial r^2} + 3\, r \frac{\partial \tau_{r\theta}}{\partial r} \, \ldots\ldots (8)$$

Eq. 8 governs the shearing stress at every point in a material in a plastic state at incipient failure. Eq. 8 turns out to be independent of body forces and therefore becomes identical with that obtained by Mr. Nádai[13] in an investigation, which did not involve body forces. Following the general procedure, adopted by Mr. Nádai, solutions of Eqs. 3 and 4*b*, for the plastic state, are investigated herein because they are independent of the coordinate r.

The determination of the stresses in the wedge requires first the solution of the fundamental differential for the stresses σ_θ and σ_r. For this purpose the assumption is made that the shearing stress is a function of θ only. Integrating $\tau_{r\theta}$ with respect to θ:

$$\frac{\partial \tau_{r\theta}}{\partial \theta} = \mp 2 \sqrt{\tau^2_{\max} - \tau^2_{r\theta}} + 2\, C\, \tau_{\max} \, \ldots\ldots\ldots\ldots\ldots (9)$$

in which the constant of integration is designated by $2\, C\, \tau_{\max}$. Integrating Eq. 9, in turn,

$$2\, \theta + \alpha = \int \frac{\partial \tau_{r\theta}}{\tau_{\max}\, C \mp \sqrt{\tau^2_{\max} - \tau^2_{r\theta}}} \, \ldots\ldots\ldots\ldots (10)$$

---

[13] "Plasticity," by A. Nádai. Eng. Societies Monographs, McGraw-Hill Book Co., Inc., New York, N. Y., 1931.

An auxiliary function ψ is introduced such that

$$\tau_{\max} \sin \psi = \tau_{r\theta} \qquad (11)$$

Eq. 10 then becomes

$$2\,\theta + \alpha = \int \frac{\cos \psi}{C \mp \cos \psi}\, \partial\, \psi \qquad (12)$$

Using the lower plus sign of Eq. 12 only:

$$\partial\theta = \frac{\cos \psi}{2\,(C + \cos \psi)}\, \partial\psi \qquad (13)$$

Eq. 13 represents the conditions in which the stresses are brought into play in resisting the boundary loading, as distinguished from the case, in which the boundary loads are induced as reactions of the stresses.[12] From the equilibrium Eqs. 3 and 4*b*, by substituting the value of $\frac{\partial \tau_{r\theta}}{\partial \theta}$ and $\tau_{r\theta}$ from Eqs. 9 and 11 and introducing now the body forces:

$$r\,\frac{\partial \sigma_r}{\partial r} = -\,2\,\tau_{\max}\, C - r\,\gamma\, \cos\theta \qquad (14a)$$

and

$$\frac{\partial \sigma_\theta}{\partial \theta} = -\,2\,\tau_{\max} \sin \psi + r\,\gamma\, \sin\theta \qquad (14b)$$

Having determined the values of $\partial\theta$ and $\partial\psi$, the fundamental differential stress Eqs. 14 for σ_r and σ_θ can now be solved by substituting for $\partial\theta$ from Eq. 13. Eq. 14*b* then becomes

$$\partial\sigma_\theta = -\int 2\,\tau_{\max}\, \frac{\sin\psi \cos\psi}{2\,(C + \cos\psi)}\, \partial\psi + \int r\,\gamma\,\sin\theta\, d\theta \qquad (15)$$

Integrating Eq. 15, the expression for σ_θ is:

$$\begin{aligned}\sigma_\theta = {} & +\,\tau_{\max}\,(C + \cos\psi) - \tau_{\max}\, C \log\,(C + \cos\psi) \\ & -\, r\,\gamma\,\cos\theta + f_2(r) \qquad (16)\end{aligned}$$

in which the constant of integration is a function of r only. Integrating Eq. 14*a*:

$$\sigma_r = -\,2\,\tau_{\max}\, C \log r - r\,\gamma\,\cos\theta + f_1(\psi) \qquad (17)$$

in which the constant of integration is a function of ψ only. In order to satisfy the condition of plasticity (Eqs. 4*b* and 11), the variables in r and θ must vanish identically. Since—

$$\sigma_r - \sigma_\theta \approx 2\,\tau_{\max} \cos\psi \qquad (18)$$

—it follows that the functions of $f_2(r)$ and $f_1(\psi)$ must equal, respectively,

$$f_2(r) = -\,2\,\tau_{\max}\, C \log r + C_1 \qquad (19a)$$

and

$$f_1(\psi) = \tau_{\max}\,[\cos\psi - C \log\,(C + \cos\psi)] + \tau_{\max}\, C + C_1 \qquad (19b)$$

Let the constant

$$C_1 = \tau_{\max} C \log a^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

in which a is a length measured radially from the apex of the wedge. Substituting these values of the functions into Eqs. 16 and 17 the equations for the stresses σ_r and σ_θ in their final form are:

$$\sigma_r = -\tau_{\max} C \log \frac{r^2}{a^2} (C + \cos \psi) - \tau_{\max} \cos \psi - r \gamma \cos \theta + \tau_{\max} C \quad (21a)$$

and

$$\sigma_\theta = -\tau_{\max} C \log \frac{r^2}{a^2} (C + \cos \psi) + \tau_{\max} \cos \psi - r \gamma \cos \theta + \tau_{\max} C \ldots (21b)$$

To obtain the values of the function ψ Eq. 12 is integrated to yield the values of ψ implicitly as a function of θ and C:

$$2\theta + \alpha = \pm \frac{2C}{\sqrt{C^2 - 1}} \tan^{-1} \left(\frac{\sqrt{C + 1}}{\sqrt{C - 1}} \tan \psi/2 \right) \mp \psi \ldots\ldots\ldots (22)$$

The curves in Fig. 11 were obtained from Eq. 22 (with $C > 1$ and $0 < \theta < \theta_0$) for determining the numerical values of the stress Eqs. 21.

The general expressions for the stresses σ_r, σ_θ, and $\tau_{r\theta}$ (see Eqs. 11 and 21) should satisfy the boundary conditions of the soil slope. These conditions require that the shearing stress $\tau_{r\theta}$ be equal to zero along line OD. (θ equals θ_0, the wedge angle in Fig. 10(a)) and that the normal stress σ_θ be approximately uniform as originally assumed along [the boundary OD.

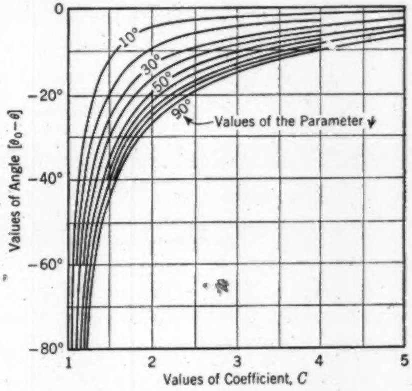

FIG. 11.—VALUES OF THE PARAMETER ψ FOR DETERMINING THE SHEARING STRESS τ IN A WEDGE OF PLASTIC MATERIAL

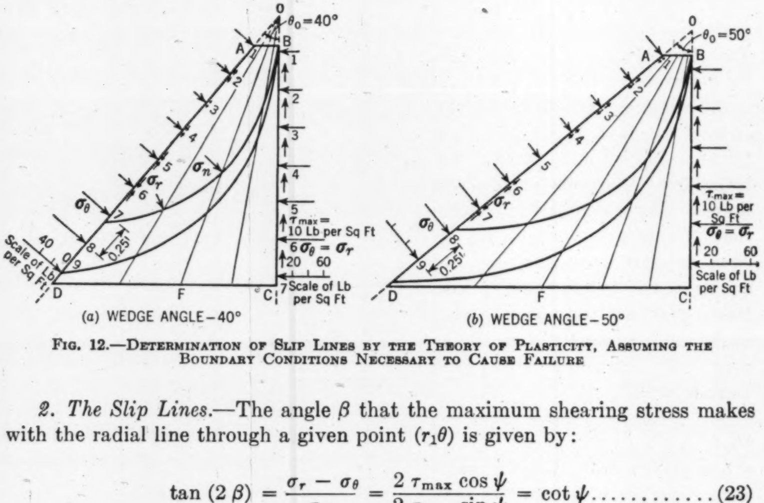
1. Boundary Conditions.—A study of the curves of Fig. 11 shows that, in order that the shearing stress given by Eq. 11 may have real values throughout the entire wedge, it must have its maximum value $\tau_{r\theta} = \tau_{\max}$ along boundary OC, Fig. 10, where ψ is equal to 90° by Eq. 11. Along plane OD where θ equals θ_0 the shear stress must be equal to zero. Hence, by Eq. 11, ψ must also equal zero along plane OD. A plastic region exists where $\tau_{\max}$ has become equal to the maximum shearing strength that can be mobilized.

For a wedge angle θ_0 of 40°, the value of coefficient C is determined from Fig. 11 for $\theta = \theta_0$ and $\psi = 90°$, where $\tau_{r\theta}$ is a maximum, and C is found to be 1.6. The value of $\tau_{\max} =$ (10 lb per sq ft) was obtained from Fig. 2 for a slope of 50° (θ equals 40°).

A comparison of the magnitude of σ_θ for the boundary OD in Fig. 12 for wedge angles of 40° and 50°, respectively, shows that lower boundary stresses are required for a wedge angle of 50° in a plastic condition (that is, less equivalent cohesion is required for stability) than for a wedge angle of 40°. On the boundary OC the normal stress should increase linearly in the y-direction in accordance with the usual concepts of earth-pressure phenomenon. This condition is satisfied reasonably well except near the top of the slope. The normal stress loading on boundary OD, on the other hand, does not satisfy quite so well the required assumed condition of a uniform loading, except possibly in the upper part of the slope. It is believed that the distribution of σ_θ is reasonably uniform, as assumed, and that it represents a good approximation for the upper sliding curves. The boundary condition for the wedge can therefore be assumed to be satisfied reasonably well. Fig. 12 shows also that, in the upper part of the slope, tension can exist (σ_r is positive); and, therefore, tension cracks may develop in cohesive soil.



(a) WEDGE ANGLE-40°

(b) WEDGE ANGLE-50°

FIG. 12.—DETERMINATION OF SLIP LINES BY THE THEORY OF PLASTICITY, ASSUMING THE BOUNDARY CONDITIONS NECESSARY TO CAUSE FAILURE

2. The Slip Lines.—The angle β that the maximum shearing stress makes with the radial line through a given point $(r_1\theta)$ is given by:

$$\tan(2\beta) = \frac{\sigma_r - \sigma_\theta}{\tau_{r\theta}} = \frac{2\,\tau_{\max}\cos\psi}{2\,\tau_{\max}\sin\psi} = \cot\psi \ldots\ldots\ldots\ldots (23)$$

When the directions of maximum shearing stress are found by Eq. 23 and Fig. 11, for a large number of points in the plastic region, the slip lines can be drawn as shown in Fig. 12 for wedge angles of 40° and 50°. These slip lines are arcs of circles and have the same general forms as the sliding curve actually observed in nature and in the model tests.

The stress conditions at failure were investigated along the sliding curve by the photoelastic method (inclination of gelatin slope, 49°), Swedish circular arc method (inclination of sand slope, 49°), and by the theoretical plasticity method (analysis of the potential slip line, wedge angle, and slope inclination, 45°). The distribution of the shearing stress in relation to the shearing strength along the sliding curve is shown in Fig. 13. The stress and strength relation obtained from the Swedish circular arc method is quite different from that determined by the photoelastic and plasticity analyses, which indicate that failure is initiated in a plastic region near the top of the slope which encroaches on the region having a reserve of strength, until a failure curve develops.

(*c*) PLASTICITY ANALYSIS

Fig. 13.—Distribution of Maximum Shear Stresses and of the Shearing Strength Along the Slip Lines

CONCLUSION

The angle of repose of cohesionless soil was found to be entirely a superficial phenomenon. Therefore, it is independent of the height of the slope. The angle of repose for any given material lies between two limiting values—a maximum just before a slide, and a minimum just after a slide. It appears to be independent of the density but is affected by the coarseness of the material. On the other hand, the inclination and the height of a stable slope of a cohesive soil were found to be direct functions of the cohesion and were greatly influenced by the density of the material. By creating an equivalent cohesion in a cohesionless soil, it was possible to reproduce slides in the laboratory which were remarkably similar to those observed in nature, the failure curve receding from the surface deeper into the slope with increasing cohesion. It was also possible to observe the mechanics of failure, and the deformations and strains within the slope. The distribution of strain along the failure curve was found to form a consistent pattern with a maximum near the top of the slope where a failure appeared to be initiated after the strain exceeded a rather well-defined value.

The photoelastic studies in gelatin models afforded a clear picture of the distribution and relative order of magnitude of the maximum shearing stress in the slope. There was a close resemblance between the pattern of the shearing stresses and the pattern of the shearing strains obtained by means of the sand model, the plastic regions coinciding with the regions of maximum strain. The plastic regions develop gradually near the top of the slope and encroach upon the regions of reserve of strength, until a rupture curve is formed, followed by a slide.

The plasticity theory permitted the determination of the possible position and form of the sliding curves and of the approximate stress conditions leading to failure. The slip lines were found to be arcs of circles which agree closely with observed natural slide phenomena. The analysis shows that it is possible to have tensile stresses in the upper part of the slopes which might lead to tension cracks and final failure. A failure is imminent whenever the height and inclination of slope and the shearing properties of soil bear such a relation to each other that a plastic region develops.

ACKNOWLEDGMENTS

This paper is based on a thesis entitled "Stability of Soil Slopes."[14] The writer wishes to express his appreciation to the following members of the faculty of Columbia University in New York, N. Y.: J. K. Finch, M. ASCE, chairman of the Civil Engineering Department and now Dean of the Engineering School; to D. M. Burmister, Assoc. M. ASCE, for advice, encouragement, and innumerable and invaluable discussions on every aspect of the research and critical review of this paper; and to R. D. Mindlin, Assoc. M. ASCE, for his helpful suggestions and advice on the photoelasticity and plasticity analysis. G. P. Tschebotarioff, M. ASCE, of Princeton University at Princeton, N. J., and M. G. Salvadori, Assoc. M. ASCE, of Columbia University, reviewed the paper critically before presentation.

[14] "Stability of Soil Slopes," by Ek-Khoo Tan, thesis submitted to Columbia Univ., New York, N.Y., n 1945, in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Engineering.

DISCUSSION

Paul Baumann,[15] M. ASCE.—Research in the mechanics of slides in soil slopes has been aided materially by this paper. This is particularly true from an academic point of view as the sand models were necessarily confined to a definite boundary at the base. The models were not influenced by part or full saturation and therefore could not be expected to incorporate the complexities which seem to be typical of slides in prototypes such as dams, canal banks, and mountain slopes. An ingenious device was used to simulate "cohesion" in the materials used in the soil tests.

Sand Model Tests.—The application of atmospheric pressure on the exposed surfaces of the sand models does not truly represent cohesive action. It represents the compressive effect of these outer forces. Hence, it lends support to these surfaces and causes consolidation of the soil and, thereby, changes the stress distribution that would be established in the presence of true cohesive forces in the prism. The latter would be mutually balanced within the mass without the aid of outer forces.

To avoid confusion, the term "outside pressure" will hereafter be used in referring to the simulated cohesion. It must also be kept in mind that the lateral pressures in the prism are affected, to some extent, by the sloping top which is established in the course of tilting the model, and that the shear distribution along the inclined base is likewise affected. In the course of this discussion the effect of outside pressure and of tilting prisms will be further studied and compared with the conditions that would establish themselves without tilting.

It would have been helpful if the author had shown a screen analysis and had furnished information on the density and moisture content of the material in question. It is hoped that this will be done in the closing discussion to complete the paper.

A most interesting and valuable feature was brought out in the course of the tests on the sand models—the relation of depth to the limit of disturbance and to the surface of rupture. The insight into the mechanics of sliding failure and its division between a plastic and an elastic zone is thereby enhanced.

Prototype slides, however, are usually related to soil moisture, and to the pore water stress that results from it. This is particularly true of slopes that are exposed to water subject to fluctuation. With few exceptions, landslides observed in nature have likewise been closely linked with the moisture content in the soil and the stresses caused by this moisture, either static or dynamic. The tests described in the paper naturally do not shed any light on these phenomena; they are limited entirely to gravitational influences on the soil itself, and to the pressure acting on the outer surface.

The problem of analyzing the initial stress distribution in a soil prism, such as that used in the tests, has never been uniquely solved. This solution may be approached in the following manner:

---

[15] Asst. Chf. Engr., Los Angeles Flood Control Dist., Los Angeles, Calif.

Let line CB in Fig. 8 be the axis of symmetry of an embankment, the dimensions of which are equal in feet to the values specified in inches by the author. Then, distance CD is equal to one half of its base. The shear distribution along the base may be approximated[16] in distributing the later pressure E_o as shown in Fig. 14. Actually, the shear is distributed as indicated by the dashed line. The hatched area then represents the total lateral pressure per unit width of prism acting on a vertical plane through point A (see Fig. 14). Its value is ascertained by the Coulomb formula for cohesionless granular soil in:

FIG. 14

$$E_o = \frac{\gamma\, h^2}{2} \tan^2 \left(45 - \frac{\phi}{2} \right) \dots\dots\dots\dots\dots\dots (24)$$

in which γ, the unit weight of soil, equals 90 lb per cu ft (assumed); ϕ, the angle of friction, equals 33° (according to Mr. Tan); and $h = \overline{AA'}$.

It is significant to note that maximum, modified shear occurs along line AZ, which means that it also occurs near the top of the slope. This was confirmed by the test. The rapid increase in the shear intensity with the steepening of the slope is also significant (see dashed and dotted line in Fig. 14). Tilting the prism causes an increase in the shear intensity which is even more pronounced in that E_o increases with the tilt. Thus, tilting the base mobilizes forces which are different from those created by the steepening of the slope alone. Next, consider a small triangular prism near the toe of the slope which, in the initial state, is held in equilibrium by the stresses σ_x, σ_y, τ_x, τ_y, and the body force W.

---

[16] "Soil Mechanics," by D. P. Krynine, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., 1941, p. 272.

The triangle formed with σ_y as the base represents the horizontal force H which is equal and opposite to the shear S_x between points X and D in Fig. 14. The vertical (downward) shearing stress τ_y at point X is equal to τ_x. Hence, the vertical shear S_y may be determined. The weight of the prism is W. The prism is drawn to a large scale in Fig. 15 and the stresses and forces applied. The bearing pressure σ_x at point X must be determined before the principal stresses can be ascertained. This is done by combining H and S_y, and W and S_x, into resultants and by combining the two. The final resultant R falls closely in line with W and permits the σ_x-stress at point X to be determined. This stress is not equal to the pressure caused by the height XY of the prism. Fig. 16 shows the determination of the principal stresses and their directions by Mohr's circle. These directions are transferred to point X in Fig. 14. As a boundary condition for the initial state all stresses must be zero along line AD.

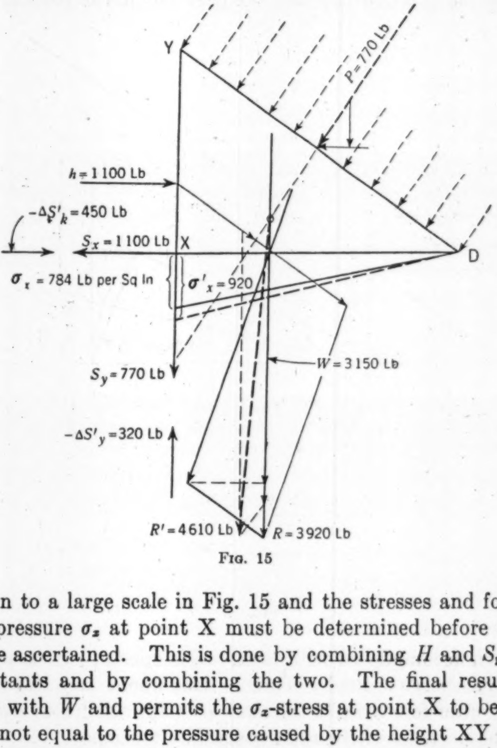

Fig. 15

Now, let the outside pressure P be applied uniformly so as to correspond to 1 ft of water column, equal to 1 in. in the model test as shown in Fig. 15 by dashed lines. Clearly, the stress condition along the surface has changed; the normal stress is no longer zero, nor is the longitudinal stress necessarily along the outside fiber. Combining P with R gives a new resultant R' which reduces τ_x and τ_y and increases σ_x. The corresponding principal stresses and their directions are shown (by the dashed line) in Fig. 16.

If the outside pressure P were increased indefinitely, the soil mass would eventually become a solid, and the section could be treated as a monolith. The stress condition would then again undergo a complete change. Hence, the application of outside pressure creates stress conditions different from those resulting from cohesion. It primarily creates a pre-stressed condition, as discussed by the writer in connection with the San Gabriel Dam No. 1 of the Los Angeles County (Calif.) Flood Control District.[17]

A better simulation of cohesion than that achieved by using the rubber membrane over the outer surface and the part vacuum in the voids of the soil could have been accomplished with mass forces created by the rotation of the model at various speeds around a center. This would have had the advantage of eliminating outer forces, since the mass (centrifugal) forces would naturally apply to all the particles of the sand mass simultaneously.

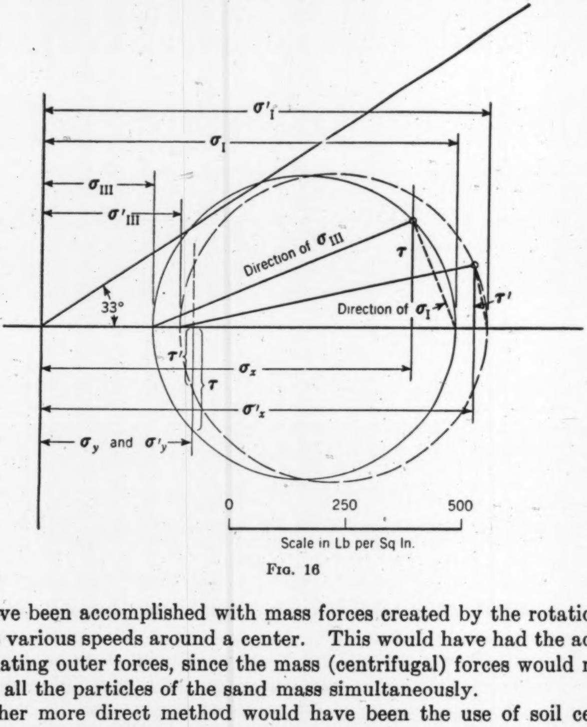

FIG. 16

Another more direct method would have been the use of soil cement of various mixes. Actual cohesion and internal friction could then be determined by tests.

Swedish Circular Arc Analysis.—It appears as if the discrepancy in the safety factor at failure in the Swedish circular arc method of analysis may be due to two principal factors: (1) The angle of internal friction evidently was considered to be equal to the minimum angle of repose of 33°, whereas, in effect, it probably was greater; and (2) the analysis apparently was made on the sand models that had been subjected to outside pressure on the rubber membrane. These forces should be superposed on the gravitational and lateral forces and the stresses along the rupture surface determined in similar manner, as outlined by the writer in connection with the soil prism (see Fig. 15). Apparently, the outside pressure was simply assumed to increase normal components along the rupture surface without simultaneously decreasing the tangential components. Thus, although factor (1) would cause an increase in the numerator, factor (2) would have the opposite effect on the denominator, and the two combined might well result in a factor of safety approaching unity.

---

[17] "Design and Construction of San Gabriel Dam No. 1," by Paul Baumann, *Transactions*, ASCE, Vol. 107, 1942, pp. 1648–1651.

Photoelastic Tests.—It is somewhat difficult to agree as to the "remarkable resemblances" between the results of the photoelastic tests and those of the sand tests, particularly in view of the fact that the photoeleastic tests do not show the formation of the surface of rupture. The shear distribution in the gelatin models is quite at variance with the one in the sand models except for the fact that both show a wave pattern.

Theoretical Plasticity Analysis.—Like most researchers in the field of soil mechanics, the author had to make considerable concessions, particularly in the way of approximations, to avoid terms of hopeless complexities for analytical solution. This circumstance, no doubt had much to do with the fact that Karl Terzaghi, M. ASCE, has defined soil mechanics as a descriptive science. The mathematical analysis is nevertheless remarkable, although the results, as shown in Fig. 13, bear little resemblance to either the Swedish circular arc or the photoelastic analyses.

Conclusion.—There is no question in the writer's mind but that the author's work will lend itself advantageously for further advance in the knowledge of the idiosyncracies of soil slopes, either natural or artificial.

Gregory P. Tschebotarioff,[18] M. ASCE.—A noteworthy feature of this paper is the attempt to apply the mathematical analysis of stress conditions within a soil mass by means of the theory of plasticity. The results of the several methods of investigation, as presented in the paper, do not appear to lead to exactly the same conclusions. However, such differences as have been registered are of value since they serve to reveal the limitations of some methods of investigation.

Fig. 3 presents, in clear graphical form, the fact that a surface of failure can develop only at some distance from a rigid boundary after the shearing strains have reached a certain value. This is a very significant finding. These shearing strains develop within the soil mass beneath the surface of failure in a soil zone which is frequently assumed as not affecting the location of the surface of failure.

Fig. 5 shows that the maximum strains occur close to the toe of the slope as determined from the displacements of lampblack lines caused by motions of the sand grains. In this respect, these curves appear to be in agreement with the general trend of stress distribution represented in Fig. 9, which summarizes the results of the photoelastic studies. There again the greatest stress concentration is shown to occur at the toe of the slope. It seems to the writer that this is a direct consequence of the presence of the rigid boundary along the base of the model slopes, and of the fact that the inclination of this boundary varied as a function of the slope i and increased with it. Judging from the isochromatic patterns shown in Figs. 9(*a*) and 9(*b*), the lubrication of the base did not noticeably reduce the stress concentration at the toe of the slope, and even appears to have increased it somewhat. In both cases (as stated by the author in Part II, section 2), the stress concentration at the toe of the slope must have been strongly influenced by the separation of the gelatin from the rear vertical face BC of the flume (see Fig. 8) which prevented the development of tension at that boundary.

---

[18] Associate Prof., Civ. Eng., Princeton Univ., Princeton, N. J.

When dealing with natural slopes in the field, one usually encounters conditions in which the cohesive soil mass extends well beyond the toe of the slope both in the vertical and in the horizontal directions. It is doubtful that stress concentrations of an intensity similar to the one shown in Fig. 9 could occur then, irrespective of whether tension cracks had, or had not, developed near the top of the slope. Accordingly, in the writer's opinion, one of the most interesting and significant contributions of the paper lies in the fact that the considerable importance of boundary conditions is made apparent, as well as the influence of these boundary conditions on the redistribution of stresses within the soil mass, and on the location of the surface of failure.

JACOB FELD,[19] M. ASCE.—The thesis of the paper is to prove—by experiment, by experience, by deduction from the measured stress distribution in gelatin models, and from mathematical analysis of stress distribution in idealized soil masses—that failure within a soil body results from plastic strain. Plastic failure methods applied to cohesive materials are consistent with present thought; but, when the failure of pure granular materials is likewise explained, a new concept has been added.

The basic differences in shear deformations of different states of materials have been explained by E. C. Bingham.[20] When a perfectly elastic solid is subjected to a shearing force, a strain develops and disappears entirely when the stress is removed. In this case of elastic deformation, there is no permanent displacement and, therefore, no flow. If the solid is not perfectly elastic, a part of the deformation remains as a permanent displacement and work has been performed in overcoming the internal resistance of the material. The flow resulting in the displacement may be of three types:

1. Viscous or linear flow in which the amount of the deformation is proportional to the acting force, although such relationship may not become apparent until the force has acted over a measurable time period;
2. Hydraulic or turbulent flow; and
3. Plastic flow in which the slightest shearing force starts a deformation which continues indefinitely.

The phenomenon, plasticity, contains the concepts of internal friction and mobility, acting simultaneously. True plasticity can only be exhibited by a material in the fluid state, for, when the material changes to a solid state, deformation ceases.

The laws of friction in solids and the laws of friction during viscous flow are quite different.[21] For solids, frictional resistance is: (1) Directly proportional to the component of the exterior forces acting normal to the surface of rupture; (2) greater before the beginning of motion than during motion; and (3) independent of the area of contact. For viscous flow, frictional resistance is: (1) Independent of the load; (2) equal to zero if the velocity is zero and is directly proportional to the velocity; and (3) proportional to the area of contact.

[20] "Fluidity and Plasticity," by E. C. Bingham, McGraw-Hill Book Co., Inc., New York, N. Y., 1922, p. 4 et seq.

[21] *Ibid.*, Chapter VIII.

A number of these concepts were enunciated by C. A. Coulomb[22,23] as "preliminary propositions" to his studies of the rupture of bodies, pressure of earth, and equilibrium of arches. He postulates that:

> *a.* Frictional shear failure resistance is proportional to the pressure acting normal to the failure surface; and
>
> *b.* Cohesion is a measure of the resistance which a body presents to a disunion into two parts, and in a homogeneous mass the cohesion is proportional to the area of the section of separation.

The author's statement that failure in earth slopes is a plastic phenomenon requires the assumption that the materials immediately adjacent to the fractures are in a fluid condition; otherwise failure would be localized and not progressive. Examination of slide failures in soil masses indicates that such an assumption is possible. It explains the existence of void spaces along the rupture surfaces. Discrete particles of solid matter in motion are fluid.

To the list of references proving the existence of curved rupture surfaces, the author should add Coulomb's derivation of the same type of surface. It is somewhat involved mathematically, but, nevertheless, it is the earliest derivation of the rupture curve of a soil having both frictional and cohesive resistances.[24]

The apparatus used by the author to induce variable cohesive properties to granular soils is ingenious. For materials with high angles of slope, the fixed bottom surface will affect the properties of the internal mass. The diagram in Fig. 1 does not give the angle of the side walls, but the gelatin models in Fig. 9 show an angle of 29°. The apparatus tests should be repeated with a bottom sloping downward from the toe, so that the angle of soil is at least as large as the largest angle of natural slope to be measured.

The artificially induced "cohesion" by partial evacuation of granular materials brings to mind an interchange of discussions between the late H. de B. Parsons, M. ASCE, and the writer about 1932. In an attempt to explain why readings in lateral pressure tests were lower than expected, Mr. Parsons[25] postulated the existence of a partial vacuum in the soils tested. The writer summarized his arguments by showing how the existence of cohesion within a soil mass gave the necessary explanation of the pressure readings and the internal stress relationship was the same as when a partial vacuum was assumed.[26]

[26] "Vacuum or Cohesion in Soils," by Jacob Feld, *ibid.*, April, 1934, p. 219.

In sections 1 and 2 under the heading, "I. Investigation of Soil Slopes by Models," the author distinguishes between the angle of repose phenomena in "dry cohesionless materials" as purely a surface readjustment and in "cohesive soils" as a deep-seated internal rupture. There must be a zone of gradation in action, and some relationship between the minimum cohesion (probably as a ratio of internal frictional resistance) in a soil to place it into the "cohesion class." All soils that show the superficial phenomenon are not totally lacking in cohesion.

The author explains the existence of cohesion in natural soil deposits (section 2) as the result of capillary forces in the moisture between the finer soil grains. This explanation is not probable. The writer has experimented with pulverized bentonite (a colloidal natural clay) which when perfectly dry shows no cohesive properties and acts exactly the same as a very fine sand. However, a very slight moisture content makes the bentonite a slimy gel. Dry particles cannot be packed close enough (in soils) to permit intermolecular attraction. Powders can be made to stick together without adding a fluid medium, but only under very high pressures. On the other hand, thin moisture films will draw particles closely together; but, even in this case, the force of capillarity of the moisture films is much larger than the gravitational attraction between the molecules of the separated particles.

Cohesion is more likely to be generally explained as the interplay of dissimilar materials in intimate contact. For instance, the introduction of a liquid into a granular mass results in cohesion only if the solid aggregate is wetted by the liquid. If the liquid does not wet (adhere to) the solid grains, the physical resistance of the granular mass is not increased. Actually, for some lubricating types of liquids, the internal friction may be decreased. If a gas and a liquid are added to a granular mass, with conditions such that the gas is occluded on the surface of the grains and the liquid tends to dissolve the gas, a very plastic mix is obtained. Similarly, large cohesive properties result from the addition of colloidal ingredients or the mixing of materials which form colloidal covering of the soil grains. Any of these conditions increases the "resistance to disunion" between grain particles, the increase being many times the natural gravitational attraction of like grains to each other. The author's experimental method permits a study of varying equivalent cohesive strengths in any type of soil to be easily made.

The results given in Fig. 2, at zero vacuum, for loose and dense sand are not consistent with the values in Table 1. Possibly, the dashed line extrapolations in Fig. 2 should be eliminated, and the graphs for loose and dense state extended to meet at a value of 36° for the angle of slope with no vacuum acting.

In section 4 of the test results, the author reports a linear relation between the critical height of an unsupported embankment and the cohesion of the soil. In 1773 Coulomb developed a formula for the height h_f of a bank which will stand vertically unsupported as

$$h_f = c \frac{l}{m} \qquad \text{(25)}$$

in which c is the coefficient of cohesion; and m and l are coefficients depending on the weight of the soil and value of the internal friction, such that the earth pressure,[24] p, equals:

$$p = m\,h^2 - c\,l\,h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Coulomb's result also gives a linear relation between the free standing height h_f and the cohesion c.

All the author's methods, as well as the reports by H. G. Moulton[27] and the late J. C. Meem,[28] the late David Molitor,[29] Lazarus White,[30,31] D. P. Krynine,[32] Members, ASCE, and the references listed by the author under the heading, "Introduction," tend toward a solution defining the surfaces of rupture and of stable unsupported slope as circular, conchoidal (Mr. Moulton),hyperbolic (Mr. Molitor), and sometimes spiral. The unanimity of determination is the form of the curve—namely, concave; yet, the problem cannot be declared solved as long as the largest experimental report, from the Panama Canal slide correction work, gives just the opposite type of curve, definitely convex.[33]

Earl M. Buckingham,[34] Assoc. M. ASCE.—The preparation of this paper has required a considerable amount of painstaking work. To the writer, however, it seems that the planning and interpretation were not commensurate with the effort expended in the laboratory. Tests as simple as working a lump of clay between the fingers will demonstrate the fallacy of trying to simulate the action of impervious cohesive soil by increasing the friction in sand. The forces of capillarity, molecular attraction, and pore pressure are much too complicated to be replaced by a simple external pressure. Part I of the paper must therefore be considered applicable only to clean dry sand.

Although the internal structure of clay has been known for years,[35,36] the profession has been slow to accept the application of this knowledge. Soils that have a high percentage of sand possess a true internal friction, and some of the more permeable silt clays may consolidate rapidly enough to develop an increase in strength when loaded. However, the application of the Coulomb conception of cohesion plus friction to an impermeable clay may be highly misleading. This is true even though values of "cohesion" and "friction" may have been determined in the laboratory.

Consolidation is frequently difficult to prevent in the laboratory; but it might occur very slowly in the natural deposit from which the sample was taken. Instead of developing more frictional resistance, an increase in loading might cause sufficient deflection to develop dangerous pore pressures and materially reduce the shearing strength. Figs. 17 and 18 show typical results of some shear tests made recently by the writer with equipment of the three-ring type. Fig. 17 represents an unconsolidated estuary mud composed of particles of the silt and clay sizes. Each sample had a constant shearing strength for all normal pressures below a critical value at which the granular structure broke down and the mud began to liquefy and lose its strength.

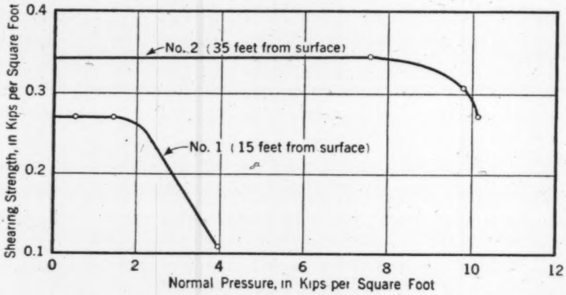

FIG. 17.—SHEAR TESTS, ESTUARY MUD

After the principle had been demonstrated with mud, an attempt was made to obtain the same effect with a stiff and fairly dry marly clay, as shown in Fig. 18. The sample was first tested at zero normal load, and failed at a shearing load of 3,030 lb per sq ft. After shifting the sample to expose new shear faces, a normal load of 12,700 lb per sq ft was applied. When the shearing stress reached 3,030 lb per sq ft, water appeared on the surface of the sample between the rings. Failure did not occur until the shear oad reached 5,760 lb per sq ft. In the natural deposit, the escape of even a small quantity of water might not be possible, and slow failure might begin at the stress under which water began to extrude from the test sample. A casually run test would have indicated an "angle of friction" of 12° 10′.

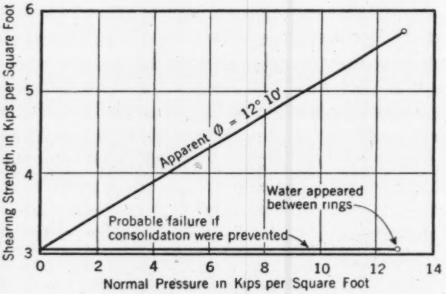

FIG. 18.—SHEAR TESTS, MARLY CLAY

Because a saturated clay ordinarily loses its strength when it is deformed, complete failure may result from a local concentration of stress even if the average stress is below the safe strength of the soil. Progressive failure of this type is common in natural slopes; but it is not considered in any analysis based on "cohesion" plus "friction."

In Part I, section 5, Mr. Tan states: "The significance of a factor of safety of less than unity at failure is not fully understood." Lack of understanding in this respect is due to the failure to distinguish between the angle of internal friction and the angle of repose. For the arc analyzed, the angle of internal friction, $\phi_i = \tan^{-1} \frac{16.95}{20.95} = 39°$. Failure along either a straight line or a circular arc does not involve internal deformation, and the only resisting forces are those acting on the failure surface. Hence, if the condition that causes failure comes into being slowly, the factor of safety at failure cannot be less than unity. Other failure sections, such as a logarithmic spiral or a broken line, involve internal deformations which are not ordinarily considered in the computation. For this condition, a computed factor of safety of less than unity is possible. Assumed failure sections of all types are arbitrary and probably differ from the section of least resistance along which failure will occur. Therefore, a factor of safety greater than unity at failure is at least theoretically possible for all assumed sections. Uneven distribution of stress should not be of major importance when dealing with a material that can yield without losing its shearing strength. If it were a factor, it would increase rather than decrease the apparent factor of safety at failure.

The author does not state how he computed the distribution of shearing stress by the Swedish arc method. Although the interfacial pressures between slices are neglected when dealing with the arc as a whole, they are quite important when considering an individual slice. The distribution of both stress and frictional resistance depends on these pressures, and a method of solution would be of considerable interest.

The straight-line relationship between critical height of a vertical bank and vacuum is not surprising. Considering unit thickness, volumes and weights vary as the square of the linear dimensions, whereas the areas to which the vacuum is applied vary as the first power. Therefore, it is necessary for the vacuum to vary as the dimensions to maintain similitude. The relation between vacuum and angle of slope is not so simple geometrically, but could probably be reduced to a constant coefficient of friction if the shapes of the failure sections were known. The writer recommends that Mr. Tan include, in his closing discussion, detailed measurements of representative failure sections which he produced. These may well prove to be the most valuable part of the investigation. Unless an actual slip has occurred and has been located, current methods of analysis depend on an assumed section. Although the various methods yield fairly comparable results, experimental data might make possible a more intelligent choice between the several conventional sections.

K. B. HIRASHIMA,[37] ESQ.—This paper, which is a valuable contribution to the literature on slope stability in that it provides an insight into the mechanics of slope failure, should be of interest to all engineers dealing with earth structures, such as highway cuts and embankments, earth dams, etc. In spite of considerable literature on the subject, cited by the author in the "Introduction," it is a phase of engineering science to which most engineers pay altogether too little attention. The subject of slope stability is one of great complexity involving many factors that are indeterminate and not fully understood. One needs only

---

[7] Testing Engr., Territorial Highway Dept., Honolulu, Hawaii.

to observe the number of slope failures that actually occur to realize the truly complex nature of slope stability.

The stability of slopes in cohesionless soil is easy to understand. Slope failure in such cases is, as the author concludes, purely a superficial phenomenon. Hence, for a mass of cohesionless soil to be stable, it is only necessary that the side slopes be less than the angle of repose. It is noteworthy that Table 1 gives two values of the angle of repose, a maximum and a minimum, whereas most textbooks give but a single value. In regions subject to earthquakes and other such disturbances, important earth structures should perhaps have slopes not exceeding the minimum angle of repose, thus decreasing the tendency to slide.

In a cohesive soil, the cohesion is sometimes defined[38] by

$$c = P_i \tan \phi \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

in which P_i is the hypothetical internal pressure and $\tan \phi$ is the coefficient of internal friction. The internal pressure P_i acts uniformly in all directions.

In his model test, the author uses an ingenious arrangement to impart an "equivalent cohesion" to a sandy mass by applying a uniform atmospheric pressure to the side slopes and top. This externally applied force gives rise to a stress system within the mass which can be resolved, at any given point, into a uniform direct stress, the same in all directions, and a shear stress. Theoretically, if this shear stress is of any consequence, it should affect the stress distribution due to the gravitational forces.

In the present model study it is not possible to reproduce all the conditions that exist in the prototype. An actual earth structure, such as a highway embankment, is bonded to the foundation soil—that is, there is a certain continuity to the soil mass. In a model, the soil mass is necessarily discontinous because of the model's rigid base. The change in boundary conditions affects the stress distribution; for instance, it is possible for the circle of sliding failure to undercut the toe of the slope, the so-called "Swedish break." For an embankment built on solid rock, that is, a rigid base, the failure line must necessarily pass through or above the toe of the slope.

In Fig. 6 is given the maximum height at which an unsupported bank of cohesive soil will stand vertically. It would have been interesting if the author had given additional data so as to make possible a comparison with the usual theoretical formula:[39]

$$H = \frac{2\,c}{w} \tan \left(45 + \frac{\phi}{2} \right) \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

in which H is the maximum height of unsupported bank of cohesive soil; c is the cohesion; w is the unit weight of soil; and ϕ is the angle of internal friction. The paper presents a comparison of three methods of slope analysis: The photoelastic analysis, the Swedish circular arc method, and the theoretical plasticity analysis. For routine use, the Swedish circular arc method is the only practical one. This method deals essentially with averages. Thus, if the shearing stress tending to cause sliding failure is less than the shearing strength of the soil along the assumed arc of failure, the soil mass is assumed to be safe according to the usual rule. However, a careful study of the author's analysis will show that a dangerous condition may, nevertheless, exist—that is, certain regions within the soil mass may be so highly stressed that a condition of plasticity prevails. The gradual spreading of the plastic zone may lead to eventual failure, and it is well to remember in this connection that the spreading of a plastic zone within a large mass of earth is an extremely slow process that may require weeks, months, or even years.

[38] "Soil Mechanics," by D. P. Krynine, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., 1941.

[39] "Present Status of Soils Investigations," by C. A. Hogentogler and E. S. Barber, *Proceedings*, 19th Annual Meeting, Highway Research Board, National Research Council, Washington, D. C., 1939, p. 377.

In actual engineering earth structures, the pore water pressure[40, 41] must be known. The author does not give any data as to moisture content in any of his experiments. Apparently, it was necessary to use the sandy material in a dry state in order to control the "equivalent cohesion" within narrow limits.

The writer is familiar with a soil which has a natural moisture content of more than 200%, based on the dry weight of the soil, in its undisturbed state. A vertical bank from 8 ft to 10 ft high can be cut through this material. The slope will be stable and there will be no drainage of water from the sides, in spite of the tremendous water content. On the other hand, building a highway embankment of any great height with such a soil is quite a problem, in view of the fact that rainfall conditions in the region where this particular soil is found are such that drying out the soil is impractical. Plastic zones will readily form within such a mass because of the high water content. The progressive creep of these plastic zones which may take years, has given rise to sudden settlements. However, it is the pore water pressure that is the basic cause of these difficulties, and the designer must have some idea of how this pressure acts in order to arrive at a safe design. Incidentally, in this particular soil a type of failure occurs that has not been mentioned thus far. If for any reason the moisture content of this soil drops below a certain critical value, as, for example, in times of drought, it turns irreversibly into a granular sandy mass, and the side slopes will fail in chunks along the surfaces separating the dry mass from the wet mass.

DONALD M. BURMISTER,[42] Assoc. M. ASCE.—A distinctive contribution to the subject of stability of soil slopes has been made by the author—first, by presenting a new technique which may be used for investigating the broad field of stress displacement and failure phenomena in soils by the use of an "equivalent cohesion"; second, by providing an insight into the mechanics of failure of soil slopes and a better understanding of the conditions leading finally to failure; and, third, by interpreting such phenomena by photoelastic studies and by a mathematical treatment of the subject of failure in the plastic state. The writer wishes to consider in detail certain fundamental concepts involved in this study.

The first is the concept of cohesion. The author states in Part I (under the heading, "2. Phenomenon of Slides in Slopes of Cohesive Soils"):

> "Cohesion is essentially an intergranular stress phenomenon created in one case by capillary forces arising from the capillary moisture film at the grain contact * * *."

The truth of this statement should be obvious for sands and silts of cohesionless character. For example, the moisture films left in the fine sand at Daytona Beach, Fla., when the tide recedes converts the sand (most unstable when completely dry) to a firm hard surface, which makes an excellent race track. The importance of capillary cohesion can be judged from the fact that stable slopes in sands and silts of cohesionless character, but containing moisture films at the grain contacts, rarely have to be cut to angles flatter than about 45°. This cohesion is relatively permanent and can be relied on by engineers, otherwise all slopes in such materials would have to be cut to the angle of repose. The water in the contact moisture films does not evaporate entirely, or as readily as does free water, particularly if fine silt has been deposited at the grain contacts by rain water percolating downward through the deposit. The stress conditions induced by capillary forces acting in the contact films are shown in Fig. 19. Three zones are involved: A saturated zone below the ground-water level; a capillary zone extending to the upper limit of the capillary rise, in which interconnected capillary films form a continuous system through which capillary flow can take place; and a zone of condensation and evaporation above the upper limit of the capillary rise, in which discrete water films occur at the grain contacts, but are not interconnected. The film relations are shown in Fig. 19(*a*); the state of stress in the contact water films is given by La Place's equation:

(*a*) CAPILLARY FILMS (*b*) DISTRIBUTION OF SOIL MOISTURE (*c*) STRESS IN SOIL MOISTURE

FIG. 19.—CAPILLARY FORCES AND INITIAL STRESSES IN COHESIONLESS SOILS

$$p_c = g \rho h_c = T_s \left(\frac{1}{R_1} = \frac{1}{R_2}\right) \qquad (29)$$

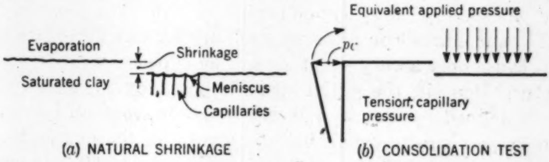
in which g is the acceleration of gravity; ρ is the mass density; h_e is the equivalent height of capillary rise; T_s is the surface tension of water; R_1 is the radius of the meniscus whose center is outside the film and is negative; and R_2 is the radius of the contact film. Eq. 29 does not limit the magnitude of either p_e or h_e, which in fine soils may considerably exceed the value for water in the normal state (30 ft of suction head).

Distribution of the moisture in the soil column, in percentages of that required for saturation, is shown in Fig. 19(*b*). The state of stress in the interconnected water films below the limit of capillary rise is shown in Fig. 19(*c*), the maximum tension in the water films occuring at the limit of capillary rise. This maximum stress condition in the water films must be exactly balanced by a stress condition in the grain structure of the soil—that is, by compressive stresses at the grain contacts. In the capillary region the stress conditions in the grain structure of the soil are identically the same as those that would be imposed either by applying a uniformly distributed vertical pressure at the limit of capillary rise equal to the maximum tension, as shown, or by evacuating the region beneath a rubber membrane, which takes the place of the water films at the same level. The stress condition in the grain structure of the soil would be uniform with depth, but would not be isotropic, since the relation between the vertical and horizontal stresses is given by

$$p_h = p_v \left(\frac{\mu}{1 - \mu}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

in which p_h and p_v are, respectively, that part of the horizontal stress and the vertical stress due only to capillary forces at a point, and μ is Poisson's ratio, varying from 0.2 to 0.3 for sands. Above the limit of capillary rise, in the region of evaporation and condensation where the films are not interconnected, the stress conditions should be isotropic.

The most important fact is that under such circumstances an initial stress condition exists in the grain structure of the soil due to forces other than gravity. These stresses greatly increase the resistance of particles to relative displacements, particularly near the surface, where the gravitational forces may be small as compared with these initial stresses due to capillary forces. Therefore, the concept of an "equivalent cohesion" is applicable to such problems, because, as stated by the author, capillary cohesion is equal to the capillary force (or tension) times the tangent of the angle of friction.



(*a*) NATURAL SHRINKAGE (*b*) CONSOLIDATION TEST

FIG. 20.—CAPILLARY FORCES AND INITIAL STRESS IN CLAY

It may not be so obvious that the concept is also applicable to clay-soils and clays. First, it is necessary clearly to separate two concepts: Cohesion, which is essentially an initial stress condition, whatever its source; and cohesive action, which involves plasticity and is quite another matter. The second concept will be deferred to the subsequent discussion on plasticity.

Conditions existing in a natural deposit of clay, exposed for the first time to evaporation forces by an excavation, are shown in Fig. 20. Evaporation of water from the surface of the clay results in an equal volume change in the region affected. Shrinkage of a mass of clay represents a strain, and hence the existence of a corresponding stress causing it must be recognized. This stress originates in the capillary meniscii formed at the surface of the shrinking clay by the evaporation processes, which bring into play active capillary forces at the surface of the clay, as shown in Fig. 20(*a*). The clay mass is subjected to a uniform stress. An identical situation is produced by applying an external pressure in a consolidation test, and the magnitude of the capillary pressure acting at any stage can be determined, inasmuch as a certain stress must be associated with a certain strain for the given material. Shrinkage is really a compression of the clay under capillary forces. At the shrinkage limit, the resistance to further compression exceeds the maximum value of the capillary pressure that can be developed. Further evaporation merely causes the soil to dry out and causes air to enter the voids. Sufficient water (which cannot be completely evaporated at ordinary temperatures) remains in the soil as very fine capillary films to maintain this final stress condition, which may exceed 200 kg per sq cm.

If a series of clay specimens is prepared for unconfined compression tests—the first being tested immediately and the remainder tested at increasing intervals of time so that the water lost by slow evaporation produces approximately equal changes in water content and therefore in density—the strength of the specimens will show a regular increase with the increase in density. It may be properly reasoned, therefore, that cohesion is not an inherent, single-valued property of clays, as frequently thought, but is a function of density or water content. The really significant fact, however, is that the strength, and hence the cohesion, is a function of the initial stress conditions imposed on the specimen, whatever the source. Identical results would be obtained by preconsolidating each specimen under a series of increasing external pressures and permitting equilibrium to be reached by free drainage of the excess pore water. As soon as the specimen is removed from the consolidating device to be tested in unconfined compression, capillary forces will replace the external pressures, because only a very slight expansion is necessary.

In a natural deposit, the initial stress imposed by the action of capillary forces will be defined by Eq. 30 and will range between an isotropic state of stress when Poisson's ratio equals 0.5 and a ratio of the horizontal stresses to the vertical stresses of 0.667 when Possion's ratio equals 0.40. In some deposits of clays the material has been consolidated under much greater pressures than those imposed by the present overburden. In nature the initial state of stress is maintained under such conditions because of the impermeable nature of the clay, which does not readily permit absorption of water and hence volume increase, and because of the relatively small vertical expansion associated with the reduction of the vertical stress to that imposed by the present overburden.

Therefore, the most significant fact about natural clay deposits is their initial stress condition, regardless of the source. It should be clear that, from the standpoint of the initial stress conditions, the new technique of imposing an "equivalent cohesion," or rather an initial stress condition, is a most valuable contribution for investigating and studying the field of stress, displacement, and failure phenomena in soils. The influence of the size of the mass of soil involved in the displacements or in failure cannot be learned from a small-scale model, but the model does give an insight into the mechanics of the phenomena and a better understanding of the stress displacement relationships and of the conditions leading to failure.

The second concept is that of plasticity, as a distinctive clay quality, which may be defined as the capacity to be deformed continuously under the action of a constant shearing stress without appreciable volume change. This quality is due primarily to the colloidal scale-like character of the true clay minerals, and to the very impervious nature of clay. On the other hand, fine sand and silt are not plastic, because if a ball of the moist soil is shaken in the hand, the surface becomes wet and shiny, indicating a densification and a much more pervious character. If the ball is squeezed between the thumb and forefinger, the surface dries and water is sucked into the ball by the expansion of the soil under such action. In such a material the initial stress condition can change during deformations, because the stress in the pore water changes, becoming a positive hydrostatic stress with a compression and a negative stress or tension with a tendency for expansion. In clays, with their characteristic qualities and impervious nature, the initial stress condition is maintained unless the rate of deformation is exceedingly slow so that volume changes may occur. The dry sand model test with an imposed initial stress condition conforms more closely to the situation for a saturated clay than for a saturated fine sand or silt, particularly if Coulomb's equation for the shearing strength of clay—

$$S = c + N \tan \phi \ldots\ldots\ldots\ldots (31)$$

—can be considered to apply reasonably well. The chief difference is the magnitude of the angle of friction, ϕ, of clay, if such a factor exists for clays. The ratio of the horizontal to vertical stresses will be somewhat different, being of the order of from 0.667 to 0.875 for clay and of from 0.25 to 0.50 for sand.

As noted previously, plasticity is a distinctive characteristic of clay. Viscous or fluid flow is characteristic of liquids and suspensions and depends on only one property of the liquid, as expressed by

$$v \approx \frac{F}{\eta} \ldots\ldots\ldots\ldots (32)$$

in which v is the velocity of flow; F is the force or head causing the flow; and η is the viscosity of the liquid or suspension. Plastic flow is basically different in one important respect. Bingham's[21] law states that plastic flow depends on two properties of the plastic material, such that

$$v \approx \frac{F - F_o}{\lambda} \ldots\ldots\ldots\ldots (33)$$

in which F_o is the yield value of the material, and λ is its consistency.

In viscous flow no static equilibrium is possible even under the slightest pressure or head. The significant fact about plastic flow is that, for stresses below the yield value, static equilibrium is possible and plastic flow or yielding ceases in time. If it were not for this important fact, it would be impossible to found any structure on clay. Below the yield value the flow is in the nature of a very slow plastic creep, which in most cases ceases after a time; above the yield value plastic flow can take place indefinitely at a constant rate under a constant shearing force and without appreciable volume change. The magnitude of the yield value is determined by the initial stress condition imposed on the clay at some time in its geologic history.

The third concept is that of the plastic state. It is necessary to differentiate clearly between plasticity as a clay-like quality (as previously defined), and the plastic state defined as a definite state of stress in the theory of plasticity without regard to the nature or the kind of material involved. A region can be said to have reached the plastic state when everywhere within the region the shearing stresses have become equal to the shearing strength of the material. This condition of plasticity has been expressed mathematically in Eq. 4, where the maximum shearing stress has become equal to the maximum shearing strength or cohesion, *c*. The maximum shearing stress can become equal to but cannot exceed the shearing strength of the material. This means that the plastic zone must spread to areas having a reserve of shearing strength until the total shearing load is carried—if such a condition is possible. In clays there will be a zone in which Eq. 4, the law of plastic flow, applies, and the failure will proceed essentially without volume change. In sands it is conceivable that flow failure may occur if a volume decrease occurs during the failure and the failure can take place rapidly.

Certain significant facts are shown in Figs. 3 and 4, and three regions may be defined. Above the final slip line is a plastic region in which the shearing stresses have become equal to the shearing strength. Below this is a transition zone, in which relatively large displacements have occurred, but below values required to mobilize the full shearing strength. Below this transition zone is an elastic zone, in which deformations are insignificant. Fig. 4 shows that, as the initial stress is increased, the angle of slope at failure being related to this initial stress through Fig. 2, the phenomenon changes from an essentially superficial one typical of cohesionless sand under very low values of the initial stress to one which is typical of the deep-seated character associated with slides in clays. The final sliding curve in each case appears to be localized at a definite depth, depending on the magnitude of the initial stress. The phenomenon shown in Fig. 3 is typical of the "toe failure slides," wherein the horizontal bottom of the excavation is at the level of the toe, or where a slide occurs in a weaker material in a bank. Usually this weaker soil is underlain by a higher strength material which limits the failure curve to the interface between the two materials. The phenomenon associated with a lubricated base (Fig. 9) is of interest because a number of rolled earth dams, built on foundations containing a plastic clay layer relatively near the surface, have shown considerable lateral movement during construction.

It is also significant to note that in the plasticity theory developed by the author the existence of an initial stress condition is an essential condition for deep-seated sliding failure curves, as shown in Fig. 12, and that the surface of the upper part of the slope is in tension (above point 3 in Fig. 12(*a*) and above point 5 in Fig. 12(*b*)). A fact of great practical importance is that failure is imminent when the strain in the embankment exceeds a certain rather definite limiting value for the given material. This is a consequence not only of the stress deformation characteristics of the soil, but also of the progressive failure phenomena due to the actual distribution of shearing stresses within an embankment and to the spreading of the plastic zone. These factors, together with the concentration of shearing stresses in the middle area of the rigid base (see Fig. 9), may account for the wave pattern in the shearing strain (Fig. 5) and the corresponding stress pattern (Fig. 9), which are associated phenomena. In clays the phenomenon of progressive failure is likely to be more important than in sands (except in the dense state), because the stress-strain curves of clays usually show a characteristic large decrease in shearing strength after the maximum strength has been reached, when the test is made by strain control methods. This decrease in shearing strength is the result of disturbance effects resembling strain softening.

The fourth concept is that strains in soils and the stress conditions for failure depend exclusively on effective stresses, as stated by K. Terzaghi,[41] M. ASCE. The total stresses in a saturated soil consist of two parts. One part is the effective stress, which acts in the grain structure of the soil and causes compression; the other is the pressure in the pore water, which may be greater (or less) than the natural hydrostatic pressure, and even negative, depending on conditions. The shearing resistance that can be mobilized in a soil mass under any given circumstances depends only on the effective stresses. A change in stress in a saturated soil is always associated with a tendency toward change in its water content or volume of voids. If the soil tends to compress during shearing and the loading is rapid enough so that the water cannot escape within that short period, positive hydrostatic stresses are induced in the pore water in excess of the natural hydrostatic pressure. As a consequence, part of the load on a potential plane of shearing is carried by positive pore water pressures. The shearing resistance of the soil is then expressed by—

$$S = (N - u) \tan \phi \qquad (34)$$

in which N is the total normal pressure acting on the potential surface or rupture or sliding; u is the pore water pressure (positive or negative excess over the natural hydrostatic pressure); $(N - u)$ is the effective stress (less than N, if u is positive and greater than N, if u is negative); and ϕ is the angle of friction.

The value of the pore water pressure, whether positive or negative, depends not only on the nature of the soil and its initial state with respect to density and to stress, but also on the rate of stress application, the permeability of the soil, and the size of the soil mass involved. The influence of the mass of soil involved in the displacement, or in the failure, cannot be learned from a small-scale model because the effect of mass in such phenomena primarily concerns the effective stresses acting throughout the mass. These stresses are determined as to distribution and magnitude by the drainage conditions and by the pore water pressures. The magnitude and distribution of the pore water pressures, whether positive or negative, depend not only on the initial density of the soil with respect to the critical density (the original concept stated by A. Casagrande,[43] M. ASCE), but also on the pressure on the potential sliding surface with respect to the pressure which is critical for the soil in the given density state (an extension of the original concept). Wherever the soil stresses are less than this critical pressure, the soil will tend to expand during shearing and the effective stress in Eq. 34, since u is negative, will be greater than the applied normal stresses. Thus, the soil will have greater shearing resistance if failure by a rapid slide is a possibility. Otherwise the failure will occur slowly, if at all, after the pore water pressures are relieved by drainage. On the other hand, whenever the stresses are greater than the critical value, failure is imminent, because the soil will tend to compress during shearing, and thus will induce positive pore water pressures. The effective stress in Eq. 34 will be considerably less than the applied normal pore water pressure stresses. It is probable that in a large structure certain regions may be in the critical state whereas adjacent regions are not, because in these adjacent regions the pressures are less than the critical. It is evident that a small-scale model can give no information on this phenomenon, because the stress conditions for the critical state cannot be satisfied, either relatively or as to distribution. These stability conditions are primarily a matter of laboratory determination of the shearing strength characteristics of the soils involved and of analytical analyses of the stability conditions. The only check is the behavior of full-scale structures. The small-scale model test on dry sand with controlled initial stress conditions does, however, give a valuable insight into the mechanics of the phenomenon and a better understanding of the stress displacement relationships and of the conditions leading to failure.

EK-KHOO TAN,[44] JUN. ASCE.—The writer is grateful for the discussions of his paper and for the interest shown in this subject. Mr. Feld's remarks on the concept of plasticity and failure of soil slopes are appreciated as they lead to a better understanding of the basic phenomenon. The writer has attempted to show by a small-scale sand model the possibility of sliding failure. The purpose of the tests is to acquire an insight into the actual mechanics of failure of large soil masses by slides. The present method of analysis is to assume a failure curve and then to calculate the factor of safety. If a plastic condition is initiated at any region in a soil slope that is overstressed locally and the region of overstress is allowed to spread, a progressive failure will eventually take place. Therefore, the factor to be considered in the design of slope, it seems, is to avoid regions of stress concentration.

Mr. Feld states that not all soils showing the superficial phenomenon are totally lacking in cohesion. The tests show that for cohesionless materials the failure could not be a deep-seated one, but is essentially a surface one. It does not preclude the case of surface movement of cohesive material where no deep-seated mass movement results in a slide.

---

[43] "Characteristics of Cohesionless Soils Affecting the Stability of Slopes and Earth Fills," by A. Casagrande, *Journal*, Boston Soc. of Civ. Engrs., Vol. 23, 1936, p. 13.

[44] Shanghai, China.

In commenting on Fig. 2, Mr. Feld states that it would be more logical to extend the graphs for the loose and dense states to meet at 36°. At very low values of the vacuum, however, the restraining effect of the rubber membrane becomes rather important. It shifts the lines of failure for the loose and dense states parallel to themselves from an angle of repose of 36° maximum at actual zero equivalent cohesion to their positions shown in Fig. 2. The restraint effects are thus of the order of a vacuum of 0.55 in. of water, or 3 lb per sq ft, which represents an equivalent cohesion of 1.95 lb per sq ft.

Both Messrs. Baumann and Hirashima state that soil slope failure basically is due to pore water pressure. The writer agrees that this is an important factor contributing to failure of soil slopes. The pore water pressures developed in any given case will depend on the initial density and on the magnitude of the minor principal stress in relation to the critical values, which may vary from point to point in the mass of soil undergoing shearing deformations. The pore water pressure, conceivably, can be either positive or negative, depending on whether the soil tends to compress or to expand during shearing. Such relationships can only be studied in carefully controlled triaxial compression tests, in which the phenomena can be assumed to be sensibly uniform and homogeneous throughout the soil specimen. Introducing moisture conditions in the model studies would unduly complicate the situation. It was apparent that any attempt to simulate such phenomena in a model was impractical. Many more uncontrollable conditions also would be introduced, such as a lack of homogeneity, uniform density, and uniform moisture content; unknown failure conditions; and difficulty in obtaining actual failures in such models.

Mr. Baumann suggests the use of soil cement mixtures. Such a model would have to be a full-scale model, because the forces involved in the model used are relatively small, a vacuum of 1 in. of water representing an equivalent cohesion of only 3.4 lb per sq ft. Mr. Baumann also suggests that centrifuge methods would simulate cohesion better. It is obvious, however, that if the gravity forces are increased in a certain ratio the shearing resistance that can be mobilized is also increased in exactly the same ratio. Hence, if the slope were stable before centrifuging, it would remain stable during such a test at any increase in the mass or gravitational forces, excepting only if the model were tilted during the operation.

To overcome all the various difficulties, and to limit the number of variables, this new technique was developed by introducing an equivalent cohesion. Dry sand was used throughout all the tests. The sieve analysis of the sand used is:

Sieve No.	Percentage finer by weight
4	100
8	90
16	76
30	54
50	28
100	9
200	0

The maximum density was 116 lb per cu ft and the minimum, 99 lb per cu ft. The loose state used in the tests had a density of about 100 lb per cu ft and the dense state, one of about 110 lb per cu ft. The angle of friction in the loose state by shearing tests was 33°; in the dense state this angle was 41°.

As Mr. Feld points out, cohesion is a very complicated phenomenon taking into consideration the size of soil particles, intermolecular attraction, and capillarity of moisture films, as well as the interplay of dissimilar materials in intimate contact. The experiments on the soil slopes were set up to permit a study of the influence of varying, equivalent cohesive strength in an ideal soil and to avoid all uncontrollable factors.

Messrs. Baumann and Buckingham suggest that the discrepancy in the analysis by the use of the Swedish circular arc method may be due to the fact that the angle of repose (33°) was used as the angle of internal friction. The angles of internal friction of some sands may vary between 27° for a loose state and 45° for a dense state. The 33° angle used in the computation was taken to be the average consistent with the density of the model sand, which was slightly above the loosest possible state. Tests on gelatin models indicate that the stress pattern in a soil slope is rather different from that assumed in the Swedish circular arc method of analysis. This conventional method is essentially one dealing with averages along the whole failure curve. The experiments have shown that failure is initiated through a local concentration of stresses. Spread of this concentration thus produces a slide.

Professor Tschebotarioff points out the importance of boundary conditions in the distribution of stresses within a soil mass. This is of particular importance when the soil mass is subjected to external applied pressure. The writer agrees with Professor Tschebotarioff that the rigid boundary as used in the test on gelatin models has an influence on the stress distribution of the model.

Mr. Buckingham stresses an important concept—that for clay deposits whose moisture content is prevented from escaping, thereby making consolidation of the deposit impossible, failure may take place when the deposit is subjected to a superimposed load. It is true that in such cases the laboratory shear test employed should approximate conditions in the field, and the quick unconsolidated shear test results should be employed.

Mr. Hirashima asks that additional data be supplied to make possible a comparison between the experimental and theoretical determination of the maximum height of the unsupported bank of cohesive soil that will stand vertically. The formula for the theoretical determination should read

$$H = \frac{4\,c}{w} \tan\left(45 + \frac{\phi}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

The restraining effect of the rubber membrane was found to be rather large. The curve for the loose state in Fig. 6 should be a straight line through the origin, approximately parallel to the experimental line. By producing the experimental line to the vertical axis, the effect of the restraint can be estimated to be approximately equivalent to 4 in. of height. Introducing the values of the unit weight and of the angle of friction into Eq. 35, and deducting the 4 in. gives values within the order of magnitude to be expected.

EXPERIMENTAL OBSERVATIONS ON GROUTING SANDS AND GRAVELS

By Alfred Machis,[1] Jun. ASCE

With Discussion by Messrs. James B. Hays, William S. Foster, Frederick J. Smith, and Alfred Machis.

Synopsis

The laboratory research reported in this paper was conducted to provide data on the use of cement slurries to prevent the contamination of water wells. The initial impetus for this investigation was the acute situation resulting from the infiltration of salt water into wells that threatened, severely, the quality of the Baltimore, Md., underground waters.

A water-bearing formation may be contaminated by salt water in one of two ways. If the formation has an outcrop under the sea, the sea may move into the formation when excessive pumping reduces the internal pressure. Such a situation may exist in some parts of the upper aquifers of the Baltimore industrial area. However, there is no way in which this condition may be alleviated by the use of cement. Many industries which originally had wells in these formations abandoned them and drove new wells tapping deeper fresh-water strata.

In many instances the new wells also became contaminated by salt water and the question then arose as to how the salt water entered the new formations. Investigation revealed that in general the deeper formations were not receiving salt water directly from the sea but were being contaminated chiefly by salt water leaking down between the well casing and the drilled hole from the upper strata. This leakage may at first seem impossible since almost all wells are drilled through clay beds. However, it has been shown by the use of caliper logs that the actual diameter of a drilled well usually is considerably larger than the diameter of the bit. Therefore, the reason why leakage does occur down the outside of a casing set into such a hole should be obvious. In some instances this leakage occurs in the same well that is producing the water; in other cases, it may occur in some distant well, often an abandoned one, and

[1] Formerly 1st. Lt., Corps of Engrs., U. S. Army, Baltimore, Md.

may then pass into the producing formation. For cases of leakage around the outside of the well casing, grouting may be used to prevent further deterioration of water quality.

The seriousness of the situation was emphasized in 1944 by John C. Geyer,[2] Assoc. M. ASCE. In some instances the wells were producing water with a salt content as high as 3,000 ppm whereas other wells in the same formation contained only from 8 ppm to 12 ppm of salt.

The problem cannot be solved by abandoning (without sealing) the contaminated wells and drilling new ones. The capital investment in the average well of this region is about $15,000. On the other hand, a well may be repaired successfully in most cases for less than 10% of $15,000. In this light it becomes difficult to justify the extra expenditure of drilling a new well; and, in addition, an abandoned well that has not been properly sealed is a greater hazard to the area as a whole than is the same well when it is being pumped. In the latter case the well may serve to contaminate all the lower fresh-water formations by acting as an open conduit between the strata. In fact such cases as this do exist and are increasing materially the difficulty of solving the salt-water contamination problem.

Grouting New Casing

Many methods may be used to grout new casing into a well. Essentially, however, all these methods fall into one of the three main classes known as bailer, tubing, or casing methods. In each method the cement mixture commonly employed is a "neat" proportion of water and cement without any addition of sand. This mixture is also variously referred to as "cement slurry" or "cement grout." In all cases, the cement is mixed with the desired proportion of water before it is allowed to pass into the well.

Dump Bailer Method of Cementing.—In the dump bailer method, the slurry is lowered to the bottom of the well in a cylindrical container and is emptied through a foot valve. This method of cementing is too limited in its scope and, therefore, has been superseded by improved methods.

Tubing Method of Cementing.—In the tubing method of cementing, the slurry is pumped into the bottom of the well through a tube down the center of the well. Since the cement must be forced out around the outside of the casing, it is obvious that there must be a free passage for the entire length of the casing. This condition is usually insured by establishing the free circulation of water down around the casing shoe and up to the surface.[3]

Casing Method of Cementing.—In this method of cementing, the slurry is pumped directly through the casing down to the bottom of the well. The slurry is usually enclosed between two moving plugs to keep it from becoming diluted or contaminated.[4]

[4] *Ibid.*, plate facing p. 48.

Repair of Leaking Wells

The repair of a leaking well is a much more difficult problem than the grouting of a new casing. Where possible, the casing of a leaking well should be pulled and the well should be grouted in the same manner as a new well. This is seldom possible, however, because the casing will usually be tightly bound by cavings of the earth wall. For this same reason, it may also be impossible to establish a circulation of water or mud around the outside of the casing. For such a circumstance the method of "squeeze cementing" developed in the oil industry must be applied. "Squeeze cementing" is the name applied to a process whereby the cement slurry is forced into, or against, a formation through perforations in the casing. The method is very similar to the tubing method of cementing except that the slurry is forced directly against the salt-water formation instead of down around the casing shoe. The highly successful utilization of this process in the oil well industry warrants close study for possible adaptation to the water well industry.

Sealing Abandoned Wells

The sealing of wells which are to be abandoned is highly essential to prevent them from acting as open conductors between fresh and contaminated water-bearing formations. It is first necessary to pull all casing that is not too securely bound in the formation. The remaining sections must then be completely slotted or perforated so that the slurry can enter behind them at many points, thus insuring the complete filling of all cavities and channels behind the casing. The previous practice of simply filling the inside of the casing has shown itself to be insufficient, for leakage may still follow a path down the outside.

After the casing has been removed or perforated, a process similar to squeeze cementing may be used to seal the well. The hole should be grouted by progressive stages from bottom to top. An attempt made to seal the entire well in one operation without raising the outlet of the grout tube may cause the grout pipe to stick and thus make a failure of the job.

Cement Penetration Through Sands

In determining what happens to the grout that is pumped into a well, the first question that must be answered pertains to the penetration of the cement grout through the sand strata. Thus, with a given sand formation, may the grout be expected to remain in the hole or will it pass into the pores of the sand and away from the well?

In addition to solving the problem of the water well industry, such data should also be valuable in shedding light on the problems of shutting off water leakage through earth dams, levees, railroad embankments, foundations, etc. In the water well industry the problem is to prevent the excessive loss of slurry into the formation; but, in these other cases, the problem is to find the best method of forcing the grout into the pores of the sand so as to form an impermeable wall.

Materials.—The type of cement used may be a factor in determining the quantity of slurry that will pass into the formation. There are three general grades from which a cement may be chosen—high early strength, regular Portland, or special oil well cement. For this work, a Portland cement was chosen since it is the type most often used.

The characteristics of the sand used will also have an effect upon the penetration of the slurry into the sand. It is easy to understand that a sand with large pores will readily admit the passage of cement slurry whereas a sand with pores smaller than the cement grains will not pass any of the slurry. By considering the pore size and shape together as a single quality of the sand, a measure of this quality may be obtained in the expression of the sand permeability. To secure a wide range of permeabilities, sands of uniform size were used in this work. The permeabilities of all the samples are given in a subsequent section of this paper. Since an expression of the permeability completely defines the hydraulic characteristics of the sand, natural formations with the same permeabilities should react to cement penetration in the same manner as the laboratory samples.

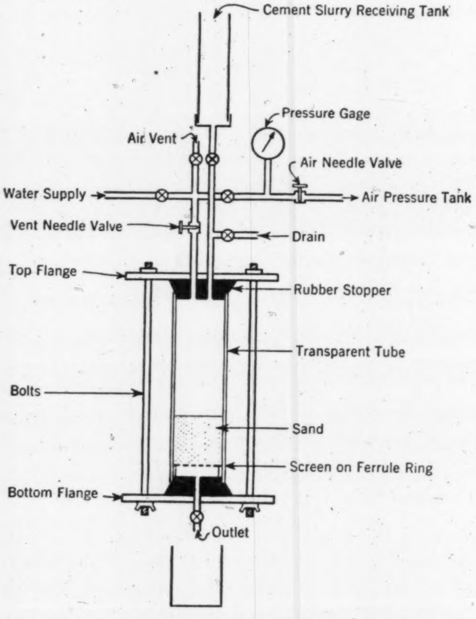

FIG. 1.—SCHEMATIC DIAGRAM OF CEMENT SLURRY PENETRATION APPARATUS

Other Factors Affecting Penetration.—In addition to the type of sand and cement used, the factors of temperature and pressure may change the properties of the cement slurry and, therefore, also may affect the penetration of the slurry into the sand. In work done by R. Floyd Farris,[6] a number of cements were tested at various temperatures and pressures to determine the effect of these factors on the change of consistency with time. From an examination of the study it appears that, in cementing water wells, the temperature and pressure effects probably will not be of any significance.

---

[6] "Effects of Temperature and Pressure on Rheological Properties of Cement Slurries," by R. F. Farris, *Transactions*, A.I.M.M.E., Vol. 142, 1941, p. 117.

Apparatus.—The apparatus, shown in Fig. 1, used in this investigation, consisted of a transparent tube of glass or plastic which contained the sand sample being tested. The tubes used were 1½ in. in diameter and from 7 in. to 11 in. long. The sand was supported within the tube by a wire cloth soldered to a ferrule ring. Rubber stoppers, used as gaskets in the ends of the tubing, were squeezed tightly between two steel flanges by four long bolts. The flanges were drilled and tapped at the three points shown, to receive ¼-in. steel pipe.

Procedure.—The sand sample to be tested was weighed and poured into the transparent tube. The best procedure for removing all air completely from the sand was to immerse the tube in a beaker of water and to allow the water to rise slowly from the bottom of the sand. The transparent tube was placed in the apparatus and the excess water was allowed to flow out until the meniscus was just at the top of the sand. The sand was vibrated to compact it by tapping the bottom flange with a rubber hammer.

The porosity of each sample was determined by measuring the height of the sample and computing the porosity from the volume and specific gravity of the sand. The cement and water were proportioned to give the desired consistency and mixed. The slurry was poured into the receiving tank from which it could be added to the transparent tube. A fresh slurry was used for each run.

[a] Gallons of water per sack of cement; in the text referred to as "6-gal slurry," etc. [b] Pounds per square inch. [c] Percentage of dry cement (by weight) that passed the testing apparatus. [d] Ratio of final volume to initial volume of slurry. [e] Test was stopped before the slurry passed through. [f] Pressure was applied slowly. [g] Apparatus clogged; test incomplete.

After the slurry had been placed, the desired pressure was admitted from an air pressure tank, and the outlet valve was opened. The slurry that passed through the sand was caught and dewatered by boiling. In this manner the weight of dry cement that passed could be determined. The initial weight of dry cement added to the sand was computed from the volume and specific weight of the slurry.

To study the effect of the foregoing method of applying the pressure suddenly, some data were also taken, using a slow application of pressure—first by opening the outlet valve and then by slowly applying the pressure. A distinct difference in results was obtained.

Data and Discussion of Results.—The data on the penetration of a cement slurry through a sand are presented in Table 1. The sand size is given as the mesh of the screen through which the sand will pass and the mesh upon which it will be retained. Mesh sizes, in millimeters, for the standard Tyler sieves are given in parentheses in Table 1.

Effect of Squeeze Pressure.—When a sand sample of a grain size smaller than 28 mesh (0.589 mm) is used, no amount of pressure will make a slurry pass through the sand. Slurries as dilute as 14.5 gal of water per sack of cement (hereinafter called "14.5-gal slurry," etc) were tested, and the results showed that the cement particles would penetrate into the sand only about three or four grain diameters before they lodged in a restricted pore. The pressure then acted only to squeeze the water from the slurry so that in a few minutes it was possible to reduce a 14.5-gal slurry to a 4-gal or 5-gal slurry. A pressure of 1,000 lb per sq in. was used to test this principle and was found to give exactly the same results as a pressure of 10 lb per sq in. The only difference was that the higher pressures squeezed the water from the slurry more rapidly.

When grain sizes greater than 28 mesh are used, the pressure becomes a more important factor. In this case some slurry can be expected to pass through the sand, and the amount passed will depend on how the pressure is applied. With a given slurry and a given sand, a large quantity of slurry may be made to pass through the apparatus by applying a high pressure very rapidly. This procedure was followed in all the tests in which the percentage of dry cement passed was measured, except the four tests given in lines 2, 4, 7, and 10 of Table 1(*b*) (see footnote[f]). In the first three cases mentioned, a pressure up to 30 lb per sq in. was applied at a rate of about 3 lb per sec. In each case the cement particles ceased to pass through before the full 30 lb per sq in. was reached and any additional pressure simply caused the water in the slurry to filter out more rapidly. In the last case about half of this rate of pressure application was used, and a smaller percentage of slurry was passed than was in the other three tests. This condition held in spite of the fact the slurry was more dilute—a factor more conducive to the passage of cement particles.

A comparison of these four tests with the other tests on the same sand where the full pressure application was instantaneous (less than 1 sec) shows that in the latter case the percentage of cement passed is considerably greater. For example, a comparison of lines 4 and 5, Table 1(*b*), each on an 8-gal slurry, shows that a rapid pressure application will cause the weight of dry cement passed to increase from 31% to 95%.

The main reason why this difference in penetration occurs with increased rate of pressure application is probably that, when a cement slurry is allowed to stand quiescent for a few moments, it will thicken. If violently stirred, the slurry will return to its initial thin concentration. It is very probable that the sudden application of pressure causes a violent surge of the lower layer of slurry which destroys the gelling properties. With the fluidity thus increased, the slurry does not bridge across the sand grains and easily passes into the sand.

Effect of Porosity.—A change in porosity of any given sand will serve to change the size of the pore in the sand and, of course, the amount of slurry which will pass through; but a better method of measuring the effect of a change in pore size can be obtained by changing the sand size. For this reason, an attempt was made to compact each sand into as stable a condition as possible and to maintain the same porosity in each test.

Effect of Core Length.—An examination of Col. 5, Table 1 (which gives the ratio between the final volume of the slurry after all the water has been squeezed from it and the initial volume), will show that the cement may be made to filter even on the coarse (4-mesh to 8-mesh) sand. The plug left on the sand is not the result of an inability of the cement particles to move through the pores of the sand, for observation through the glass sample tube shows that the particles in the pores are continually being washed out by the water filtering from the plug above. Instead, this cement plug is caused by an inability of the cement particles to enter the pores as a result of a strong tendency of the cement to bridge across the sand grains. This bridging has sufficient strength to support the cement particles so that the pressure on the slurry simply forces the water out and leaves a solid cement core. Since this filtering depends only on the action at the sand-cement interface, the length of the core has no effect in the results of the penetration tests.

By comparing the results of Col. 5, Table 1, the amount of slurry that will pass into the sand may be appraised. However, in comparing the results of tests using different consistencies of slurries, allowance must be made for shrinkage that would take place because of the loss of the excess water. To facilitate this comparison, tests on shrinkage of the cement slurry are reported in a following section. In addition to this information, the weight of dry cement that passed through the apparatus, computed as a percentage of the cement in the initial slurry volume, is also given in Col. 4, Table 1. These values would be affected to some degree by the void volume of the sample. With the more dilute slurries, the proportion retained in the pores after the sand was blown out with compressed air would be negligible. With the thick slurries, more would be retained in the pores of the sand; but, even then, the values of Col. 4 would be affected only by a slight percentage.

Effect of Sand Size and Slurry Concentration.—The sand size and the slurry concentration are two factors which have a very marked influence on the percentage of slurry passing into the sand. The large sand sizes give large pore sizes into which the grout may pass readily. When the cement is mixed with a large amount of water to give a thin slurry, the cement particles are too dispersed to bridge across the pore and so are carried into the sand. This bridging of cement particles is increased if the slurry is allowed to remain quiescent above the sand for several minutes.

To aid in giving a better description of the appearance of a grouted sand formation, photographs of a number of the samples were taken. In each instance the squeezing was stopped just before the air blew the cement out of the pores of the sand. The reason for this was to show the appearance of the sand as it would look if it were in a well that had been grouted by one of the methods previously described. The samples shown were removed from the tube and allowed to set. Part of the core was then cut away to show the interior of the sand and slurry. The bar above the letter $\overline{\text{C}}$ in Fig. 2 is used to indicate the sand-cement interface so that the part of the core below the letter $\overline{\text{C}}$ is the grout used to fill the section between the casing and the sand formation. The core section above the letter $\overline{\text{C}}$ is the sand formation penetrated by the grout. Each division on the scale beside the core is 1 mm so that the size of the core is apparent.

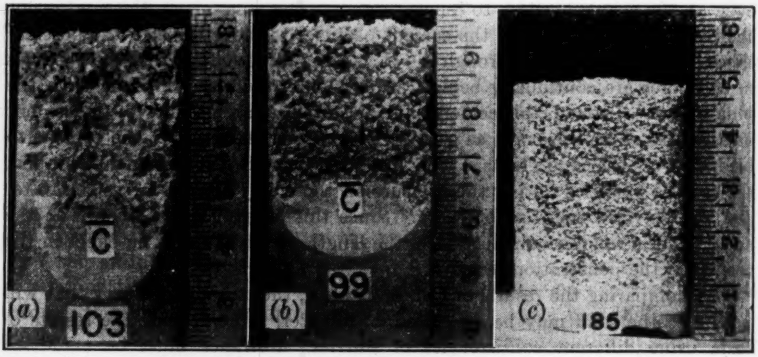

FIG. 2.—RELATIVE TEXTURE OF CORE SPECIMENS GROUTED BY SLURRY

(a) No. 8 to No. 10 Sand and 6-Gal Slurry
(b) No. 14 to No. 16 Sand and 8-Gal Slurry
(c) No. 20 to No. 28 Sand and 20-Gal Slurry

Fig. 2(*a*) shows an 8-mesh to 10-mesh sand grounted with a 6-gal slurry. The slurry has penetrated all the pores, forming a strong solid concrete. The slurry column that has not penetrated the sand has had all the excess water squeezed from it so that it is in its densest and most compact condition. The slurry columns that do not penetrate the sand can always be made to compact into this dense condition regardless of the initial water content.

Fig. 2(*b*) shows a 14-mesh to 16-mesh sand core grouted by an 8-gal slurry The pores of the sand have become too small to allow the slurry to pass a sufficient percentage of cement to fill the pores completely. In contrast to this case, a 9-gal slurry will pass about 80% of the initial dry weight of cement, and a 14.5-gal slurry will pass 100% of the cement—emphasizing the importance of the slurry concentration on penetration as the pore size decreases.

Fig. 2(*c*) shows a 20-mesh to 28-mesh sand grouted with a 20-gal slurry. About 50% of dry cement passed through the sand but the concentration within the pores of the sand was rather low. This sand was the finest into which any measurable quantity of slurry could be forced when slurries as dilute as 14.5 gal of water per sack of cement were used.

WEIGHT, VOLUME, AND SHRINKAGE OF CEMENT SLURRY

To make a comparison of the volume of slurry passing into the sand from the data of Col. 5, Table 1, it was necessary to know how much each slurry will decrease in volume as a result of the excess water in the mix. In addition to this information, it was also necessary to know the volume of the slurry per unit weight of cement in the mix to compute the amount of dry cement in the slurry above the sand prior to squeezing. To secure these data, a weighed quantity of cement and a measured quantity of water were mixed in a chemical graduate and the resultant volume was found. The results were then converted to cubic feet of slurry per 94-lb sack of cement; and these values were plotted as ordinates with the values of gallons of water per sack of cement as abscissas in Fig. 3. This curve may be considered sufficiently accurate for use on any brand of ordinary Portland cement. The values of the weight of a slurry in pounds per gallon of slurry would be of interest in field work to control the consistency of the slurry. Since a curve showing these values could be computed easily from the same data, it, too, is given in Fig. 3.

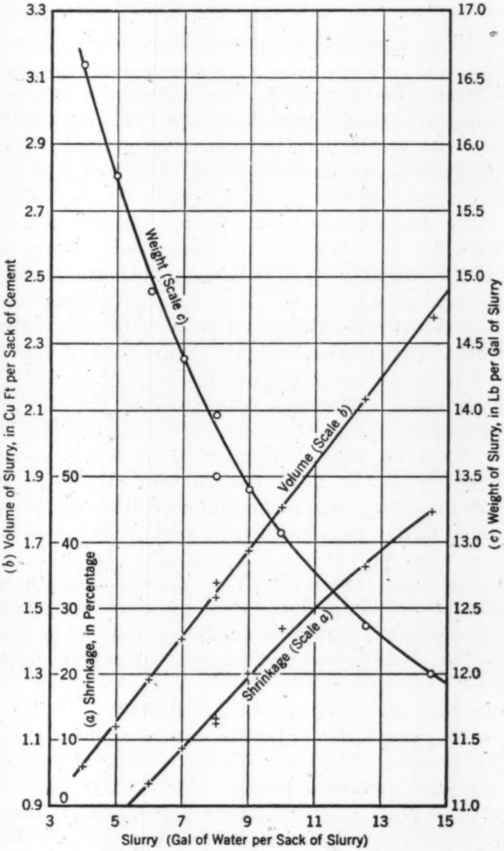

FIG. 3.—WEIGHT, VOLUME, AND SHRINKAGE OF CEMENT SLURRY

These slurries were then poured into test tubes about 5 in. high and allowed to stand for two days. The amount of shrinkage of each tube was measured and computed as a percentage of the initial height. These values also were plotted in Fig. 3. Extrapolation of this curve to zero shrinkage would give a 5.4-gal slurry—apparently containing just the amount of water necessary to hydrolyze the cement.

Sand Permeabilities

Under the heading, "Cement Penetration Through Sands: Materials," the reason why graded sands could be used to represent natural sand formations is given. For laboratory investigations this method of securing a wide range of characteristics is very convenient; but, to correlate these data on penetration with penetrations to be expected in natural sands, a better method than mesh size is necessary to describe the sand. Since the flow of slurry into a sand would depend on the hydraulic characteristics of the sand, the permeability would be the best property with which to correlate penetration. In truth, the penetration of a cement would depend on the ratio of the cement particle size to the sand pore size. However, the permeability is a measure of the sand pore size; and, since it is easy to determine, it is the most practical characteristic on which to base a correlation. From an academic point of view, the ratio of cement particle size to sand pore size is of interest; it is the key to further developments in the art of increasing or decreasing the cement penetration. Therefore, both qualities, the permeability and the sand pore size, were determined.

For most water-bearing sands, the simple variable-head apparatus of the type described by L. K. Wenzel, Assoc. M. ASCE, in 1942[6] will be found suitable for determining permeabilities. However, on this work sands were to be tested having permeabilities beyond the range of this instrument; and, therefore, a constant-head apparatus had to be used. A second important reason necessitating the use of a constant-head apparatus was that it furnished, with absolute certainty, data in the region of streamlined flow. To calculate the average size of pore from the flow of water through sand, Poiseuille's law may be used; but this law applies only to streamlined flow of fluids—not to turbulent flow. Consequently, it was necessary to find a way of determining whether the flow was streamlined or turbulent.

An examination of the literature shows that the well-known curve obtained by plotting the friction factor, calculated from Darcy's law, against the Reynolds number applies to flow through porous media as well as to flow through pipes. Several groups of investigators have worked on this same problem, Joseph Chalmers, D. B. Taliaferro, Jr., and E. L. Rawlins[7] obtained such a curve by computing the Reynolds number from the mean effective pore diameter. G. H. Fancher and J. A. Lewis[8] derived another curve of a similar shape by using the diameter of the average grain. With a knowledge of the mechanical analysis of the sand, the permeability and pore size, supposedly, could be computed from the latter curve.[8] Before this was done, however, the curve was transposed to the units used by Messrs. Chalmers, Taliaferro, and Rawlins. It was found that the two curves did not agree, and neither of the two curves could be used safely for the sand in these experiments. Nevertheless, the basic principle used by these investigators is sound; and, by obtaining such curves for the sands used in this work, the permeability and pore size of each sand could be computed.

---

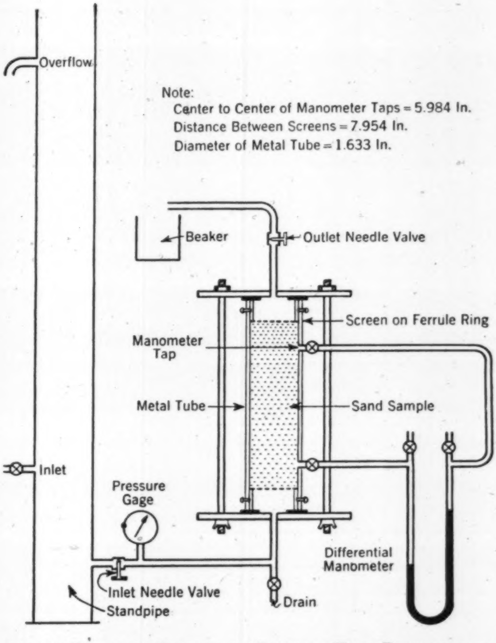
[6] "Methods for Determining Permeability of Water-Bearing Materials," by L. K. Wenzel, *Water Supply Paper No. 887*, U.S.G.S., U. S. Govt. Printing Office, Washington, D. C., 1942, p. 59.

[7] "Flow of Air and Gas Through Porous Media," by Joseph Chalmers, D. B. Taliaferro, Jr., and E. L. Rawlins, *Transactions*, A.I.M.M.E., Vol. 98, 1932, p. 388.

[8] "Flow of Simple Fluids Through Porous Materials," by G. H. Fancher and J. A. Lewis ,*Industria and Engineering Chemistry*, Vol. 25, 1933, p. 1145.

Apparatus.—To secure the data, the constant-head apparatus, shown in Fig. 4, consisting of a metal tube 12 in. long and 1.633 in. in diameter, was used. The sand sample was packed into this tube and was held in place by 65-mesh screens on ferrule rings placed at each end of the tube. Each ring was held in position by three sharp-pointed screws fitting into sharp-recessed holes. In this manner a constant volume could be secured easily for each sample. The tube was drilled and tapped for $\frac{1}{4}$-in. cone valves for manometer taps. The inner end of each tap was machined to the curvature of the tube, and wire cloth was soldered on to prevent the passage of sand. The final assembly of the taps was made carefully so that the wire cloth was flush with the tubing.

Procedure.—A weighed quantity of sand was placed in the tube and compacted by striking the tube with a hard rubber hammer. The quantity of sand added had to be just sufficient to support the top screen in its proper position. The screen could then be tightened in place. From the weight of sand, the specific gravity of the sand, and the volume of the container between the screens, the porosity of each sample could be computed.



Note:
Center to Center of Manometer Taps = 5.984 In.
Distance Between Screens = 7.954 In.
Diameter of Metal Tube = 1.633 In.

FIG. 4.—SCHEMATIC DIAGRAM OF CONSTANT-HEAD PERMEAMETER

After the standpipe was overflowing at a steady rate, water was admitted to the sand container very slowly so as not to trap any air bubbles.

An adjustment of the outlet needle valve allowed the desired rate of flow to be obtained and, at the same time, permitted the maximum possible pressure to be maintained within the tube. This maintenance of pressure within the tube reduced the possibility that the dissolved gases would separate from the water with a consequent air binding of the sand. The water passing out of the sand was timed and weighed to determine the rate of flow. The temperature of each run was measured to give the viscosity correction.

Notation.—The letter symbols in this paper defined where they first appear in the text, conform essentially with "Soil Mechanics Nomenclature" (ASCE *Manual of Engineering Practice No. 22*) and with American Standard Letter Symbols for Hydraulics (ASA—Z10.2—1942) prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942.

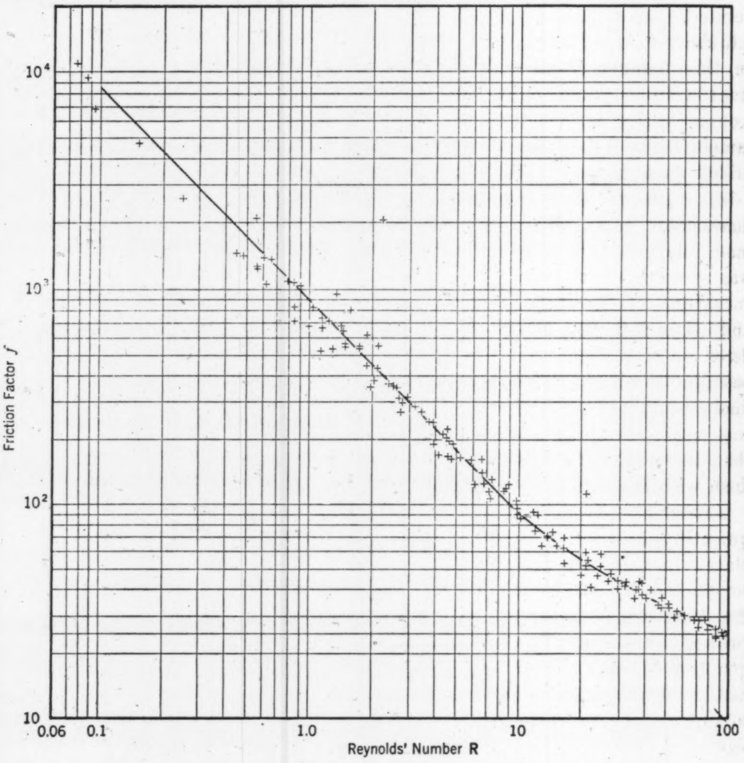


FIG. 5.—THE REYNOLDS NUMBER VERSUS FRICTION FACTOR

Data and Discussion of Results.—Six different sand sizes were tested and the value of the Reynolds number and the friction factor for each reading were computed. The plot of the two values on log-log paper gave a curve for each of the sands tested. However, all these curves were so close together that the average curve might well define them all. The plot of these two values is shown in Fig. 5.

The Reynolds number is defined as—

$$\mathbf{R} = \frac{D_g\, V\, \gamma}{\mu} \qquad \text{(1)}$$

—which is a pure number, so that any consistent set of units might well be used. If the English system is used, the values would be defined as: D_g is the diameter of the average sand grain, in feet; γ is the density of the fluid, in pounds per cubic foot; μ is the absolute viscosity, in pounds per foot per second; and V is the velocity of flow over the full area, in feet per second; that is:

$$V = \frac{B}{A_t\, t} \qquad \text{(2)}$$

in which B is the quantity of flow, in cubic feet; A_t is the cross-section area of the tube, in square feet; and t is time, in seconds. The friction factor, f, may be computed from the converted form of Darcy's law known as Fanning's formula, thus:

$$f = \frac{g\, D_g\, (p_1 - p_2)}{2\, L\, \gamma\, V^2} \qquad \text{(3)}$$

in which g is the acceleration of gravity, in feet per second per second;[9] $p_1 - p_2$ is the pressure loss due to friction, in pounds per square foot; and L is the length of core, in feet.

To determine the average grain diameter D_g, it was assumed that there was an even gradation of sizes between the two sieves used in the separation of the sand. The mean of the openings was found and used as the average grain diameter. In a case where a composite sand is used, the average grain diameter may be found by the method of Messrs. Fancher and Lewis using the formula:

$$D_g = \sqrt[3]{\frac{\sum (N\, D^3_s)}{\sum N}} = \sqrt{\frac{N_1\, D^3_{s1} + N_2\, D^3_{s2} + N_3\, D^3_{s3} + \cdots}{N_1 + N_2 + N_3 + \cdots}} \qquad \text{(4)}$$

In Eq. 4 D_s is the average diameter of the grain retained between two sieves and N is the number of such grains per gram. The values of N are given in Table 2 and were calculated from a sand density equal to 2.65 by assuming that the grains were spherical. Messrs. Fancher and Lewis proved the validity of this expression by actual microscopic count.

TABLE 2.—NUMBER OF GRAINS FOR ANY STANDARD TYLER SCREEN

Sand size (meshs per in.)	D_s, average diameter (cm)	Number (N) of grains per g
30 to 40	0.0442	8,230
40 to 50	0.0330	20,200
50 to 80	0.0227	61,900
80 to 100	0.0161	173,500
100 to 200	0.0111	530,000

Although it may at first appear incongruous to neglect the porosity completely in computing the velocity of flow (see Eq. 2), the method is found to give as good a correlation as the more complicated expression in which a porosity term is included in the velocity computation; thus:

$$V = \frac{B}{A_t\, t} \times \frac{1}{n} \qquad \text{(5)}$$

---

[9] "American Civil Engineers' Handbook," by Thaddeus Merriman and Thomas H. Wiggin, John Wiley & Sons, Inc., New York, N. Y., 5th Ed., 1941, p. 1323.

Furthermore, even the inclusion of the porosity in the calculation of the velocity would scarcely be more than an approximation of the true average velocity, for no exact method has yet been devised to measure the effect of the tortuous channel of flow or the effect of the many expansions and contractions.

When it became obvious that the curves for all sands could be represented by one line, it was no longer necessary to run tests on each sand. The permeability and pore size of any sand used in the tests on cementing could be computed from this curve.

In the region of streamlined flow the curve in Fig. 5 is a straight line with a slope of unity. When turbulent flow begins to occur, the curve gradually breaks away from the straight line. Since both the equation for permeability and the equation for pore size depend on measurements in the region of streamlined flow, only this part of the curve is of interest. A comparison between this curve and the one found by Messrs. Fancher and Lewis will show that the latter is somewhat higher in position. However, the curve found by the writer coincides (1) with the curve of T. H. Chilton and A. P. Colburn;[10] and (2) (when the data are converted to the proper units) with the curve of Messrs. Chalmers, Taliaferro, and Rawlins. An examination of the curve used by Messrs. Fancher and Lewis will show that there is a consistent difference in the friction factor which gives results exactly twice as large as those of the other workers. Thus, it appears that the difference may reflect an error in the computation of the friction factors by these writers.

TABLE 3.—SAND PERMEABILITIES AND PORE DIAMETERS

Sand size (meshes per in.) (1)	Average diameter (cm) (2)	Permeability (gal per day per sq ft) (3)	DIAMETER OF PORES (Cm)	
			Eq. 7 (4)	Corrected (5)
4 to 8.......	0.3531	127,200	0.0731	0.2535
8 to 10......	0.2007	41,400	0.0418	0.1452
10 to 14......	0.1410	18,800	0.02805	0.0972
14 to 16......	0.1080	12,100	0.02245	0.0778
16 to 20......	0.0912	8,500	0.0188	0.0652
20 to 28......	0.0711	5,200	0.01482	0.0514
28 to 30......	0.0546	3,050	0.01132	0.0392
30 to 40......	0.0442	2,015	0.00918	0.0318
40 to 50......	0.0330	1,125	0.00686	0.0238

The excellent agreement of results of data gathered by a number of different workers using widely varying granular materials and different types of apparatus indicates that this curve may be used to compute the permeability of various unconsolidated sands with a high degree of accuracy, merely from a mechanical analysis.

The permeabilities for the various mesh sizes of sand given in Table 3 were computed from velocity and pressure data taken to conform with the curve of Fig. 5. The coefficient of permeability k is given in units of gallons per day per square foot of area for a 100% gradient. All readings were adjusted to water at 60° F. To compute the coefficient of permeability, Darcy's law is used in the form:

$$k = \frac{\mu_t}{\mu_{60}} \frac{B}{A\,t\,(h/L)} \qquad \text{(6)}$$

---

[10] "Pressure Drop in Packed Tubes," by T. H. Chilton and A. P. Colburn, *Industrial and Engineering Chemistry*, Vol. 23, 1931, p. 913

in which μ_t is the absolute viscosity at the test temperature; μ_{60} is the absolute viscosity at 60° F; A is the total cross-sectional area of flow, in square feet; B is the volume of flow, in gallons; t is the time, in days; and h/L is the hydraulic gradient, in feet of water per foot of core length.

A comparison of the permeabilities of sand formations, secured from well logs with the permeabilities of Table 3, will give the equivalent sand size tested for cement penetration. On referring back to Table 1 for the data on the percentage of cement passed at various concentrations into this sand, the percentage of cement lost into the formation will be found. If the quantity lost is excessive, the slurry will have to be treated chemically to change the properties so that the loss may be reduced. On the other hand, if it is desired that the slurry penetrate into the sand as in the several cases previously described, the data will be of value in predicting the quantity of cement that will pass.

An idea of the range of permeabilities that may be expected in natural sands may be gathered from the paper by Mr. Wenzel:[6] Examples of sands tested show a range from 0.0002 gal to 90,000 gal per day.[11] The sand having a permeability of 90,000 was secured from a well on Long Island, New York, at a depth of about 200 ft. This high permeability is unusual, of course, but it is cited to show that such conditions may be encountered at times. Sands from wells at Salisbury, Md., with permeabilities from 252 to 1,190 are also reported by Mr. Wenzel. The author has tested several samples secured from outcrops in the vicinity of the Baltimore industrial area and has found sands with permeabilities of 1,000. Some samples taken from wells in the industrial area would have permeabilities of several thousand. One such sample was secured and tested to measure the passage of a 10-gal slurry. All the slurry passed through the sand readily. Whether this sample was representative of the sand in the well or whether its fines were washed off in the process of removal is unknown.

If highly permeable sands are encountered that might cause an excessive loss of cement, it would be necessary to find some method of plugging the pores. To attack the problem intelligently, it is first necessary to gain some idea of the magnitude of the pore opening. If the work of L. C. Graton and H. J. Fraser[12] is examined, it can be noted that the shape of a pore formed by spherical particles is far from a tubular opening. By systematic packing this shape may be varied to give a void ratio of from 26% to 48%. With natural sands, even more complex shapes may exist. Therefore, the only way to indicate the size of the pore is to compare it with the diameter of a capillary tube that has the same hydraulic characteristics as the sand pore—that is, with a straight tube which will pass the same amount of fluid with the same pressure loss as the tortuous path of the pore. Using the same data previously used to compute the permeabilities, the mean pore diameter may be calculated from Poiseuille's law; thus:

$$D_p = \sqrt{\frac{32\,\mu\,V\,L}{g\,e\,(p_1 - p_2)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

in which D_p is the mean pore diameter, in feet; and e is the void ratio.

---

[11] "Methods for Determining Permeability of Water-Bearing Materials," by L. K. Wenzel, *Water-Supply Paper No. 887*, U.S.G.S., U. S. Govt. Printing Office, Washington, D. C., 1942, p. 13.

[12] "Systematic Packing of Spheres—With Particular Relation to Porosity and Permeability," by L. C. Graton and H. J. Fraser, *Journal of Geology*, Vol. 43, No. 8, 1935, Pt. 1, p. 785.

The values obtained by using Eq. 7 are presented in Col. 4, Table 3. However, for the correct application of Poiseuille's law to flow through porous media, it is essential to make a number of corrections in the data. The law applies only to the pressure lost in the viscous flow of a fluid through a straight circular section. In a porous medium the cross section of the flow channels is not circular but is irregular. The path is not straight but is sinuous with many alternate enlargements and contractions. C. S. Slichter,[13] using spherical particles, showed that the path of fluid flow was from 1.2 to 1.5 times the length of the core and that the average velocity of the fluid was about 1.8 times the velocity calculated from the rate of flow through the area of the voids. Messrs. Chilton and Colburn[10] claim that only about 20% of the pressure loss is caused by the friction of viscous flow and that the loss caused by the rapid expansion and contraction of the fluid is responsible for the major part of the remainder. Making these corrections on the length of path, the velocity, and the pressure would increase the value under the radical in Eq. 7 by about twelve times and the pore diameter by the square root of 12. The pore diameters corrected by this amount are given in Col. 5, Table 3. These corrected values are much closer to the size of openings that can be observed microscopically in core cross sections than are the uncorrected values.

The cement used in this work, when tested for fineness, gave 96% passing the 200-mesh sieve (0.0074-cm opening). The 28-mesh to 30-mesh sand was the largest size which did not pass a 14.5-gal slurry. Comparing the 96% cement size with the pore size of the sand shows the average pore to be five times the cement size. Taking into account the fact that the average diameter of the pore is being compared, and not the minimum constricted diameter, it appears that the cement ceases to pass into the pore when the pore becomes small enough for two or three particles to bridge across it.

From this evidence it appears that the passage of cement into a sand is limited by the ratio of the cement particle size to the sand pore size. A sand having a permeability of less than 3,000 gal per day per sq ft will not allow any measurable quantity of cement to pass into it regardless of the squeeze pressure or of any other factors.

SLURRY FILTRATION ON FINE SANDS

Thus far in the paper, the description has dealt only with factors affecting the penetration of cement slurry into sands. The next feature that requires attention is the problem of placing a cement slurry against a fine sand. The greatest percentage of wells in the Baltimore area probably penetrates sands with permeabilities less than 3,000. Hence, the cement particles will not penetrate into the sand but will build up a filter cake as the water is forced from the slurry. If the pressure gradient between the slurry and sand is high, it is quite possible that the water may filter from the slurry more rapidly than the slurry is being pumped into the well. In such a case, the slurry cake may clog the inlet tube, stop the pump, and leave an incomplete job.

---

[13] "Theoretical Investigation of the Motion of Ground Water," by C. S. Slichter, 19th Annual Rept., U.S.G.S., U. S. Govt. Printing Office, Washington, D. C., Vol. 2, 1898, p. 305.

To solve this problem, the effect of the pressure, the rate of pumping, the slurry concentration, and the sand permeability on the rate of formation of the slurry cake must be known. By correlating all these factors it may be possible to choose the correct slurry concentration, pumping rate, and squeeze pressure to insure a satisfactory completion of a grouting job for any well. When a cement slurry is placed in a well and the pressure in the slurry is greater than the pressure in the sand formation, the water will be squeezed out of the slurry leaving a filter cake on the wall of the well. In effect, this is a giant filter press and it is possible to simulate this press with a laboratory model. By starting with the simple concept of considering the filtration rate as proportional to the pressure divided by the resistance and considering the resistance as being made of two parts, the resistance of the filter cake and the resistance of the filtering medium, it is possible to arrive at a filtration equation. This equation will include all the known factors that will affect the filtration process. By measuring the constants that depend on the slurry and the filtering media, a solution of the equation will yield the result of a change in any one of the variable factors previously discussed. In this manner a precise measure of each of the variables may be obtained.

A good treatment of filtration equations and their derivations has been published by W. H. Walker, W. K. Lewis, W. H. McAdams, and E. R. Gilliland.[14] For the cement grouting of a well, a constant-pressure filtration equation will best fit the conditions usually existing in the field; and, therefore, the following equation for constant-pressure filtration[15] will be chosen for investigation:

$$\frac{p_f\, t}{W_t/A_f} = \frac{r''\, B_c}{2\, a}\, \mu\, a\, p^{k}_{f} \times \frac{W_t}{A_f} + r'\, \mu\, p^{m}_{f} \ldots\ldots\ldots\ldots (8)$$

in which p_f is the total filtering pressure on the cake, in pounds per square inch; W_t is the total weight of filtrate from the slurry, in pounds to time t; t is the total time of operation, in seconds; A_f is the total area of the filtering surface, in square inches; r' is a constant coefficient depending on the resistance of the filter bed; r'' is a constant coefficient depending on the specific resistance of the cake; B_c is the volume of the cake as it collects on the filter, in cubic inches per pound of filtrate; a is the concentration of the slurry, in pounds of solids, per pound of filtrate greater than that necessary to make a 5.5-gal slurry; m is the coefficient of plugging for the filter media; μ is the absolute viscosity of the filtrate, in centipoises; k is the coefficient of compressibility of the filter cake; and m is the coefficient of plugging of the filter media.

The value of the concentration factor a was computed quite empirically. Ordinarily, the factor a is defined as the pounds of solids per pound of filtrate; but, when this definition was applied to the data obtained in the tests, it was impossible to secure the same results with different slurry concentrations. In the experiments on the shrinkage of slurries, it was found that 5.4 gal of water per sack of cement was the quantity of water required to just hydrolyze the cement. If the value of a is based on the amount of water in excess of this quantity, which is the quantity causing the fluidity of the slurry, the a-value secured would be comparable to that which is ordinarily used for solids that do not react chemically with the filtrate. Instead of using 5.4 as the basis, the value was rounded to 5.5. This hypothesis applied to the data was found acceptable. Since the filtration equation itself is solved empirically, this definition of a is satisfactory.

---

[14] "Principles of Chemical Engineering," by W. H. Walker, W. K. Lewis, W. H. McAdams, and E. R. Gilliland, McGraw-Hill Book Co., Inc., New York, N. Y., 1937, p. 342.

[15] *Ibid.*, p. 347.

In the laboratory, only the values of $\left(\frac{r'' B_c}{2\,a}\right)$, k, r', and m (which will be constants in Eq. 8) must be measured to reduce the equation to a relatively simple form. It is then an easy matter to measure the effect of any one variable on the filtration process by changing the variable and solving the equation for the amount of filtrate lost. When the amount of filtrate lost is known, it is necessary only to subtract this quantity from the amount pumped in to determine the concentration of the remaining slurry.

In the filtration formula (Eq. 8), the term $\left(\frac{r'' B_c}{2\,a}\,\mu\,a\,p^k{}_f \times \frac{W_t}{A_f}\right)$ is a measure of the resistance of the filter cake. For a given slurry the values of $\left(\frac{r'' B_c}{a}\right)$ and of k should be constant. In practice, however, experiments show that, even with an incompressible material such as a "kieselguhr" slurry, the values vary slightly with the pressure and with the concentration of the slurry. With compressible materials the variation is often considerable.

The last term of Eq. 8 $(r'\mu\,p^m{}_f)$ is a measure of the resistance of the filter medium. Again, the terms r' and m should be constant for a given filter medium; but in practice they usually vary somewhat with the pressure and with the slurry concentration. The resistance of the filtering medium is not the resistance of the medium when no slurry is present, but rather the resistance after the solid particles have plugged the pores of the medium. Thus, the constant terms change in value with changes in the slurry and in the pressure.

Materials.—The cement and sand used in this work were the same as those described previously under the heading, "Cement Penetration Through Sands: Materials." The coarsest sand used for a filter medium was the 30-mesh to 40-mesh material, with a permeability of 2,015 gal per day per sq ft, and the finest material tested was a blended sand of from 30 mesh to smaller than 200 mesh. This sand had a permeability of 11.6 gal per day per sq ft. The other two sands used had permeabilities of 529 and 132.

The permeability of each of the sands was computed from the Reynolds number versus friction factor diagram, by the method previously outlined, and checked by a variable-head permeameter. The Reynolds number versus friction factor diagram was found to give excellent results.

Apparatus.—The apparatus used for these tests was the same as that used for the tests of cement penetration. The schematic diagram of the apparatus is shown in Fig. 1.

Procedure.—The procedure used in testing followed lines similar to those used in the tests on cement penetration. The pressure forced the filtrate from the slurry into the sand, replacing the water already there. The excess water passed out of the sand and was caught in a chemical graduate. A knowledge of the total proportion of filtrate that could be expected from the slurry was gained from experience, and an attempt was made to catch about one sixth of the filtrate in each of six graduates. The filling of each graduate was timed by a stop watch. In this manner it was possible to secure six points for each run so that a curve could be drawn. At the end of each run the apparatus was backwashed with water to remove all the slurry in the tubing.

Data and Discussion of Results.—Eq. 8 is a formula of the form $y = m x + b$ in which W_t varies with t as the pressure is held constant. If the data fit this equation, a plot of the values of $\frac{p_f\, t}{W_t/A_f}$ against the values of W_t/A_f should give a straight line of the type shown in Fig. 6. The slope of this straight line will be $(r''\, B_c/a)\ (\mu\, a/2)p^k{}_f$ and the intercept on the ordinate at $W_t/A_f = 0$ will be $r'\, \mu\, p^m{}_f$. When the value of the slope of the line is divided by $\mu\, a/2$, the remainder will be $(r''\, B_c/a)p^k{}_f$. A plot of the values of $(r''\, B_c/a)p^k{}_f$ against the values of p_f on log-log paper will give a straight line with a slope of k. Such a plot is shown in Fig. 7. The intercept of this line on the ordinate at $p_f = 1$ will be the value of $(r''\, B_c/a)$. This method of analysis furnishes the values of the two constants $(r''\, B_c/a)$ and k for the filtration equation.

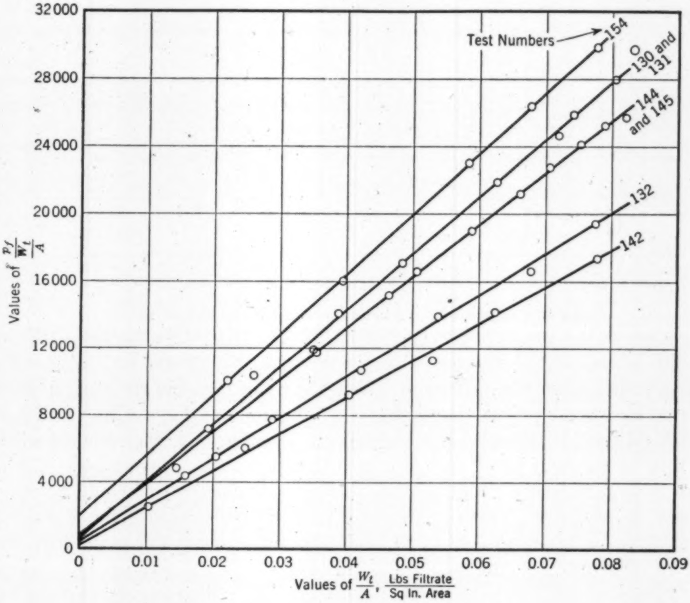

FIG. 6.—GENERAL FILTRATION CURVES

By a similar procedure it is possible to evaluate the constants r' and m. The values of $r' \mu p_f^m$, secured from the first plot of the type shown in Fig. 6, when divided by the viscosity, will give $r' p_f^m$. A plot on log-log paper of the values of $r' p_f^m$ against the values of p_f will give a straight line with a slope of m. A plot of this type is shown in Fig. 8. The intercept of the line on the ordinate at $p_f = 1$ will be the value of the constant r'.

When the constants for Eq. 8 have been found in this manner, their substitution will reduce the equation to a form which is relatively simple to handle.

The first experiments were conducted with a 30-mesh to 40-mesh sand and a 14.5-gal slurry. This very dilute slurry was chosen for the first tests because it was very fluid and easy to handle. Pressures from 5 lb per sq in. to 45 lb per sq in. were used in making the series of tests. For each run the pressure was kept constant and six readings on the quantity of filtrate with the corresponding time were taken. From these data, the series of curves of the type shown in Fig. 6 were drawn.

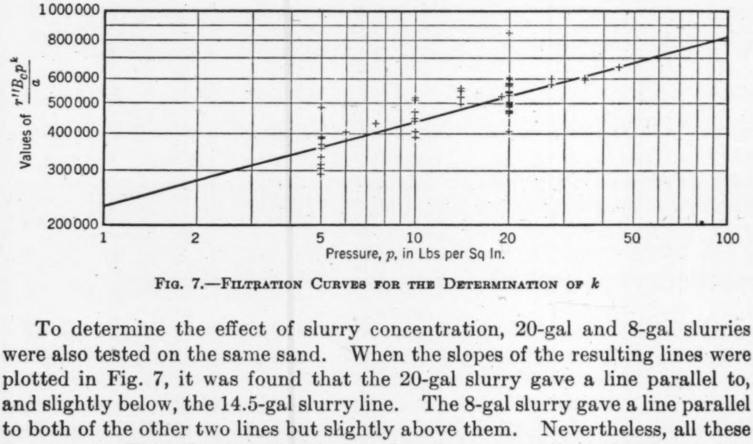

Fig. 7.—Filtration Curves for the Determination of k

To determine the effect of slurry concentration, 20-gal and 8-gal slurries were also tested on the same sand. When the slopes of the resulting lines were plotted in Fig. 7, it was found that the 20-gal slurry gave a line parallel to, and slightly below, the 14.5-gal slurry line. The 8-gal slurry gave a line parallel to both of the other two lines but slightly above them. Nevertheless, all these lines were sufficiently close together so that the average line could be used to represent any one. Furthermore, the plugging resistance given by the last term of Eq. 8 tends to counterbalance this difference. Thus, the final result will be reasonably accurate in any of the cases.

To secure the constants for the term involving the resistance of the sand, the intercepts on the ordinate at $W_t/A_f = 0$ of the original plot (Fig. 6) were divided by the value of the viscosity and plotted against the pressure readings, giving a series of curves of the type shown in Fig. 8. The intercept on the ordinate at $p_f = 1$ is the value of r' and the slope of the lines is the value of m.

The line for the 20-gal slurry is very nearly parallel to the line for the 14.5-gal slurry but is slightly above it. The value of m, therefore, is the same in each case; but the value of the intercept, r', is higher in the case of the 20-gal slurry. The 14.5-gal slurry line may be taken as representative of each case because the slight change in the constants of the slurry resistance term and the sand resistance term balance each other.

The next important step is the determination of the change in the resistance of the sand as the permeability is decreased. For this work three other sands with permeabilities of 529, 132, and 11.6 gal per sq ft were used. A 14.5-gal slurry was squeezed against each one and the filtration curves were drawn. The slopes of the "General Filtration Curves," as shown in Fig. 6, were corrected by dividing by $\mu/2$ and multiplying by a to obtain the term $\frac{r'' B_c p^{k}{}_f}{a}$. These corrected slopes are also included in Fig. 7 for the determination of $r'' B_c/a$ and k. The points define the same quantities as those previously obtained so that the cake resistance term is not affected. The filter media resistance, on the other hand, is changed considerably. The value of m is unchanged, but the value of r' increases with a decrease in the permeability. This change in r' was plotted on various types of graph paper, and it was found that, on semilogarithmetic paper (Fig. 9), it produced very nearly a straight line between the permeabilities of 2,000 gal per day per sq ft and 100 gal per day per sq ft. Somewhere between the permeabilities of 100 and 0 the straight-line relationship ceased to hold and the curve became asymptotic to the line of 0 permeability. Only one point in this region was found—the point at a permeability of 11.6. Further experience may indicate that a closer definition of this line is desirable, but for the present this paper will limit its scope to the part of the curve above a permeability of 100.

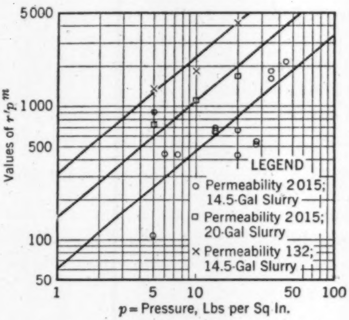

Fig. 8.—Filtration Curves for the Determination of m

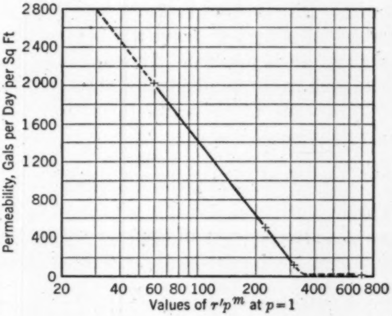

Fig. 9.—Effect of Permeability on the Value of r'

The straight-line section of the curve probably can be extended to a permeability of about 3,000. Two runs on a sand with a permeability of 5,200 were made, but about 4% of the cement passed through the sand. The filtration equation (Eq. 8) was not applicable, and no further tests in this region were made.

The slope of the curve of Fig. 7 gives a value of 0.278 for k and the intercept on the ordinate gives a value of 230,000 for $r'' B_c/a$. From Fig. 8, the slope of the line gives a value for m of 0.88. The intercept on the ordinate which is r' varies with the permeability and may be found from Fig. 9. For a sand with a permeability of 2,015, the value of r' is 60 and Eq. 8 becomes:

$$\frac{p_f t}{W_t/A_f} = 230{,}000 \left(\frac{\mu a}{2}\right) p^{0.278} (W_t/A_f) + 60 \mu p^{0.88} \quad \ldots\ldots\ldots (9)$$

To determine the importance of the various factors of Eq. 9, a typical hypothetical case of a cementing job may be assumed and the values determined. For example, assume that a 14.5-gal slurry is to be squeezed against a 10-ft salt-water formation. The hole is 18 in. in diameter and is cased with a 14-in. casing. The slurry temperature is 68° F, and the sand has a permeability of 2,015. It is desired to know how long it would take to squeeze enough water out of the slurry to leave a 5.5-gal slurry behind the casing if 30 lb per sq in. of pressure is applied. It was found that 50.8 sec would be required. The following example illustrates the solution of the problem:

The area of the sand formation is: $A_f = \pi \times 18 \times 10 \times 12 = 6{,}780$ sq in.; the viscosity of the water, $\mu = 1.005$ centipoises; and the slurry concentration factor, $a = \frac{94}{(14.5 - 5.5)\ 8.33} = 1.252$ lb of solids per pound of filtrate. The definition of a is the pounds of solid per pound of filtrate in excess of 5.5 gal of water per sack of cement. For this calculation a is the ratio of the weight of a sack of cement to the weight of 9 gal of excess water. The volume to be filled outside the casing $= \frac{\pi}{4}\left[\left(\frac{18}{12}\right)^2 - \left(\frac{14}{12}\right)^2\right] 10 = 7$ cu ft.

From Fig. 3, a 5.5-gal slurry occupies 1.22 cu ft per sack of cement. To fill 7 cu ft will require $7/1.22 = 5.74$ sacks of cement. A 14.5-gal slurry occupies 2.40 cu ft per sack of cement; and, therefore, the volume of filtrate which must be squeezed out is $(2.40 - 1.22)\ 5.74 = 6.76$ cu ft, or 423 lb. Therefore, $W_t/A_f = 423/6{,}780 = 0.0624$ lb per sq in.

The value of r' from Fig. 9 is 60. Consequently, $\frac{p_f}{W_t/A_f} = 230{,}000 \left(\frac{\mu a}{2}\right) p^{0.278}{}_f \left(\frac{W_t}{A_f}\right) + 60 \mu p^{0.88}{}_f$; $\frac{30 t}{0.0624} = 230{,}000 \frac{(1.005 \times 1.252)}{2} (30)^{0.278} (0.0624) + 60\ (1.005)\ (30)^{0.88} = 23{,}200 + 1{,}208 = 24{,}408$; and $t = 50.8$ sec.

If the sand permeability were assumed to be 11.6 instead of 2,015, the time required would be 77.6 sec. All values shown in the solution of the foregoing problem would remain the same except the value of r'. From Fig. 9, the value of r' would be 700. A sand with the permeability of 11 would be considered as a low permeability material. On the other hand, a permeability of 2,000 is very high. For comparison with these values, it may be stated that, to be considered a good aquifer, a sand should have a permeability of 250 or higher.

From these calculations it is evident that, within this range, the permeability of a sand is a factor of small importance in the filtration of a cement slurry.

Clay beds would probably absorb the filtrate so slowly that the area of clay surfaces may be neglected in the computations. Even if this were done, the time of filtration in most cases still would be so short that it would make little difference in the type of equipment necessary to place the slurry.

The concentration of the slurry is a factor of great importance when using either the tubing method or the casing method of cementing. If a slurry with a low-water content is used, the water in the slurry may filter out more rapidly than the pump can place the slurry. In this case, only a few feet of slurry may be placed behind the casing before the concentration increases to the point where it is no longer a fluid but a solid. The outlet of the grout pipe will then clog and the filter cake will build up within the pipe stopping the pump.

It becomes obvious that the pump used to place the grout must have a capacity sufficiently high to place the required volume of slurry before the concentration increases to the point where the slurry will clog the grout tube. In the previous example, a pump capacity of at least 124 gal per min would be necessary. The pump must place 13.8 cu ft of slurry, but the final volume is 7 cu ft. It should also be noted that doubling the height of hole to be cemented will double the pump capacity required, because the time computed by the filtration equation will still be the same.

The oil well industry learned long ago that high-capacity pumps were essential for the full completion of a grouting operation. Companies were formed which specialized solely in the cement grouting of wells. Operators learned that special equipment was necessary to grout a well successfully and called upon these concerns to furnish the service. In much of their advertising, great emphasis has been placed on the high-capacity, high-pressure pumps.

High pressures are neither necessary nor desirable for squeezing the excess water from the slurry. Even though high pressures are used in the oil well industry for squeeze cementing, it must be remembered that the total pressure in itself does not force the water from the slurry, but rather the pressure differential between the slurry and the sand formation. In the oil well industry, formation pressures of more than 1,000 lb per sq in. are fairly common. Before the slurry can be pumped into the well, the formation pressure as well as the friction loss of flow through the grout line must be overcome. For this reason, the pump pressure must always be higher than the effective squeeze pressure. From the example cited, it may be noted that a pressure differential of 30 lb per sq in. is sufficient to force the water from the slurry very rapidly. A low pressure differential, which increases the allowable time for pumping, would be more economical.

For an intelligent use of the filtration equation, the limits within which it applies must be understood. The equation is derived for a condition in which the slurry has immediate access to all parts of the filter medium, and the area of the medium does not change with time. Therefore, the equation can be expected to give accurate results when grouting is done by the principles of squeeze cementing. In this case, the salt-water formation is located, and the casing opposite the formation is bullet perforated. The slurry has immediate access to all parts of the formation through the many holes and is prevented from passing too far beyond the formation by cavings around the casing. Under these circumstances, it would be desirable to use a high concentration of slurry to be certain that the slurry cake forms rapidly and that the slurry does not pass down the hole away from the formation.

For the grouting of a long section of casing, Eq. 8 cannot be used. With this operation, the slurry will rapidly form a thick cake around the foot of the casing. If the pumping rate is low, the grout pipe will clog; but, if the rate is high, the velocity of flow may be sufficient to scour the cake around the casing and to keep the grout flowing up the hole. However, in its path upward the slurry will lose water to the adjacent cake so that, when it arrives at the top of the column, it will be thicker than the initial concentration. The value of a in the equation will then be different, as will also the value of W_t/A_f, because of the change in area with time.

SUMMARY

The contamination of underground fresh-water aquifers by salt-water infiltration has become a serious problem in the Baltimore industrial area and other areas. The salt water is leaking into both producing and abandoned wells from overlying formations into the fresh-water strata. This leakage generally occurs through the space between the well casing and the borehole and may be stopped by filling this space with cement slurry.

When a cement slurry is placed in a well in contact with a porous formation, the water in the slurry will be filtered from it when the pressure differential is toward the sand. If the coefficient of permeability of the sand is less than 3,000 gal per day per sq ft, the pores of the sand will be too small to allow the cement grains to enter. If the permeability is greater than this quantity, some of the cement may pass; but, since the water in the slurry may filter at the same time, the entire quantity of cement will not always move into the formation.

When a sand has a permeability of less than 3,000, the pressure will force the water out of the slurry leaving a filter cake upon the sand surface. To give an exact description of the conditions at any instant during the filtration process, the filtration equation for cement slurries was developed.

A study of the sands having permeabilities greater than 3,000 showed that three factors mainly controlled the amount of cement penetrating into the formation:

(1) The ratio of the pore size to the cement particle size;
(2) The slurry concentration; and
(3) The manner in which the pressure was applied.

Calculation of the pore diameters showed that the pore of the largest sand which would not permit the passage of a cement slurry was small enough so that two or three cement particles could form a stable bridge across the opening. No amount of pressure could be expected to force the cement into this sand. When the pores are larger, some of the cement will pass into the sand. If the slurry is thin, all the cement may penetrate; but, if the slurry is thick, the water may filter from it too rapidly to carry along all the cement particles and a filter cake will result. By using this principle, a slurry cake may be formed on a sand with a permeability as high as 127,000.

The speed with which the pressure is applied will determine the amount of cement that will penetrate. If the pressure is applied instantaneously, a greater quantity will pass than would pass if the same pressure were applied slowly. With a slow rate of pressure application, the slurry may cease to penetrate long before the maximum pressure is reached, so that high-pressure differentials are of small importance in such a case.

Under no circumstance is there any justification for using a blanket rule for the selection of the slurry concentration as has been attempted by many writers. In some cases the slurry may be very dilute, the excess water serving only as an agent to carry the cement into position, after which it is squeezed out and the cement particles are compacted. The initial slurry concentration will have no bearing on the volume, strength, or permeability of the final product. In other cases, it may be desirable to grout off a given formation without allowing the slurry to spread over other strata. In these circumstances, it would be desirable to use a thick slurry and a high squeeze pressure.

Acknowledgments

The investigations reported in this paper were made in the laboratories of The Johns Hopkins University at Baltimore. The writer is indebted to Abel Wolman, M. ASCE, professor of sanitary engineering, The Johns Hopkins University, for advice and general supervision in carrying out the investigation. The writer is also indebted to Robert R. Bennett and R. R. Meyer, Geologic Survey, United States Department of the Interior, for information on cementing practices in the Baltimore area and in the western oil fields. Special appreciation is due to John C. Geyer, associate in civil engineering, The Johns Hopkins University, for suggesting this problem.

DISCUSSION

James B. Hays,[16] M. ASCE.—Some valuable information on the gradually increasing knowledge of grouting is contributed by this paper. The forcing of cement grout into sand has generally been considered as impossible. The author has thrown light on the subject and has indicated the approximate limiting point. The principal difficulty is to adapt the laboratory results to actual conditions as found in the field. Other considerations that must generally be taken into account are variations in gradation of the material in the layer to be grouted.

One of the difficulties encountered in using thin cement grouts is the fact that sedimentation is quite rapid in such mixes as compared with thick slurries. This is due to the settling out of the coarser particles where the slurry is not moving rapidly or is not otherwise being agitated. Therefore, a natural suggestion would be to try the use of cement screened through a fine mesh—say, the 200-mesh screen. This was done at the Owyhee (Oregon) and Boulder (Arizona-Nevada) dams for grouting contraction joints. Another suggestion along the same line would be to add a dispersion agent to the cement and note the effect in grouting. Any small increase in penetration under conditions described by the author would be highly beneficial.

The writer has always found it desirable to conduct such tests under conditions as nearly normal as possible. As described by Mr. Machis, there was no water in the column above the surface of the sand when the grout was introduced. The model might have worked differently if it had been filled with water. With a column of water 100 ft long (a common condition in practice) the coarse particles of cement would have dropped to the bottom ahead of the main stream of grout. If it is possible, the sand bed should be set vertically for the test. This is a difficult matter for the laboratory.

In the field, one of the most difficult problems would be to isolate the salt-water bearing zone so that the necessary grout pressure could be applied without its escape to other zones. Grout has a tendency to follow planes or zones of weak bond such as exists between steel and clay or stone and clay.

If these zones of salt water are located during the drilling of the well, there should be better means of cementing off the unwanted section than by grouting. Such methods should involve the use of certain processes well known to the driller. Deep beds of fine sand under dams could be grouted through well holes if cost were a secondary consideration; but the process would require that the grout penetrate at least several feet—rather than inches—from the hole.

If the author has the opportunity to apply his laboratory results to a field condition, the results would be interesting.

William S. Foster,[17] Assoc. M. ASCE.—While a sanitary engineer may have been searching diligently for cross connections with an unapproved water supply in some remote corner of his distribution system, a more serious "cross connection" may have escaped notice under his very nose. This is the challenging observation presented in the Machis' paper. In well drilling the customary practice is to seal off the undesirable aquifers by producing a barrier at the casing. Nevertheless, as Mr. Machis states, and as the experience at Baltimore (Md.) shows, this undesirable water can find its way down the outside of the casing and thereby pollute the new aquifer. At Baltimore the pollution consisted of salt water which renders the supply unfit for further use.

[17] Eng. Editor, *The American City Magazine*, New York, N. Y.

Mr. Machis' system, borrowed from the petroleum industry, consists of pumping a cement slurry around the outside of the well casing and forcing it under pressure against the wall of the well. In coarse sands and gravels the cement will penetrate until the internal friction of the sand grains halts the intrusion of the slurry and allows it to block and seal off the aquifer. In fine sands the slurry will merely collect like a filter cake, and the pressure applied will squeeze out the excess water leaving a firm, strong cement barrier with a consistency of from 4 gal to 5 gal per sack. In its underground location, this barrier will have an even temperature; it will be constantly in contact with moisture; and, probably, will not be subjected to variations in pressure. Consequently, for practical purposes, it should enjoy virtually an indefinite life. As Mr. Machis states, by varying the consistency of the slurry, one should be able to seal long lengths of the well casing or to apply local applications of grout and seal off a limited area.

The fear that this application of a thin grout (often preceded by water flushed up and outside the well casing in order to establish circulation) may disturb the sand and gravel strata and make them slough against the side of the well casing, thus blocking the operation, seems unfounded. This is particularly true for wells drilled by the rotary process in which the wall of the wells is held firm by the driller's mud. In most cases the pressure of the overburden and the precipitated minerals will consolidate the sands and gravels sufficiently to make them hold their positions firmly. Actual drilling logs show that clays and shales with less internal strength slough away more readily than do sands and gravels.

One question that arises in the mind of the uninitiated (and most engineers who are not petroleum specialists fall in that class) is whether some materials other than cement might give better results. Of course, a beam or briquette made of neat cement will give an excellent account of itself on a strength basis; but it does insist on shrinking, even under favorable conditions. The writer recalls at one time helping to waterproof a curing room in a laboratory in which both temperature and humidity were to be maintained within close limits. A neat-cement layer of grout applied to the brickwork in the room shrank and cracked sufficiently to lose its effectiveness. It may be that shrinkage would not be a factor in the case of well grouting; but water has an admirable trait of persistency and an ability to enter any small opening and develop it to amazing proportions. It would seem that some other product like asphalt or a dense impervious clay, which does not shrink when temperature and humidity are constant, would do the same sealing operation equally well and would eliminate this cracking danger.

Another point that immediately comes to the attention of the practicing engineer is how he can apply this useful grouting operation in his own installations. Evidently this sealing work is not a task for amateurs. Since it is being performed in the petroleum field, there must be concerns that would be willing to do the same work in the water works field. Consequently, the water works engineer would like to know what specifications he should call for in order to encourage these concerns to bid, and at the same time protect the interests of his client.

On the basis of studies by Mr. Machis, the painstaking engineer may very well insist that, when sealing operations are required in well construction, they be accompanied by grouting the well casing in that particular area.

FREDERICK J. SMITH,[18] JUN. ASCE.—Petroleum engineers have long been concerned with the problem of leakage of fluids behind the casing of oil wells. At times their problem has been the same as that described at Baltimore, Md., in Mr. Machis' paper—namely, downward percolation of water between the casing and the well bore. At other times the problem has been the leakage of high-pressure gas or oil from the producing formation, upward between the casing and the borehole to shallower sands or to the surface. When such a leak reaches the surface around the casing there is danger of a "blowout," which results in the development of a crater around the well as the soil and subsoil is blown away by the escaping oil or gas. There is also the possibility of of the ultimate loss of the well by rupturing of the surface connections as their support is removed, as well as the danger that the escaping oil or gas may catch fire, thus adding to the general chaos.

Various methods have been developed by petroleum engineers to combat this leakage between the casing and the wall of the borehole. Some of these methods are applicable in the water works field, and others may be adapted for such use. The writer would like to submit the following suggestions, based on current petroleum engineering practices, as a solution of the leakage problem outlined in Mr. Machis' paper. It is assumed that drilling will be done by the rotary process, although these suggestions can be adapted for use in cable tool holes.

New Wells.—When a water well is drilled in an area where contaminated waters are found at shallower depths than the potable water to be exploited, the following program is suggested:

The well should be drilled to the water sand, but should not penetrate more than 3 ft or 4 ft into the sand before the protective casing is set. As shales and clays are prone to slough or "cave," a caliper survey of the borehole can be made before placing the casing in the borehole; the number and size of the "caves" can be established; and an estimate of the amount of cement needed to fill the annular space between the casing and the wall of the borehole can be prepared. Also, in light of the "caving" nature of most shales, it would be wise to have the bottom of the casing at least 1 ft below the top of the sand to prevent subsequent caving, and the development of leakage around the casing shoe, after completion of the well. The casing should be run to bottom and cemented using the "casing method" quoted by Mr. Machis (see heading, "Grouting New Casing: Casing Method of Cementing"). Enough cement grout can be pumped, by normal oil-field cementing practices, to establish circulation of the cement and to get "returns" of the cement at the surface outside the casing if so desired. During placement of the cement, the casing should be setting on the bottom of the hole. As soon as all cement has been pumped into the hole, the casing should be picked up and suspended with the bottom of the casing 1 ft below the top of the water sand.

---

[18] Geologist, Sinclair Prairie Oil Co., Seminole, Okla.

After sufficient time has elapsed for the grout to set (from 24 hours to 72 hours, depending on local conditions), the cement remaining in the casing is drilled out, and the hole is opened 1 ft below the casing shoe (which still leaves from 1 ft to 2 ft of cement in the hole). The next step is to determine whether or not any leakage exists around the casing shoe, due to a faulty cementing job. This determination can be made by using any one of several available formation testers[19] with the packer set in the bottom joint of the casing. The testers consist of a packer and a series of valves which are run into the hole on the bottom of the drill pipe or tubing. This is the standard "drill stem test" familiar to petroleum engineers. A valve, below the packer, excludes fluid from the drill pipe, and maintains atmospheric pressure inside the pipe as the testing tool is lowered into the hole. This valve is opened after the packer is set, and the resulting pressure differential between the formation pressure of the zone below the packer and the atmospheric pressure in the drill pipe allows the formation fluid (if any is present) to flow into the drill pipe above the packer. The valve automatically closes when the packer is unseated, trapping the fluid in the drill pipe; the pipe is pulled from the hole, and the amount and the nature of the fluid recovered are checked by the engineer supervising the test. A pressure recording device can be used with this testing tool to record the shut-in rock pressure, and the flowing pressure of the zone can be tested.

If the drill stem test does not recover water, the cementing job can be considered a success, and the well can then be completed using the standard practices for the area. If water is recovered on the test, however, it should be analyzed to determine if it came from the fresh-water sand below the casing shoe, or if it is contaminated water that is leaking between the casing and the wall of the borehole—indicating a poor cement job. in the latter case, the bottom 10 ft to 20 ft of the casing should be gun perforated (or bullet perforated) and cement grout should be squeezed through these perforations to seal the leakage behind the pipe. The casing shoe can again be tested following the squeeze cementing. This process of squeezing and drill stem testing should continue until a shutoff is achieved. When no further leakage is apparent the well can be completed.

Old Wells.—Three typical cases applying to old wells can be discussed.

Case 1. Well Completed in a Potable Water Sand and Later Contaminated by Leakage from Behind the Casing.—The first step in the elimination of this type of leakage should be to fill the open hole below the casing with fine sand and gravel in order to protect the face of the producing sand from any possible contamination by the cement grout. To eliminate the leakage, the bottom joint of the casing should be gun perforated, and cement grout squeezed behind the casing through the perforations. When the grout has set, the cement remaining in the casing can be drilled out, and the cement job tested as previously described. This process may have to be repeated one or more times until the leakage is completely sealed off. The sand and gravel can be removed from the hole after the shutoff is obtained, and the well then put back in production.

---

[19] "Formation Testing and Testing Equipment," by J. C. Padgett, *The Oil Weekly*, March 24, 1947, pp. 18-21.

Case 2. Leak in the Casing.—If a leak in the casing is suspected, it can be located by running a "water survey" or "electric pilot." The writer is not familiar with the details of this type of survey, although the service has been available to the petroleum industry for some time.

When the leak in the casing is located it can be eliminated in the following manner: A drillable cement retainer or plug should be set in the casing below the leak; the casing is gun perforated in the zone of leakage, and then the perforated section is squeeze cemented. When the cement has set, the cement remaining in the casing should be drilled out to a point below the leak, but above the cement retainer, and the zone of leakage drill stem tested as described herein under the heading, "New Wells." Perforating and cementing should be repeated, if necessary, until no further leakage is noted. After all leakage is sealed off, the cement retainer can be drilled out, the well cleaned out to bottom, and then put back in production.

Case 3. Squeeze Cementing of Shallow Sands Behind the Casing.—At times it may seem advisable to squeeze some cement into the shallow contaminated sands covered by the casing. This would be especially true in plugging an old well where it is impossible to reclaim the casing. These sands can easily be located if a geologist's sample log or an accurate driller's log of the hole is available. Where such logs are not available, or where the records are very poor, the sands behind the casing can be located by a "gamma-ray" survey, a relatively new process that is being used in the petroleum industry. These surveys are based on the natural radioactivity of the sedimentary rocks, the survey instrument recording the intensity of the "gamma-ray" radiation of the formations as the instrument is withdrawn from the borehole. This type of survey is advantageous because it can be run in any type of well fluid, and it will locate the various formations accurately in both cased (one or more strings of cemented casing) or uncased holes. The disadvantage of these surveys lies in the fact that some idea of the normal sedimentary sequence of the area is needed to interpret these logs properly, as sands and limestones give similar reactions. This disadvantage can be overcome (at extra cost) by making a "neutron" survey in connection with the "gamma-ray" survey, and properly correlating the two surveys (done by the service company). The "neutron" survey, in contrast to the "gamma-ray" survey, is based on the intensity of radiation from the formation as a result of bombardment by neutrons from a radioactive source suspended below the survey instrument.

It has been found that the best results are obtained, in petroleum geological studies, when the radioactivity logs are used in conjunction with any geologist's or driller's logs that are available from the same area. The aforementioned inability to differentiate between a sand and a limestone should not be too big a disadvantage in the water works field, since a porous limestone is potentially as dangerous as a sandstone as a source of contaminated water.

After the sand bodies (or limestones) have been located, they can be grouted by squeeze cementing following the procedure outlined for case 2.

The Use of Plastics to Seal Contaminated Sands.—Many oil companies have been experimenting with plastics; they have been trying to "shut off" bottom hole water by introducing liquid plastics of various types into the borehole and allowing them to harden. Some good results have been reported from such experiments, and these materials might prove very useful in the water works field. Each contaminated sand encountered in drilling a new well could be impregnated with plastic as soon as it is drilled, thereby eliminating the source of future pollution.

Service Companies.—Communities located in the areas of active petroleum exploitation are familiar with most of the service companies engaged in the activities described herein. Their characteristically colored cars and trucks are being found throughout a wider and wider area as the search for oil expands.

Locating Cement Squeezed Behind Casing.—By laboratory experiments Mr. Machis has determined the effects of such physical constants as porosity, permeability, pressure, and water-cement ratio on the problem of forcing cement grout into a sand formation. Where the porosity and permeability of a sand have been determined from cores, it should be possible, using Mr. Machis' results, to determine the theoretical quantity of cement squeezed into a subsurface sand body under set conditions of pressure, type of slurry, and time and rate of pressure application. No accurate method has been developed to check, below ground, the theoretical results to be expected from a subsurface squeeze job.

It is possible, however, to determine the vertical extent and the mass distribution of the cement following squeeze cementing. This determination is made possible by adding a radioactive mineral to the dry cement to be used, and by "gamma-ray" surveys of the borehole before and after the squeeze job. The radioactive mineral is usually "carnotite," a potassium-uranium-vanadium oxide, and is added to the cement in the ratio of from ¼ lb to 1 lb of carnotite per sack of dry cement. Carnotite, because of its nearly colloidal size and specific gravity, remains in a fairly stable mixture with the cement slurry (usually 15.5 lb per gal), and does not tend to settle out of the slurry.

In practice a "gamma-ray" survey of the borehole is made prior to the squeeze job, and is used as the reference line for all future surveys. The perforated zone is squeeze cemented, using the radioactive cement, and a second "gamma-ray" survey is run after the hole has been cleaned out. By superimposing the second survey upon the original, the vertical distribution of the radioactive cement behind the pipe can be determined by the sharp changes in the "gamma-ray" intensities between the two surveys at the upper and lower limits of cement travel.[20] Some idea of the mass distribution of the cement can be obtained from the comparison of the two surveys when it is understood that the greater the mass of treated cement at any point, the greater will be the "gamma-ray" intensity. In all such comparisons of "gamma-ray" surveys, in connection with radioactive squeeze cementing of a sand section through perforations, that the writer has seen, the "gamma-ray" intensities were highest opposite the sand section, and tapered off to the original values a short distance up or down the hole. The concentration of the "gamma-ray" intensities is due to (*a*) a filter cake mass being formed in the annular area between the casing and the wall of the borehole, or (*b*) to penetration of some of the solid particles of cement and carnotite into the sand, or (*c*) to a combination of both.

---

[20] "Some Practical Aspects of Radioactivity Well Logging," by W. J. Jackson and J. L. P. Campbell, *Technical Publication No. 1923*, A.I.M.M.E., pp. 14–16.

In some extreme cases two or more "radioactive" squeeze jobs have been performed opposite the same zone. A comparison of the "gamma-ray" surveys made after each squeeze job showed a progressive increase in "gamma-ray" intensities for each succeeding survey, indicating the probability that at least a part of the radioactive cement slurry had penetrated the sand body during each squeeze job.

This combination of radioactive cement and "gamma-ray" surveys does not give definite values to the amount of cement forced into a formation; nor does it supply the depth of penetration of the cement into the formation. The method does give an answer to the problem of the vertical travel of the cement behind the casing, and an approximate location of the main mass of the cement forced into the annular area between the casing and the wall of the hole.

Summary.—Mr. Machis' paper is an excellent addition to the literature on grouting of sands and gravels. His experiments have supplied data of much value for the solution of grouting problems. Mr. Machis has noted (see heading, "Repair of Leaking Wells"):

> "The highly sucessful utilization of this process in the oil well industry warrants close study for possible adaptation to the water well industry."

Therefore, the writer has tried to outline these oil field practices in the hope that they will aid in the practical application of the results of Mr. Machis' experiments. A positive method of locating the cement squeezed into a formation through perforations is also included.

ALFRED MACHIS,[21] JUN. ASCE.—The author is indebted to those who have taken the time to critically analyze and discuss this paper. He believes that the contribution made by Frederick J. Smith, Jun. ASCE, is especially appropriate, since it serves to focus the attention of the civil engineer on advances made in an allied field relating to a problem very similar to his own.

Conservation of a natural resource of such immense value as ground waters should be of primary importance to the engineer. Large investments are made annually in the construction of water wells and plants to treat the waters obtained from these wells. Experiences in the oil industry indicate that the leakage of an undesirable fluid down the outside of a well casing may be more economically controlled by grouting than by depending upon the separation of the fluids in refining. Similarly, it may be more economical to prevent the leakage of mineral-bearing waters into fresh-water aquifers by grouting than it would be to sustain the economic losses necessitated through the use of mineral-bearing waters.

The large number of successful results secured in the oil well industry indicates that the problem of grouting outside a well casing is not impractical. The author's attention was first directed to this problem of water contamination by an unsuccessful attempt to prevent the leakage of salt-bearing waters down the outside of a well casing into a fresh-water aquifer. Grouting was performed without a thorough understanding of the factors involved. The experimental data of this study were gathered to help provide the engineer with a basis upon which to form a logical solution to the problem.

THEORY OF INELASTIC BENDING WITH REFERENCE TO LIMIT DESIGN

By ALEXANDER HRENNIKOFF,[1] ASSOC. M. ASCE

WITH DISCUSSION BY MESSRS. GEORGE WINTER, D. C. DRUCKER, MICHAEL R. HORNE, E. P. POPOV, BERNARD A. VALLERGA, AND ALEXANDER HRENNIKOFF.

SYNOPSIS

For the most part this paper contains the description of a method for analyzing statically indeterminate flexural structures loaded beyond the elastic limit or structures comprising material that does not obey Hooke's law. The relations between the unit strains and the unit stresses (both normal and tangential), bending moments, angle changes, and deflections, produced under these circumstances, are derived. The effects of removing a load and of moving a load along the span are also considered. Furthermore, the method is applied to mild steel I-beams, and is illustrated by a number of examples bearing on the "Theory of Limit Design" presented by J. A. Van den Broek,[2] M. ASCE. Brief discussion of this theory together with observations concerning its validity, based on the results obtained, is included in Section 18.

1. INTRODUCTION

The method proposed in this paper entails the construction of several curves derived from the stress-strain curve of the material of the structure, making proper allowance for the shape of the cross section of its members. Once the requisite curves are constructed, the indeterminate moments are found by trial. The labor involved in such an analysis is not prohibitive, although it is greater than that involved in the usual elastic analysis. A new set of curves is needed if the material of the structure or the cross section of its members is different.

For the most part, this method, with its illustrative numerical solutions, is novel, although a simpler case of the same problem, involving a rectangular beam, has been treated, in a somewhat different way, by S. Timoshenko.[3]

NOTE.—Published in March, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate Prof., Civ. Eng., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B.C., Canada.

[2] "Theory of Limit Design," by J. A. Van den Broek, *Transactions*, ASCE, Vol. 105, 1940, p. 638.

[3] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 45.

The method is based on the assumption that the cross sections of the members remain plane throughout the entire range of flexure. The same assumption has also been used by Professor Timoshenko[3] and by A. Nádai;[4] and it has some experimental corroboration.[5] In certain restricted regions the sections undoubtedly become warped by shear, but on the whole the assumption is believed to be substantially true.

In addition to this assumption the theory is restricted by the following limitations:

1. The structure consists of prismatic members with I-beam, channel, or rectangular sections, symmetrical about their neutral axes;
2. The stress-strain curve is the same in tension and compression (the only limitation of the shape of this curve);
3. The bending moment diagram of the loaded structure is assumed to be bounded by straight lines (a curved diagram being approximated by a polygonal shape);
4. The effect of normal forces is ignored;
5. Deformations produced by shearing forces are disregarded;
6. Instability is not considered to be a factor; and
7. Deformations of the structure are assumed small.

Some additional assumptions, useful in expediting the work but otherwise avoidable, will be stated subsequently.

Notation.—The letter symbols in this paper are defined where they first appear, in the text or by illustration, and are assembled for convenience of reference, in the Appendix.

2. Unit Strain—Bending Moment Relation in a Rectangular Beam

The functional relationship between the unit stress, σ, and the unit strain, ϵ, for the material of the beam must be stated explicitly in one of the following forms: As an equation, $\sigma = f(\epsilon)$; as a graph, such as Fig. 1; or as a table of corresponding values of the two variables.

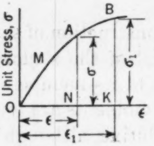

Fig. 1

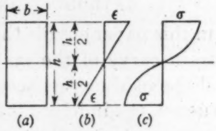

Fig. 2

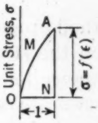

Fig. 3

Let a rectangular beam with the cross section shown in Fig. 2(*a*) be subjected to flexure. According to the stated assumptions, the unit strain diagram is linear (Fig. 2(*b*)), with zero strain at the center of the section and with equal strains ϵ at the outside fibers. It follows that the diagram of unit stress (Fig. 2(*c*)) consists of two equal parts resembling the stress-strain curve (Fig. 1) to point A, with the abscissa ϵ. The base ON = ϵ in Fig. 1 is reduced in Fig. 2(*c*) to the length $\frac{1}{2}h$. When the strain in the outside fibers of the beam is increased to a value ϵ_1, in response to a greater bending moment, the stress curve in Fig. 2(*c*) will resemble a greater length of the stress-strain curve OMBK (Fig. 1), whose base ϵ_1 is again foreshortened to the same length, $\frac{1}{2}h$.

[4] "Plasticity," by A. Nádai, McGraw-Hill Book Co., Inc., New York, N. Y., 1931, p. 164.

[5] "Mechanics of Creep," by J. Marin, *Transactions*, ASCE, Vol. 108, 1943, p. 459.

To find a relation between the bending moment M and the corresponding unit strain ϵ in the outer fibers of the beam, it is necessary to introduce a variable m_1, defined[3,4] as the statical moment, about the σ-axis, of an area under the stress-strain curve, taken to a variable point A on the curve, provided however that the variable base ϵ is reduced to unity (Fig. 3). The moment about the σ-axis of the area under the curve OA in Fig. 1 is evidently equal to $\int_0^\epsilon \epsilon\,\sigma\,d\epsilon$. Reducing the base ϵ to a unit length changes both the elements of area and their lever arms ϵ times; therefore, the mathematical expression defining m_1 is as follows:

$$m_1 = \frac{1}{\epsilon^2}\int_0^\epsilon \epsilon\,\sigma\,d\epsilon \qquad (1)$$

The variable m_1 may be considered as a function of ϵ. In cases when σ and ϵ are not related by a mathematical equation the value of the integral in Eq. 1 must be determined by summation, dividing the area under the stress-strain curve into a large number of sufficiently narrow strips parallel to the σ-axis.

The requisite relation between the bending moment M and the unit strain ϵ in the outer fibers of the beam is found by equating the internal moment of stresses and the external bending moment. It may be observed that for the same unit strain, ϵ, the internal moment is proportional to the breadth b and to the square of the depth h of the section, the coefficient of proportionality being simply related to m_1 in the following manner:

$$M = 2\,m_1\,b\,(\tfrac{1}{2}h)^2 \qquad \text{or} \qquad m_1 = \frac{2\,M}{b\,h^2} \qquad (2)$$

In the analysis of statically determinate rectangular beams, when the bending moment M and the dimensions of the cross section are known, Eq. 2 determines the value of the variable m_1. The unit strain ϵ can then be found from a table or graph representing the relation between m_1 and ϵ expressed by Eq. 1, and the unit stress σ in the outer fibers of the beam, by the stress-strain relation.

3. UNIT STRAIN—BENDING MOMENT RELATION IN AN I-BEAM OR A CHANNEL BEAM

It is possible to derive a rigorous expression for a function m, applicable to I-beams and channel beam sections, which can be used in the same manner as the function m_1, defined in Section 2. This function would contain two independent parameters, a feature restricting the field of its usefulness. For this reason, it has been considered wise to widen the scope of applicability of the function m by ignoring the variation of unit stress over the areas of flanges. An analogous approximation is often made in the elastic range, which is essentially the so-called flange-area method of design applied to plate girders. The error involved in this approximation in the region above the elastic limit is smaller than that involved in the elastic range. When this approximation is made, the web of the beam is assumed equal to the distance between the centers of flanges, and the areas of flanges are assumed concentrated at the extremities of the web (Fig. 4(*a*)).

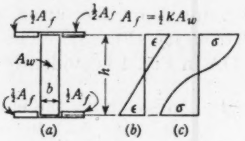

Fig. 4

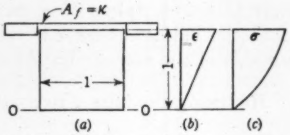

Fig. 5

To introduce the function m, imagine a section as in Fig. 5(*a*), strained and stressed as in Figs. 5(*b*) and 5(*c*). The width and depth of the web are both equal to unity, and the flange area A_f is equal to κ. The moment about the axis OO of stresses produced in this section, when it is strained as shown, is defined as the m-function. Evidently—

$$m = m_1 + \kappa\,\sigma \quad \text{(3)}$$

In Eq. 3, m_1 is the function of ϵ defined by Eq. 1, and σ is the unit stress corresponding to the same value of ϵ, thus making m also a function of ϵ.

Combining Eqs. 1 and 3:

$$m = \frac{1}{\epsilon^2}\int_0^{\epsilon} \epsilon\,\sigma\,d\epsilon + \kappa\,\sigma \quad \text{(4)}$$

The advantage of this variety of the function m over the one referred to at the beginning of this section is that it contains only one parameter κ instead of two, which widens its scope.

The function m can be easily related to the bending moment carried by the beam of Fig. 4. The web area of this beam is A_w, the depth is h, the area of one flange is A_f, and the ratio $\dfrac{A_f}{\frac{1}{2}A_w} = \kappa$.

Imagine a number of beams possessing the same flange-web ratio κ and strained to the same unit strain ϵ in the outside fibers. The following relations exist between the dimensions of the beams and the bending moments carried by them: When h remains constant and A_w varies, the internal moment varies in proportion to A_w. On the other hand, as long as A_w retains its value, the moment varies in proportion to h. Thus, the internal moment is proportional to the product $A_w\,h$. Therefore, the external bending moment M can be expressed, in terms of the function m, as follows:

$$M = 2\,m\,(\tfrac{1}{2}A_w)\,(\tfrac{1}{2}h) = \tfrac{1}{2}\,m\,A_w\,h \quad \text{(5)}$$

Eq. 5 can be applied to statically determinate I-beams and channels just as Eq. 2 can be applied to rectangular beams. The function m in Eq. 5 should be computed for the value of the parameter κ appropriate to the shape of the section.

The analysis of shear stresses requires the introduction of the function q, defined as the sum of the normal stresses developed by the section shown in Fig. 5. When the flange area κ is equal to zero, the corresponding q-function is referred to as q_1. Functions q and q_1, representing the internal normal forces, are thus analogous to the functions m and m_1, representing the internal moments, developed in the half-beam section of Fig. 5. Evidently,

$$q_1 = \frac{1}{\epsilon}\int_0^\epsilon \sigma\, d\epsilon \qquad (6a)$$

and

$$q = \frac{1}{\epsilon}\int_0^\epsilon \sigma\, d\epsilon + \kappa\,\sigma \qquad (6b)$$

4. Angle Changes

The analysis of statically indeterminate beams requires the derivation of relations between the angle changes and the unit strains and relations between the deflections and the unit strains.

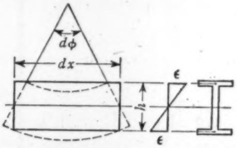

Fig. 6

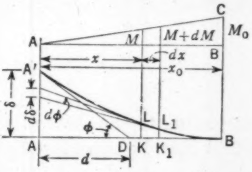

Fig. 7

Fig. 6 represents an element of length dx of a straight prismatic I-beam or channel beam with a symmetrical cross section, whose effective depth is h. It is strained to a unit strain ϵ at the centers of flanges, and the end sections rotate and form an angle $d\phi$ between them; thus:

$$d\phi = \frac{\epsilon\, dx}{\frac{1}{2} h} = \frac{2\,\epsilon\, dx}{h} \qquad (7a)$$

The angle change ϕ on a finite length of the beam is:

$$\phi = \frac{2}{h}\int \epsilon\, dx \qquad (7b)$$

to integrate Eq. 7b, ϵ and dx should be expressed in terms of the same variable.

In Fig. 7 the bending moment in the beam varies as a straight line from zero at one end to M_0 at the other end. If the shearing force in the beam is V, then, by a well-known relation:

$$dx = \frac{dM}{V} \qquad (8a)$$

Differentiating Eq. 5,

$$dM = \tfrac{1}{2} A_w h \, dm \ldots\ldots\ldots\ldots (8b)$$

Substituting Eq. 8*b* in Eq. 8*a*,

$$dx = \tfrac{1}{2} \frac{A_w h}{V} dm \ldots\ldots\ldots\ldots (8c)$$

Placing this value for dx (Eq. 8*c*) in Eq. 7*b*, the following expression for ϕ is obtained:

$$\phi = \frac{A_w}{V} \int_0^{\epsilon_0} \epsilon \, dm \ldots\ldots\ldots\ldots (9)$$

The integral in Eq. 9 represents the area between the (m-ϵ)-curve and the m-axis (Fig. 8), taken up to point A on the curve with the coordinates m_0 and ϵ_0, corresponding to the state of strain in the beam at end B with moment M_0. The integral may be considered as a function of ϵ_0. It can be computed from the (m-ϵ)-curve for different values of ϵ_0 by summing up the terms referring to a large number of narrow horizontal strips. In some special cases the integration can also be performed by calculus. The function expressed by the integral is given a symbol n, so that

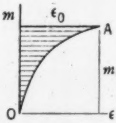

FIG. 8

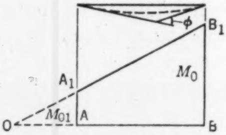

FIG. 9

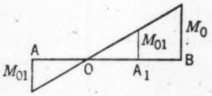

FIG. 10

$$\int_0^{\epsilon_0} \epsilon \, dm = n_0 \ldots\ldots\ldots\ldots (10)$$

Eq. 9 then becomes

$$\phi = \frac{A_w}{V} n_0 \ldots\ldots\ldots\ldots (11)$$

The loading conditions of the beam, to which Eq. 11 applies, are presented in Fig. 7. To solve for ϕ, compute m_0 from M_0 by Eq. 5. For the resulting value of m_0 select the value of the unit strain ϵ_0 from the (m-ϵ)-curve. For this value of ϵ_0 find the value of n_0 in the (n-ϵ)-curve, and then substitute it into Eq. 11. If the values of the m-functions and n-functions are plotted on the same sheet, or listed as in Table 1(*a*), the necessary n_0-value can be read directly against the corresponding m_0-value without referring first to ϵ_0.

Eq. 11 can be easily extended to a trapezoidal shape of the moment diagram by adding, algebraically, angle changes contributed by different parts of the beam. Thus, in Fig. 9, the angle change caused by the moments on the length AB is equal to the difference of the angle changes contributed by the triangular parts OBB_1 and OAA_1; and, since A_w and V are the same in both these parts,

$$\phi = \frac{A_w}{V}(n_0 - n_{01}) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

The functions n_0 and n_{01} in Eq. 12 correspond to the strains present in the outer

[a] Units are as follows: m, $10^3 n$, $10^3 n_r$, σ, and σ_r are in kips (thousand pounds) per square inch; and $10^3 u$ and $10^3 u_r$ are in $\frac{\text{kips}^3}{\text{in}^4}$.

fibers at points B and A, respectively. Eq. 12 is also applicable to the setup of Fig. 10, in which the bending moment changes its sign on the length AB, because the resultant angle change over the length AA_1 is zero.

Eq. 11 can be given a different form by substituting $\frac{M_0}{x_0}$ for the shear V and using Eq. 5:

$$V = \frac{M_0}{x_0} = \frac{A_w\, h\, m_0}{2\, x_0\,.} \qquad (13a)$$

Substituting Eq. 13a into Eq. 11:

$$\phi = \frac{2}{h}\, x_0 \left(\frac{n_0}{m_0} \right) \qquad (13b)$$

The ratio $\frac{n_0}{m_0}$ can be calculated as a new function. Eq. 13b is less convenient for computing the angle changes than is Eq. 11, but it will be used to advantage subsequently in reaching certain theoretical conclusions.

5. DEFLECTIONS

Referring again to Fig. 7, end B, at which the moment is M_0, is assumed to be fixed; and it is necessary to find an expression for the deflection of the other end, A, where the moment is zero. Consider an element dx of this beam, a distance x from the left end. The angular change $d\phi$ occurring on the length of this element causes a deflection $d\delta$ of the left end, so that

$$d\delta = x\, d\phi \qquad (14a)$$

The total deflection of the left end is then

$$\delta = \int_0^{x_0} x\, d\phi \qquad (14b)$$

which is the same expression as in the elastic theory. By Eq. 7a, $d\phi = \frac{2\, \epsilon\, dx}{h}$. Consequently,

$$\delta = \frac{2}{h} \int_0^{x_0} x\, \epsilon\, dx \qquad (15)$$

From Eq. 5 and Fig. 7,

$$x = \frac{M}{V} = \tfrac{1}{2}\, A_w\, h\, \frac{m}{V} \qquad (16)$$

Substituting Eqs. 8c and 16 in Eq. 15:

$$\delta = \frac{h}{2} \left(\frac{A_w}{V} \right)^2 \int_0^{\epsilon_0} m\, \epsilon\, dm = \frac{h}{2} \left(\frac{A_w}{V} \right)^2 u_0 \qquad (17a)$$

in which the integral—

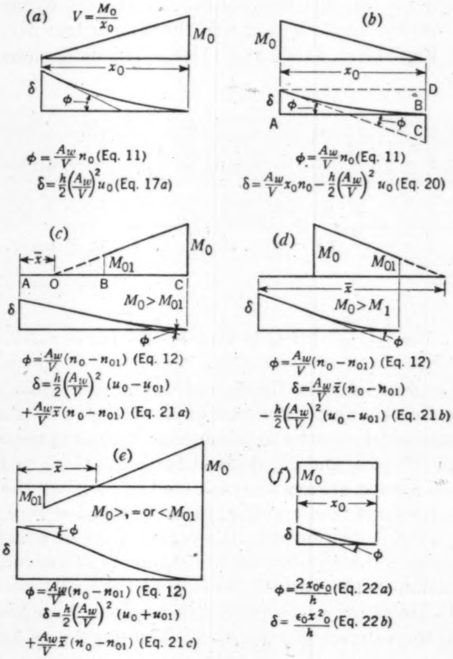
$$u_0 = \int_0^{\epsilon_0} m\, \epsilon\, dm \qquad (17b)$$

—represents a new function which signifies the statical moment about the ϵ-axis of the area between the (m-ϵ)-curve and the m-axis taken to point A on the curve with coordinates ϵ_0 and m_0 (Fig. 8). The function u_0 can be evaluated by summation. The function u_0 in Eq. 17*b* pertains to the strain condition existing at point B in the beam, where the bending moment is M_0.

The other version of this equation analogous to Eq. 13*b* is:

$$\delta = \frac{2\,x^2_0}{h}\,\frac{u_0}{m^2_0}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18)$$

In the following discussion and tables the subscript 0 in the symbols of n_0 and u_0 will be omitted, as a rule, when no specific point of the beam is under consideration.



(a) $\phi=\frac{A_w}{V}n_0$ (Eq. 11)

$\delta=\frac{h}{2}\left(\frac{A_w}{V}\right)^2 u_0$ (Eq. 17*a*)

(b) $\phi=\frac{A_w}{V}n_0$ (Eq. 11)

$\delta=\frac{A_w}{V}x_0 n_0-\frac{h}{2}\left(\frac{A_w}{V}\right)^2 u_0$ (Eq. 20)

(c) $\phi=\frac{A_w}{V}(n_0-n_{01})$ (Eq. 12)

$\delta=\frac{h}{2}\left(\frac{A_w}{V}\right)^2(u_0-u_{01})$

$+\frac{A_w}{V}\bar{x}(n_0-n_{01})$ (Eq. 21*a*)

(d) $\phi=\frac{A_w}{V}(n_0-n_{01})$ (Eq. 12)

$\delta=\frac{A_w}{V}\bar{x}(n_0-n_{01})$

$-\frac{h}{2}\left(\frac{A_w}{V}\right)^2(u_0-u_{01})$ (Eq. 21*b*)

(e) $\phi=\frac{A_w}{V}(n_0-n_{01})$ (Eq. 12)

$\delta=\frac{h}{2}\left(\frac{A_w}{V}\right)^2(u_0+u_{01})$

$+\frac{A_w}{V}\bar{x}(n_0-n_{01})$ (Eq. 21*c*)

(ʃ) $\phi=\frac{2\,x_0\epsilon_0}{h}$ (Eq. 22*a*)

$\delta=\frac{\epsilon_0 x^2_0}{h}$ (Eq. 22*b*)

FIG. 11

Formulas for the deflections, corresponding to various types of trapezoidal moment diagrams, are summarized in Fig. 11. They can be easily developed either by the method used to derive Eq. 17*a*, or from simple geometrical considerations, on the basis of Eqs. 11 and 17*a* which are fundamental. This condition is illustrated by Fig. 11(*b*). Let it be required to find the deflection at point A of a beam with a moment M_0, in relation to the tangent at point B, where the moment is zero. The deflection, of course, is assumed to be small. By Eq. 11:

$$\overline{\text{CD}} = x_0\,\phi = \frac{A_w}{V}\,x_0\,n_0\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19a)$$

By Eq. 17*a*

$$\overline{BC} = \frac{h}{2}\left(\frac{A_w}{V}\right)^2 u_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (19b)$$

Finally:

$$\delta = \overline{CD} - \overline{BC} = \frac{A_w}{V} x_0\, n_0 - \frac{h}{2}\left(\frac{A_w}{V}\right)^2 u_0 \ldots\ldots\ldots\ldots (20)$$

It is necessary to remember that the two cases dealing with the triangular moment diagrams (Figs. 11(*a*) and 11(*b*)) are quite distinct. Therefore, the corresponding formulas for deflections, Eqs. 17*a* and 20, cannot be converted from one to the other by direct algebra; and the same is true regarding the three trapezoidal cases, Figs. 11(*c*), 11(*d*), and 11(*e*). The deflections for these cases are, respectively:

For case (*c*)—

$$\delta = \frac{h}{2}\left(\frac{A_w}{V}\right)^2 (u_0 - u_{01}) + \frac{A_w \bar{x}}{V}(n_0 - n_{01}) \ldots\ldots\ldots\ldots (21a)$$

for case (*d*)—

$$\delta = \frac{A_w \bar{x}}{V}(n_0 - n_{01}) - \frac{h}{2}\left(\frac{A_w}{V}\right)^2 (u_0 - u_{01}) \ldots\ldots\ldots\ldots (21b)$$

and, for case (*e*)—

$$\delta = \frac{h}{2}\left(\frac{A_w}{V}\right)^2 (u_0 + u_{01}) + \frac{A_w \bar{x}}{V}(n_0 - n_{01}) \ldots\ldots\ldots\ldots (21c)$$

In the first two trapezoidal cases the sign of the moment does not change, but in the last case it does change. The triangular cases can be obtained from the corresponding trapezoidal cases by assuming one of the end moments to be zero.

In Eqs. 11, 12, 17*a*, 20, and 21, derived for Figs. 11(*a*) to 11(*e*), the quantities A_w, V, n, and u must always be considered as positive; the same condition is true for x_0 and $\bar{x}$, except that $\bar{x}$ in Fig. 11(*c*) may either represent a positive quantity (when point A lies outside the region OB) or a negative quantity (when point A is within the distance OB). Moments M are considered positive when there is tension in the bottom fibers, and the angle changes caused by positive moments are taken as positive. Deflections δ are assumed positive, if they are above the tangent of reference. The quantities n_0 and u_0 refer to the points with the moments M_0, and the quantities n_{01} and u_{01} to the points with the moments M_{01}.

Curvilinear moment diagrams can be treated by dividing the curves into a number of sufficiently narrow trapezoids and applying appropriate equations. When a large number of trapezoids is necessary, the computation is quite laborious.

A special case, which cannot be solved by the foregoing equations, Eqs. 11, 12, 17*a*, 20, and 21, involves the rectangular moment curve shown as Fig. 11(*f*). In this case the flange strain ϵ_0 is constant all along the beam and, by Eq. 7*b*:

$$\phi = \frac{2\, x_0\, \epsilon_0}{h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22a)$$

and

$$\delta = \tfrac{1}{3}\, x_0\, \phi = \frac{\epsilon_0\, x^2{}_0}{h} \quad \text{(22}b\text{)}$$

Angle changes occurring in the elastic range are proportional to bending moments, which follows from the well-known formula:

$$d\phi = \frac{M}{E\,I}\, dx \quad \text{(23}a\text{)}$$

and the moment diagram may thus be considered as a scale picture of the angle changes. At the same time:

$$d\phi = \frac{2\,\epsilon}{h}\, dx \quad \text{(23}b\text{)}$$

These relations will be utilized in Section 8, in computations pertaining to the elastic range.

Beyond the elastic range the angle changes increase much faster than the moments, and the moment diagram does not represent the angle changes to scale. Referring to Fig. 7, point D, where the tangents at the ends of the deflected beam meet, is a distance $\bar{d}$ from the point of zero moment, point A. By geometry and by Eqs. 13*b* and 18:

$$\bar{d} = \frac{\delta}{\phi} = x_0\, \frac{u_0}{m_0\, n_0} \quad \text{(24)}$$

In the elastic range, $\bar{d} = \frac{2}{3}\, x_0$, but beyond it $\bar{d}$ increases and may even approach x_0.

Once the expressions for the deflections and angle changes in beams are known, the indeterminate stress analysis outside the elastic range is in no way different from conventional analysis, and it merely consists in setting up the equations between the deflections and the angle changes prescribed by the conditions of restraint.

6. SHEARING STRESSES IN BEAMS

The greatest shearing stress existing on a normal or a longitudinal plane of an I-beam is present in the web of the beam at the neutral axis, and an expression will be derived for the value of this stress τ_0, following the method used in the elastic analysis.

Fig. 12 represents one half of the cross section of an I-beam and the free body diagram of the length *dx* of this section. The greatest strains at the left and right sides of this section are ϵ and $(\epsilon + d\epsilon)$, respectively. Recalling the definition of the function *q* in Eq. 6*b*, the following expression is obtained from the condition of equilibrium of horizontal forces:

$$\tau_0\, b\, dx = \tfrac{1}{2}\, A_w \left[q\,(\epsilon + d\epsilon) - q(\epsilon)\right] = \tfrac{1}{2}\, A_w\, dq \quad \text{(25}a\text{)}$$

and

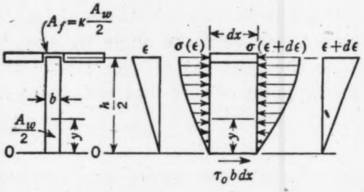
$$\tau_0 = \frac{h}{2}\, \frac{dq}{dx} \quad \text{(25}b\text{)}$$

If Eq. 8c is substituted for dx in Eq. 25b:

$$\tau_0 = \frac{V}{A_w}\frac{dq}{dm} \qquad (25c)$$

The function $\frac{dq}{dm}$ must be computed point by point, by taking increments of the functions q and m corresponding to the same increments in ϵ.

Thus, shearing stresses in inelastic range are dependent not only on the shearing force V, but also on the bending moment, since the latter determines the strain ϵ, and the derivative $\frac{dq}{dm}$ is a function of ϵ. The ratio $\frac{V}{A_w}$ represents uniform shearing stress per square unit of area of the web. The function $\frac{dq}{dm}$ therefore signifies a coefficient allowing for nonuniformity of shear distribution over the web.



(a) (b)

FIG. 12

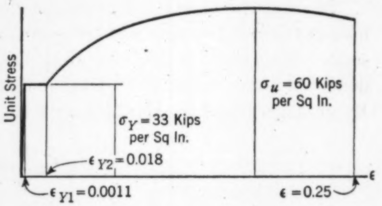


FIG. 13

A similar procedure leads to a more general formula for the value of the horizontal or vertical shearing stress at a distance y from the neutral axis (Fig. 12):

$$\tau = \frac{V}{A_w}\frac{d\left[\,q(\epsilon) - \frac{y}{\frac{1}{2}h}q_1\left(\frac{y}{\frac{1}{2}h}\epsilon\right)\right]}{dm(\epsilon)} \qquad (25d)$$

In Eqs. 25a and 25d, $q(\epsilon)$ and $m(\epsilon)$ signify the values of the functions q and m corresponding to the value ϵ of the strain in the outer fibers of the beam, whereas $q_1\left(\frac{y}{\frac{1}{2}h}\epsilon\right)$ represents the value of the function q_1 corresponding to the value of the strain $\frac{y}{\frac{1}{2}h}\epsilon$.

7. FUNCTIONS m, n, u, AND $\frac{dq}{dm}$ FOR MILD STEEL BEAMS

The foregoing bending theory will be applied to mild steel beams, whose stress-strain curve is presented in Fig. 13 and in Table 1(a). The main mechanical properties of this steel satisfy the material requirements of the 1940 Specifications of the American Railway Engineering Association for fixed-span railway bridges. They are as follows:

Unit Stresses, in Kips Per Square Inch—	
Yield point	33
Ultimate strength	60
Modulus of elasticity	30,000
Unit strain (%) at the beginning of yielding	0.11
Percentage elongation in 8 in.	25

In comparison with the actual curve, the stress-strain curve in Fig. 13 is idealized in two respects: First, the elastic section of the curve is assumed to continue straight to the yield point without any curved transition; and, second, the yield section is assumed to extend horizontally to the point where the strain hardening begins—at $\epsilon = 1.8\%$. These approximations do not distort the mechanical behavior of beams materially, and they are introduced merely for the purpose of reducing the labor of computation and not because they are inherent in the theory presented.

The necessary derived curves are computed for four values of the parameter κ—0, ½, 1, and 1½. The first of these values corresponds to a rectangular beam, whereas the remaining three cover the range of standard I-beams. Formulas pertaining to the elastic and plastic parts of the derived curves (that is, the parts within the limits of ϵ from zero to 0.11% and from 0.11% to 1.8%, respectively) can be developed by algebra as demonstrated in Sections 8 and 9.

8. Elastic Part

In the elastic range, $\sigma = E\,\epsilon$. Substituting this value in Eq. 4 and integrating:

$$m = (\kappa + \tfrac{1}{3})\,\sigma = E\,(\kappa + \tfrac{1}{3})\,\epsilon \qquad (26a)$$

Differentiating Eq. 26*a* and substituting *m* and *dm* in Eqs. 10 and 17*b* for *n* and *u*:

$$n = \tfrac{1}{2}\,E\,(\kappa + \tfrac{1}{3})\,\epsilon^2 = \tfrac{1}{2}\,(\kappa + \tfrac{1}{3})\,\sigma\,\epsilon \qquad (26b)$$

and

$$u = \tfrac{1}{3}\,E^2\,(\kappa + \tfrac{1}{3})^2\,\epsilon^3 = \tfrac{1}{3}\,(\kappa + \tfrac{1}{3})^2\,\sigma^2\,\epsilon \qquad (26c)$$

Similarly, by Eq. 6*b*,

$$q = (\kappa + \tfrac{1}{2})\,E\,\epsilon \qquad (27a)$$

and

$$\frac{dq}{dm} = \frac{\kappa + \frac{1}{2}}{\kappa + \frac{1}{3}} \qquad (27b)$$

Eqs. 26 and 27 are valid to the beginning of yielding, where the coordinates of the stress-strain curve are $\epsilon = \epsilon_{Y1}$ and $\sigma = \sigma_y$.

The specific values of these functions at the yield point under the conditions of the assumed stress-strain curve are as follows:

$$m = 33\,(\kappa + \tfrac{1}{3})\left(\frac{\text{kips}}{\text{in.}^2}\right) \qquad (28a)$$

$$n = 0.01815\,(\kappa + \tfrac{1}{3})\left(\frac{\text{kips}}{\text{in.}^2}\right) \qquad (28b)$$

and

$$u = 0.3993\ (\kappa + \tfrac{1}{3})^2 \left(\frac{\text{kips}^2}{\text{in.}^4}\right) \ldots\ldots\ldots\ldots\ldots\ldots (28c)$$

Expressions for the angle change and deflection in the elastic range, obtained by substituting Eqs. 26*b* and 26*c* in Eqs. 11 and 17*a*, and simplifying, are:

$$\phi = \frac{x\,\epsilon}{h} \ldots\ldots\ldots\ldots\ldots\ldots (29a)$$

and

$$\delta = \tfrac{2}{3}\,\frac{x^2\,\epsilon}{h} \ldots\ldots\ldots\ldots\ldots\ldots (29b)$$

9. Plastic Part

In the plastic range, $\sigma = \sigma_y$ = constant, as ϵ varies between the limits of ϵ_{Y1} and ϵ_{Y2}. Although the expression for the m-function can be obtained from the basic formula, Eq. 4, it is derived more conveniently from the first principles (Fig. 14) by taking moments about the axis OO of the normal stresses distributed over the section as shown:

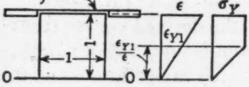

Fig. 14

$$m = \kappa\,\sigma_Y(1) + \sigma_Y(1)\tfrac{1}{2} - \frac{\sigma_Y}{2}\,\frac{\epsilon_{Y1}}{\epsilon}\,\frac{1}{3}\,\frac{\epsilon_{Y1}}{\epsilon} = (\kappa + \tfrac{1}{2})\,\sigma_Y - \frac{\sigma_Y}{6}\left(\frac{\epsilon_{Y1}}{\epsilon}\right)^2 \ldots (30a)$$

By Eq. 10,

$$n = \int_0^{\epsilon_{Y1}} \epsilon\, dm + \int_{\epsilon_{Y1}}^{\epsilon} \epsilon\, dm \ldots\ldots\ldots\ldots\ldots\ldots (30b)$$

By Eq. 26*b*,

$$\int_0^{\epsilon_{Y1}} \epsilon\, dm = \frac{E}{2}\,(\kappa + \tfrac{1}{3})\,\epsilon^2_{Y1} \ldots\ldots\ldots\ldots\ldots\ldots (30c)$$

From Eq. 30*a*,

$$dm = \frac{\sigma_Y}{3}\,\frac{\epsilon^2_{Y1}}{\epsilon^3}\,d\epsilon \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

Eq. 31 makes it possible to evaluate the second integral in the expression for n. Then:

$$n = E\,\epsilon^2_{Y1}\left[\tfrac{1}{2}\,(1 + \kappa) - \tfrac{1}{3}\,\frac{\epsilon_{Y1}}{\epsilon}\right] \ldots\ldots\ldots\ldots\ldots\ldots (32a)$$

By applying the same procedure to u,

$$u = \tfrac{1}{3}\,E^2\,\epsilon^3_{Y1}\left[\left(\kappa^2 + \frac{5}{3}\,\kappa + \frac{5}{9}\right) - (\kappa + 0.5)\,\frac{\epsilon_{Y1}}{\epsilon} + \frac{1}{18}\left(\frac{\epsilon_{Y1}}{\epsilon}\right)^3\right] \ldots (32b)$$

From Fig. 14,

$$q = (\kappa + 1)\,\sigma_Y - \frac{\sigma_Y}{2}\,\frac{\epsilon_{Y1}}{\epsilon} \ldots\ldots\ldots\ldots\ldots\ldots (32c)$$

Then, by differentiating Eqs. 30*a* and 32*c* and simplifying:

$$\frac{dq}{dm} = \frac{3}{2}\,\frac{\epsilon}{\epsilon_{Y1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

At the beginning of yielding, where $\epsilon = \epsilon_{Y1}$, $\dfrac{dq}{dm} = \frac{3}{2}$, as in a rectangular beam.

At the end of yielding, where $\epsilon = \epsilon_{Y2} = \dfrac{1.8}{0.11}$, $\dfrac{dq}{dm} = 24.54$.

10. Strain-Hardening Part

Values of the derived functions above the plastic range can be computed only by successive summation of the increments of integrals, with all the necessary values properly tabulated in a systematic manner. The method is illustrated by an example of quantities referring to $\kappa = 1$ and $\epsilon = 0.020$. First, the necessary values of functions corresponding to the value of $\epsilon = 0.018$, immediately below $\epsilon = 0.020$, are found either by integration, or by step-by-step summation.

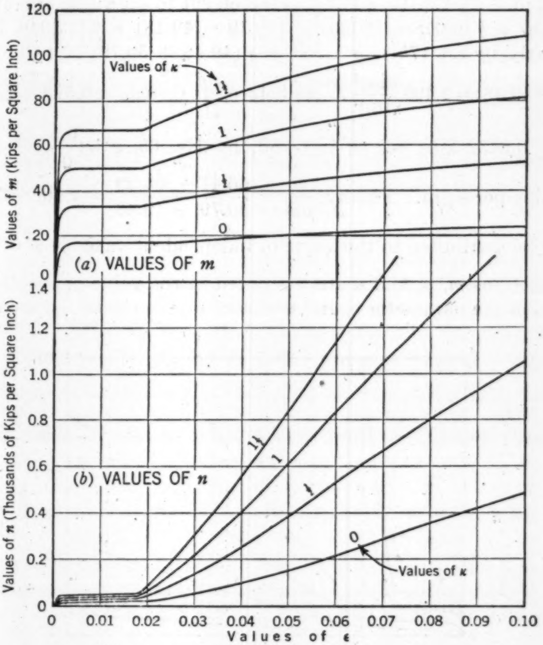

Fig. 15.—Constants for the Design of Mild Steel Beams

For $\epsilon = 0.018$.—

Solving Eqs. 30*a* and 32: $m = 49.48$ kips per sq in.; $n = 0.03556$ kips per sq in.; $u = 1.250 \frac{\text{kips}^2}{\text{in.}^4}$; and $q = 64.99$ kips per sq in. Furthermore, $\int_0^{0.018} \sigma \, d\epsilon = 0.576$ kips per sq in.; and $\int_0^{0.018} \epsilon \, \sigma \, d\epsilon = 0.005340$ kips per sq in.

For $\epsilon = 0.020$.—

The stress-strain curve gives $\sigma = 34.25$ kips per sq in. for $\epsilon = 0.020$, from which $\int_0^{0.020} \epsilon \, \sigma \, d\epsilon = 0.005340 + \frac{1}{2}(0.018 + 0.020) \times \frac{1}{2}(33 + 34.25) \times 0.002 = 0.006618$ kips per sq in. By Eq. 4, $m = \frac{0.006618}{0.020^2} + 1 \times 34.25 = 50.79$ kips per sq in. By Eq. 10, adding an increment to the value of n at $\epsilon = 0.018$, $n = 0.03556 + \frac{1}{2}(0.018 + 0.020) \times (50.79 - 49.48) = 0.006046$ kips per sq in. Similarly, by Eq. 17*b*, $u = 1.250 + \frac{1}{2}(49.48 + 50.79) \times \frac{1}{2}(0.018 + 0.020) \times (50.79 - 49.48) = 2.499 \frac{\text{kips}^2}{\text{in.}^4}$. As before, $\int_0^{0.020} \sigma \, d\epsilon = 0.576 + \frac{1}{2}(33 + 34.25) \times 0.002 = 0.6432$ kips per sq in.; and, by Eq. 6*b*, $q = \frac{0.6432}{0.020} + 1 \times 34.25 = 66.41$ kips per sq in. Finally, $\frac{dq}{dm} = \frac{66.41 - 64.99}{50.79 - 49.48} = 1.10$. This value of $\frac{dq}{dm}$ should be attributed to the value of independent variable $\epsilon = 0.019$.

The functions m, n, and u are computed to the value of $\epsilon = 0.100$, for the four values of the parameter κ, and the results of computation are presented in Figs. 15 and 16 and, in a greatly expanded form, in Table 1(*a*). The graphs, not being very accurate, serve merely as illustrations, whereas the more comprehensive table, of which Table 1(*a*) is a part, is intended for use in the analysis.

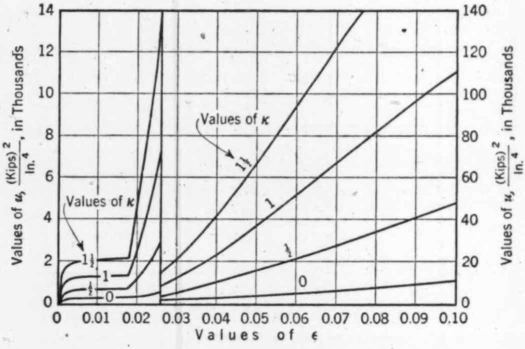

Fig. 16.—Curves for the Constant u, in Mild Steel Beams

11. EFFECT OF SHEAR STRESSES

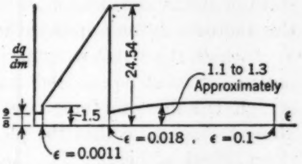

FIG. 17 (Not to Scale)

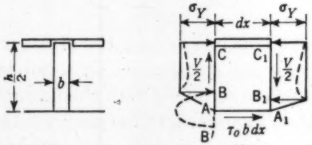
Only one set of values of the shear coefficient $\frac{dq}{dm}$, corresponding to $\kappa = 1$, is given in Fig. 17 and in Table 1(*a*), in view of the comparative unimportance of this coefficient in design. Some comments are needed on the numerical values of this coefficient, however. Everywhere outside the plastic range (that is, outside the limits of ϵ from 0.0011 to 0.018) this coefficient has a magnitude of from approximately 1.1 to 1.3, which signifies that the greatest shearing stress in the web of the beam is only from about 10% to 30% higher than the average stress per unit area of the web. In the plastic range, however, this coefficient varies independently of the value of κ, and in a straight line from the value 1.5 at $\epsilon = \epsilon_{Y1}$ to a very high value of 24.54 at $\epsilon = \epsilon_{Y2}$.

The correctness of this rather startling phenomenon is made plain by reference to Fig. 18 representing the free body diagram of a small element of an I-beam. Since normal stresses on the parts of the sections BC and B_1C_1 are constant and equal, no shearing stresses acting either on horizontal or on vertical planes are possible in these outer parts of the web BC, all shear on the cross section thus being localized on a small central part of the web BB′. The intensity of stress on BB′, indicated by a dotted parabola, may rise very high, because the resultant shearing stress over the cross section must equal the shearing force.



(*a*) (*b*)

FIG. 18

Of course, this deduction is only as authentic as the underlying assumption of plane cross sections. If the cross sections warp (which seems inevitable in the presence of high shearing stresses), some redistribution of stresses and strains, both normal and tangential, must follow—a condition which raises some doubts as to the validity of the present theory of bending in the plastic range.

In appraising the effect of this stress irregularity, several aspects of the situation will be distinguished and discussed: (1) The high value of shear stresses (2) the redistribution of normal stresses; and (3) the additional angle changes caused by warping.

(*1*) *High Value of the Shearing Stress.*—Shear stresses reach an intensity of 24.5 times the average stress per unit area of the web. From general considerations it appears certain that, if the absolute value of this stress is high, it is relieved by warping, perhaps to the level of yielding, because a high concentration of stress, sharply localized over a small area, is inconceivable in the absence of concentrated loads.

(2) *Redistribution of Normal Stresses in the Planes of Cross Sections Produced by Warping.*—Although this effect is undoubtedly present, it is likely to be small since, in the plastic and strain-hardening regions, only a slight change in the normal stresses is possible, even after an appreciable change in the strains.

(3) *Additional Angle Changes Caused by Warping.*—Such angle changes influence the values of static unknowns and, through them, affect the general state of stress and deformation over the entire structure. The significance of this factor may be appraised indirectly by estimating the length of the beam, over which the stress irregularity considered may possibly occur. In this connection, it must be realized that, if the average unit shearing stress in the web is high, the shearing force is great, and the bending moment builds up quickly along the span, so that the plastic range of normal stresses is passed over in a short length of beam. On the other hand, if the plastic state occupies a great length of the beam, the shearing force (and with it the average shearing stress in the web) must be small, and even a high coefficient of nonuniformity would not raise the maximum shearing stress beyond the yield point.

By using appropriate values for Δq and τ_0 in Eq. 25*b* the greatest length, on which the warping is possible in the most extreme case is of the order of $\Delta x = \frac{1}{4} h$. This length appears too small to produce an appreciable effect on the static unknowns.

The foregoing material seems to warrant the conclusion that the stress irregularity occurring in the plastic region of normal stresses is too small to affect the strength of beams noticeably or to interfere seriously with the flexural theory based on linearity of the cross sections. Therefore, in Sections 14, 15, and 16 no allowance will be made for the warping of cross sections in the plastic region.

12. STRESS RECESSION

In many important construction materials the stress-strain curve of unloading, in straight tension or compression, may be closely approximated by a straight line YO_1Y_1 parallel to the elastic part of the curve OA (Fig. 19). The

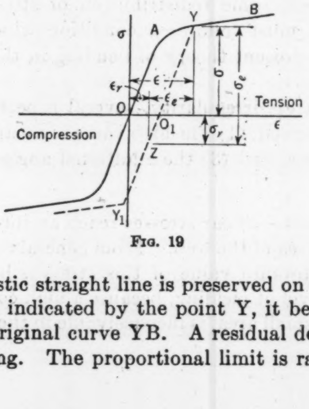


FIG. 19

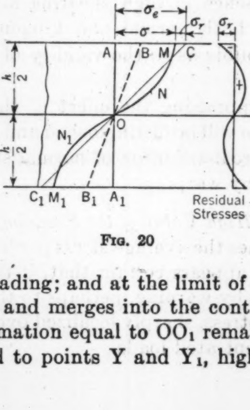

FIG. 20

new elastic straight line is preserved on reloading; and at the limit of the first loading, indicated by the point Y, it bends and merges into the continuation of the original curve YB. A residual deformation equal to $\overline{OO_1}$ remains after unloading. The proportional limit is raised to points Y and Y_1, higher than before, whereas the modulus of elasticity retains its former value. These experimental facts, together with the assumptions stated in Section 1, form the basis of the theory of bending past the elastic limit when there is a stress recession.

Imagine a beam subjected to bending, whose normal stresses in the section AA_1 Fig. 20 are represented by the curve $MNON_1M_1$. If there is a decrease in the bending moment, the assumption of plane cross sections, combined with the mechanics of stress recession, explained in Fig. 19, demands that the decrease in stresses should be linear, so that the remaining stresses correspond to the difference of ordinates between the original curve $MNON_1M_1$ and an appropriate straight line BB_1. Further reduction in moment causes the straight line BB_1 to move farther from AA_1; and, when the moment is brought to zero, the residual stresses are represented by the difference between the ordinates of the curves $MNON_1M_1$ and CC_1, whose statical effect is zero.

An important deduction is that removal of bending moment from the beam does not result in the disappearance of all stress or of all strain. If point Y in Fig. 19 represents the state of stress in the outer fibers of the beam when the loads are first applied, the removal of the moment causes a reduction in stress σ by an amount σ_e, which brings the state of stress to point Z, Fig. 19, with a residual stress σ_r and strain ϵ_r. The presence of the latter is accompanied by a residual angle change:

$$d\phi_r = 2\frac{\epsilon_r}{h}dx \qquad (34)$$

Let the bending moment in the beam created by applied loads be M, then the corresponding m-function is computed by Eq. 5. The elastic strain ϵ_e and stress σ_e superimposed on the outer fibers of the beam by a complete removal of the moment, are found by Eq. 26a, using this value of m:

$$\epsilon_e = \frac{m}{E(\kappa + \frac{1}{3})} \qquad (35a)$$

and

$$\sigma_e = E\,\epsilon_e = \frac{m}{\kappa + \frac{1}{3}} \qquad (35b)$$

The residual strain and stress in the outside fibers of the beam are:

$$\epsilon_r = \epsilon - \frac{m}{E(\kappa + \frac{1}{3})} \qquad (36a)$$

and

$$\sigma_r = \sigma - \frac{m}{\kappa + \frac{1}{3}} \qquad (36b)$$

The residual strain ϵ_r has the same sign as the original strain ϵ, whereas the residual stress σ_r proves to be negative (that is, of the opposite sign from σ). These facts follow clearly from Figs. 19 and 20.

The angle change and the deflection caused by the release of bending moment, in the case of the simple triangular moment diagram in Fig. 7, are found by substituting the expression for strain caused by the moment removal, Eq.

35*a*, in the equations for the elastic angle change and deflection, Eqs. 29*a* and 29*b*:

$$\phi_e = \frac{x\,m}{E\,h\,(\kappa + \frac{1}{3})} \qquad \text{(37a)}$$

and

$$\delta_e = \frac{2}{3}\,\frac{x^2\,m}{E\,h\,(\kappa + \frac{1}{3})} \qquad \text{(37b)}$$

The form of Eqs. 37 is not entirely convenient. Replacing x by $\frac{M}{V}$ and substituting for the moment its expression in terms of the m-function, Eq. 5, the following expressions result:

$$\phi_e = \frac{1}{2}\,\frac{A_w}{V}\,\frac{m^2}{E(\kappa + \frac{1}{3})} \qquad \text{(38a)}$$

and

$$\delta_e = \frac{h}{6}\left(\frac{A_w}{V}\right)^2 \frac{m^3}{E(\kappa + \frac{1}{3})} \qquad \text{(38b)}$$

Subtracting Eqs. 38 from the corresponding deformations brought about by creation of the moments, Eqs. 11 and 17*a*, the residual values, ϕ_r and δ_r, remaining after complete disappearance of moments, are found to be:

$$\phi_r = \frac{A_w}{V}\left[n - \frac{1}{2}\,\frac{m^2}{E(\kappa + \frac{1}{3})}\right] \qquad \text{(39a)}$$

and

$$\delta_r = \frac{h}{2}\left(\frac{A_w}{V}\right)^2 \left[u - \frac{1}{3}\,\frac{m^3}{E(\kappa + \frac{1}{3})}\right] \qquad \text{(39b)}$$

The values of the functions m, n, and u in Eqs. 39 refer to the state of stress at the end of beam B, Fig. 7, under full loading. Expressions in the square brackets do not depend on the dimensions of the beam, except for the parameter κ, and they may be considered as the new derived functions n_r and u_r, defined as follows:

$$n_r = n - \frac{1}{2}\,\frac{m^2}{E(\kappa + \frac{1}{3})} \qquad \text{(40a)}$$

and

$$u_r = u - \frac{1}{3}\,\frac{m^3}{E(\kappa + \frac{1}{3})} \qquad \text{(40b)}$$

Eqs. 40 can be used for the determination of residual deflections and angle changes in exactly the same fashion as the original functions n and u are used for computing the deformations produced by creation of the moments. For this reason, Eqs. 11, 12, 17*a*, 18, 20, and 21 hold equally true for the residual deformations in their respective conditions, if the functions n and u are replaced by the corresponding functions n_r and u_r. In the elastic range the residual functions are evidently zero. Numerical values of the functions ϵ_r, σ_r, n_r, and u_r computed for different values of the independent variable ϵ and the value of the parameter $\kappa = 1$ are presented in Table 1(*b*).

When a residual deformation occurs in a statically determinate structure, it meets with no impediment and materializes freely. The situation is different in statically indeterminate structures, in which the conditions of restraint make a free adjustment of the beam to a "no moment" state impossible. As a result, residual moments are created when the structure is unloaded, and the stresses and strains caused by the residual moments, are added to "no moment" stresses and strains. Thus, a "no loading" condition following the removal of load in a statically indeterminate beam must not be confused with the "no moment" condition. The transition from a fully loaded condition to "no loading" condition is probably always elastic, and can be analyzed by the usual formulas of the elastic theory. Since this last statement is quite important for further discussion, particularly in the analysis of moving loads, it is worthy of some elaboration. It can be expressed in the following shorthand form:

$$(\text{ALS}) - (\text{ELS}) = (\text{RS}) \quad \dots\dots\dots\dots\dots\dots (41)$$

in which (ALS) signifies the actual state of stress in the loaded structure, including moments, stresses, and strains, found by the theory presented herein; (ELS) denotes the state of stress under the same loading, found by the usual formulas of the strength of materials (although it is known that the moments so found project beyond the elastic range); and (RS) represents the residual state of stress after removal of all load. The minus sign in the left-hand side of Eq. 41 signifies the ordinary algebraic subtraction of the moments, stresses, and strains pertaining to the two states.

Eq. 41 holds true also when the beam has been pre-stressed past the elastic limit by one or several applications of loads, including movable loads, previous to the application of the load whose effect is being considered. In this case, (ALS) should signify the state created as a result of all loadings, including the last one; (RS) represents what remains after the last load has been removed; and (ELS) indicates the elastic stress condition created by the last loading alone. The details of application of this principle to movable loads will be explained in Example 3, Section 16.

13. Computation of Shape Constants of an I-Beam

The computation is illustrated by an example involving the standard I-beam (18 I 54.7) shown in Fig. 21: $h = 18.00 - \frac{1}{2}(0.46 + 0.92) = 17.31$ in.;

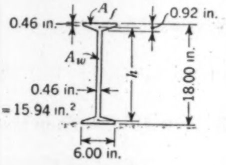

FIG. 21

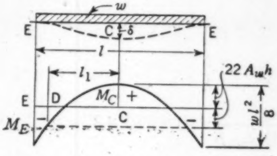

FIG. 22

$A_w = 0.46\,(17.31) = 7.96$ in.^{2}; $A_f = \frac{1}{2}(15.94 - 7.96) = 3.99$ in.^{2}; and $\kappa = \dfrac{3.99}{\frac{1}{2}(7.96)} = 1.00$.

The following examples are solved in general terms using a mild steel I-beam with $\kappa = 1$. If specific values are needed, pertaining to an 18 I 54.7, they can be obtained by substituting the foregoing values of h and A_w in the formulas derived.

14. Example 1

Given a uniformly-loaded, fixed-ended, I-beam with $\kappa = 1$ (Fig. 22), find the value of the load (referred to as the capacity load) for which the stress at the center just reaches the yield point. For this value of the load find the stress conditions at the ends and the deflection at the center. Find also the residual state (RS) brought about by removal of this load.

Because of symmetry, there is only one static unknown, the moment at the end M_E. This is larger than the moment at the center, M_C, and therefore, at some point near the end, such as point D, the moment is equal to the moment at the center.

The method of solution consists in assuming an appropriate value for M_E, or better, in assuming an appropriate value for the maximum strain at the end ϵ_E, and on this assumption determining the angle change produced on one half of the length of the beam. This angle change should be equal to zero.

From Table 1(*a*) and Eq. 5, the following conditions exist at points C and D: $1{,}000\,\epsilon = 1.1$; $\sigma = 33$ (kips/in.^{2}); $m = 44$ (kips/in.^{2}); $1{,}000\,n = 24.2$ (kips/in.^{2}); and $M = 22$ (kips/in.^{2}) $A_w\,h$. The units accompanying the expression for M actually belong to the numerical coefficient; and, in combination with the units of A_w and h, they produce the proper moment units.

Trial 1.—At point E, Fig. 22, assume $1{,}000\,\epsilon_E = 22$. Then, by Table 1(*a*), $m_E = 52.06$ (kips/in.^{2}); $1{,}000\,n_E = 87.13$ (kips/in.^{2}); and $M_E = 26.03$ (kips/in.^{2}) $A_w\,h$.

By the properties of a parabola, the length $l_1 = \overline{\mathrm{DC}}$, over which the stress is elastic, is found as follows: $l_1 = \frac{1}{2}\,l\sqrt{\dfrac{22 + 22}{22 + 26.03}} = 0.4787\,l$; then, $\overline{\mathrm{ED}} = x = 0.0213\,l$.

Assuming that the moment curve on the length ED is straight, the shearing force on this length is $V = \dfrac{(26.03 - 22)\,A_w\,h}{0.0213\,l} = 189.0$ (kips/in.^{2}) $\dfrac{A_w\,h}{l}$.

Remembering that in the elastic region $\dfrac{M}{E\,I} = \dfrac{2\,\epsilon}{h}$, the angle change occurring on the elastic part DC is $\phi_{DC} = \dfrac{2}{h}\,(10^{-3})\,[\frac{2}{3}\,(2)(1.1)(0.4787)\,l - (1.1)(0.4787)\,l] = 0.351\,(10^{-3})\,\dfrac{l}{h}$. The angle change in the length ED, by Eq. 12, is $\phi_{ED} = -\dfrac{A_w\,l}{(189.0)\,A_w\,h}\,(10^{-3})(87.13 - 24.2) = -\,0.333\,(10^{-3})\,\dfrac{l}{h}$. Then the total angle change in one half of the span length is $\phi_{EC} = 0.018\,(10^{-3})\,\dfrac{l}{h}$. Since ϕ_{EC} is positive, the values of the moment and of the strain at the end of the beam have been underestimated.

When the procedure is repeated in trial 2, assuming $\epsilon_E = 23\,(10^{-3})$, the resultant angle change is $\phi_{EC} = -\,0.058\,(10^{-3})\,\dfrac{l}{h}$. The true value of ϵ_E can be found by linear interpolation, assuming that ϵ_E varies in proportion to ϕ_{EC}. Thus, $\epsilon_E = \left(22 + \frac{18}{18 + 58}\right) 10^{-3} = 22.25\ (10^{-3})$.

The third trial made with this value of ϵ_E yields $\phi_{EC} = -\ 0.002\ (10^{-3})\ \frac{l}{h}$. Since this is negligible, the value $\epsilon_E = 22.25\ (10^{-3})$ may be considered as the true value. The corresponding value of the m-function can be found by interpolation in the design Table 1(a): $m_E = 52.06 + \frac{0.25}{2}\ (53.33 - 52.06) = 52.22$ (kips/in.²); and

$$M = 26.11\ (\text{kips/in.}^2)\ A_w\, h = C_M\, A_w\, h \ldots\ldots\ldots\ldots (42a)$$

in which $C_M = 26.11$ kips per sq in., is a coefficient. Linear interpolation has been found to work quite well, when the requisite statically unknown strain extends, as in this particular case, into the strain-hardening region. Under these circumstances, two reasonably close trials are sufficient for the solution. When the unknown strain is found in the plastic range, its variation with ϕ is not linear, and more than two trials may be needed for accurate results. In that case ϵ is very unstable.

The required intensity of the uniform loading (w) is now found by statics: $(26.11 + 22)\ A_w\, h = \frac{1}{8}\, w\, l^2$ and

$$w = 384.9\ (\text{kips/in.}^2)\ \frac{A_w\, h}{l^2} = C_w\, \frac{A_w\, h}{l^2} \ldots\ldots\ldots\ldots (42b)$$

in which $C_w = 384.9$ kips per sq in. is a coefficient.

The deflection δ at the center of the beam is found, by reference to Fig. 23, as the sum of two deflections caused by deformations of the parts ED and DC: $\overline{DC} = 0.5\, l \sqrt{\frac{22 + 22}{26.11 + 22}} = 0.4782\ l$; and $\overline{ED} = 0.0218\, l$.

The position of point F, Fig. 23, where the straight line ed cuts the axis, is found from $\bar{x} = 0.5\, l - \frac{26.11}{26.11 - 22}\ (0.0218\, l) = 0.3614\, l$.

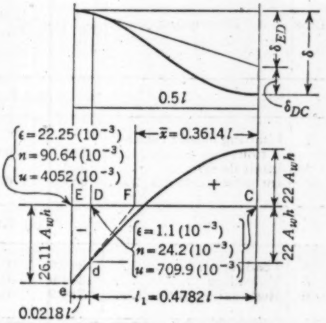

FIG. 23

The shearing force on the length ED is

$$V = \frac{4.11\ A_w\, h}{0.0218\, l} = 188.5\ (\text{kips/in.}^2)\ \frac{A_w\, h}{l} = C_V\, \frac{A_w\, h}{l} \ldots\ldots . (42c)$$

The values of n and u at point E are found from Table 1(a) by interpolation. They are stated in Fig. 23 together with the values of the same functions at point D. By Eq. 21a, $\delta_{ED} = -\left[\frac{h}{2}\left(\frac{1}{188.5}\,\frac{l}{h}\right)^2 (4{,}052 - 709.9)\ (10^{-3})\right.$

$+ \frac{1}{188.5} \frac{l}{h} (0.3614\, l)(90.64 - 24.2)\, 10^{-3} \Big] = -\, 0.1743\, (10^{-3}) \frac{l^2}{h}$. By elastic relations, $\delta_{DC} = -\, (\tfrac{2}{3}) \frac{2}{h} (1.1)\, 10^{-3} (0.4782\, l)(\tfrac{3}{8})(0.4782\, l) + \frac{1.1}{h}(10^{-3})(0.4782\, l) \times \tfrac{1}{2} \times (0.4782\, l) = 0$. Therefore,

$$\delta = -\, 0.1743\, (10^{-3}) \frac{l^2}{h} = -\, C_\delta \frac{l^2}{h} \qquad \text{(42}d\text{)}$$

The results are summarized in line 3, Table 2(*a*) under the title "Inelastic Condition." For comparison, two other sets of capacity loads and stresses are also given, one determined by the theory of limit design (line 2) and the other by the elastic theory (line 1), corresponding to the condition when the yield point has first been reached in the beam. In computing these additional data, the following values of the beam constants have been used: $E = 30{,}000$ kips per sq in. and

since $\frac{A_f}{\frac{1}{2} A_w} = \kappa = 1$.

The residual state of stress (RS) is determined by adding to the moments, stresses, and strains determined in Table 2(*a*) the corresponding functions found by the elastic application of the same loads in the opposite direction.

This is done in Table 2(*b*). The functions added to the original ones are stated in line 5. They are found by increasing the values pertaining to "Limiting Elastic Condition" in Table 2(*a*) in the ratio of the loads, and changing the signs. The negative sign of stresses and strains in Table 2(*b*) indicates an action opposite to the one created by the original loading.

15. Example 2

Given a fixed-ended I-beam with $\kappa = 1$, loaded with a concentrated load P at one eighth of its span length (see Fig. 24), find the value of the load for which the moment under the load just reaches the yield point. Find also the corresponding stresses and strains.

The conditions in this problem are purposely assumed so as to create a great disparity in the moments at the three critical points—that is, at the two ends and at the load. The structure is twice statically indeterminate. For this reason, the solution involves guessing at two moments or corresponding strains at once, and necessitates at least three trial assumptions instead of the two in the first problem. The moment and strain under the load are known, and the strains at the ends are assumed, using some judgment and bearing in mind the relation between the moments in the elastic range. With the conditions of strain thus known, the angle change on the entire length of the beam and the deflection of end E in relation to the tangent at end E_1 are determined and compared to zero, which value they should possess to satisfy the conditions of restraint. These deformations are found by the double application of Eqs. 12 and 21*c* in the same manner as in Example 1. The quantities entering these formulas are mostly taken from Table 1(*a*) or are computed by geometry in Fig. 24. They are all conveniently arranged in Table 3. The values of the strain functions below the proportional limit are determined by comparison with the values at the proportional limit, where $\epsilon = 1.1\ (10^{-3})$, by the following relations evident from Eqs. 26: m is proportional to ϵ, n is proportional to ϵ^2, and u is proportional to ϵ^3.

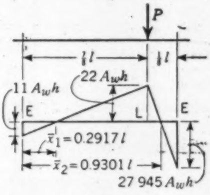

FIG. 24

TABLE 3.—TRIAL 1 (SEE FIG. 24)

Trial 1.—From values assembled in Table 3: $\phi = \left(\frac{18.15}{37.72} - \frac{158.7}{399.6}\right) 10^{-3}\frac{l}{h} = +\,0.0836\,(10^{-3})\,\frac{l}{h}$; and $\delta = \left\{\left[\frac{1}{2}\,\frac{798.64}{(37.72)^2} + \frac{18.15}{37.72}\,(0.2917)\right] - \left[\frac{1}{2}\,\frac{9{,}754.9}{(399.6)^2} + \frac{158.7}{399.6}\,(0.9301)\right]\right\} 10^{-3}\,\frac{l^2}{h} = +\,0.0211\,(10^{-3})\,\frac{l^2}{h}$.

TABLE 4.—RESULT OF SUCCESSIVE TRIALS, EXAMPLE 2

Trial (1)	$10^3\,\epsilon_E$ (2)	$10^3\,\epsilon_L$ (3)	$10^3\,\epsilon_{E1}$ (4)	$C\varphi = \varphi(10)^3\,h/l$ (5)	$C\delta = \delta(10)^3\,h/l^2$ (6)
One....	0.55	1.1	28	+0.0836	+0.0211
Two....	0.77	1.1	28	−0.1085	−0.0346
Three..	0.55	1.1	30	−0.0034	−0.0650

Two other similar trials are now made, changing the values of the assumed unknown strains ϵ_E and ϵ_{E1}, one at a time. The corresponding values of ϕ and δ are computed, and the results are given in Table 4.

Assuming a linear variation of ϕ and δ with ϵ_E and ϵ_{E1} in the vicinity of zero, the rates of variation are:

$$\frac{\partial\phi}{\partial\epsilon_E} = \frac{-\,0.1085 - 0.0836}{0.77 - 0.55}\,\frac{l}{h} = -\,0.873\,\frac{l}{h}\ldots\ldots\ldots\ldots(44a)$$

$$\frac{\partial\delta}{\partial\epsilon_E} = \frac{-\,0.0346 - 0.0211}{0.77 - 0.55}\,\frac{l^2}{h} = -\,0.253\,\frac{l^2}{h}\ldots\ldots\ldots\ldots(44b)$$

$$\frac{\partial\phi}{\partial\epsilon_{E1}} = \frac{-\,0.0034 - 0.0836}{30 - 28}\,\frac{l}{h} = -\,0.0435\,\frac{l}{h}\ldots\ldots\ldots\ldots(44c)$$

and

$$\frac{\partial\delta}{\partial\epsilon_{E1}} = \frac{-\,0.0650 - 0.0211}{30 - 28}\,\frac{l^2}{h} = -\,0.0430\,\frac{l^2}{h}\ldots\ldots\ldots\ldots(44d)$$

The unknown increments $d\epsilon_E$ and $d\epsilon_{E1}$, which must be added to the values of the unknowns ϵ_E and ϵ_{E1}, assumed in the first trial, to make ϕ and δ both equal to zero, are found from the two simultaneous equations:

$$-\,0.873\,d\epsilon_E - 0.0435\,d\epsilon_{E1} + 0.0836\,(10^{-3}) = 0$$
$$-\,0.253\,d\epsilon_E - 0.0430\,d\epsilon_{E1} + 0.0211\,(10^{-3}) = 0$$

From these: $d\epsilon_E = 0.101\,(10^{-3})$; and $d\epsilon_{E1} = -\,0.108\,(10^{-3})$. Then the required strains are $\epsilon_E = (0.55 + 0.101)10^{-3} = 0.65\,(10^{-3})$; and $\epsilon_{E1} = (28 - 0.108)\,10^{-3} = 27.9\,(10^{-3})$.

FIG. 25

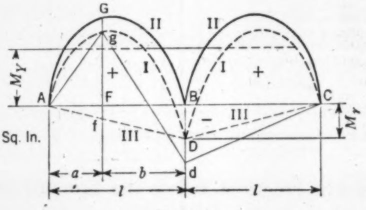

FIG. 26

The values of stresses and moments (Fig. 25) are now found by interpolation from Table 1(*a*). The load P equals the sum of the shearing forces in the two parts of the beam:

$$P = \left(\frac{13.00 + 22.00}{0.875} + \frac{22.00 + 27.91}{0.125} \right) \frac{A_w h}{l}$$

$$= 439.32 \left(\frac{\text{kips}}{\text{in.}^2} \right) \frac{A_w h}{l} = C_P \frac{A_w h}{l} \ldots\ldots\ldots\ldots\ldots (45a)$$

The maximum deflection δ occurs in the elastic region of the beam at point K, Fig. 25, where the slope is zero. It is found by the elastic formula:

TABLE 5.—DEFLECTIONS, STRAINS, STRESSES, MOMENTS UNDER CAPACITY LOADINGS

Load	Description
1	Limiting elastic condition in which P is such that the yield point is first reached in the beam.
2	Limit design.
3	Inelastic condition 1; beam loaded as in Example 2.
4	Inelastic condition 1; residual quantities after removal of load.
5	Inelastic condition 2; beam loaded, and the yield point is just reached at the far end E.
6	Inelastic condition 2; residual quantities.

These results are incorporated in Table 5, together with the conditions of loading, given for comparison.

16. EXAMPLE 3

Given a two-span continuous I-beam (Fig. 26), with $\kappa = 1$ acted on by a movable concentrated load; find the value of the load for which the stress at the support just reaches the yield point. It is assumed that the passage of the load producing this stress condition is preceded by several passages of smaller loads, whose values increase gradually to the capacity value.

A concentrated load passing over the beam creates certain maximum positive moments under the load; and in numerical value these moments exceed the negative moments produced at the middle support. Therefore, under the conditions of the problem, the inelastic deformations occur only under the loads. Curve I in Fig. 26 represents the curve of maximum positive moments. The middle sections of both spans, on which the moments exceed the yield point value $M_Y = 22\,A_w\,h$, undergo inelastic deformations, making the beam concave upward. When the load is removed, the residual deformations demand the presence of downward reactions at the outer supports to preserve the conditions of restraint. Therefore, the residual moment condition is such that it can be represented by the line III, Fig. 26. The final location of curve III has been reached gradually in the course of several previous passages of the increasing load P, and it will not be displaced farther, on a new passage, as long as the load P remains constant.

Curve II, Fig. 26, represents the curve of positive moments existing under the load, caused by the elastic application of the load P. When load P arrives at an arbitrary point F, the actual moment diagram is AgdC, Fig. 26. By the principle expressed in Eq. 41, this diagram differs from the diagram caused by the elastic application of the same load, by the ordinates of the curve III. Therefore, $\overline{\mathrm{Gg}} = \overline{\mathrm{fF}}$, and $\overline{\mathrm{Dd}}$ is the moment produced by the elastic application of the load. The value of the intercept Dd, Fig. 26, varies depending on the location of the load. Since the intercept BD is constant, the greatest negative bending moment Bd occurs at the same position of the load as in the elastic range, and by the conditions of the problem it is equal to 22 (kips/in.^{2}) $A_w\,h$.

The solution of this problem involves the use of the elastic formulas for the moments and consists of the following operations:

a. The unknown load P is assumed;
b. Using this value of P, the maximum elastic ordinate dD and the ordinates of the curves II and III are computed;
c. Curve I is found by combining the curves II and III;
d. Residual deflection of end A, Fig. 26, in relation to the tangent at the central support B, caused by the moments of curve I is computed by Table 1(*b*); and
e. The reaction necessary to bring end A back is computed, and the moments produced by it are compared with curve III, to check the assumed value of the load P.

In computing the deflection, curve I is replaced by a polygon. Although this curve does not represent a moment diagram for any single position of the load, it must be treated as if it were one. The slopes of its polygonal sides must be used as the shearing forces in the corresponding formulas for the deflection.

The elastic formulas are as follows (Fig. 26):

$$M_B\,(\text{max}) = 0.0961\,P\,l \ldots\ldots\ldots\ldots\ldots\ldots (46a)$$

and

$$M_f = \frac{P\,a\,b}{4\,l^3}\left[4\,l^2 - a(l + a)\right] \ldots\ldots\ldots\ldots\ldots\ldots (46b)$$

Trial 1.—In Fig. 26, let $P = 136\ \frac{\text{kips}}{\text{in.}^2} \times \frac{A_w\,h}{l}$. Then, by Eqs. 46, the elastic moment, $M_B\,(\text{max}) = 13.08\ (\text{kips/in.}^2)\ A_w\,h$; the residual moment at point B is $M_r = (22 - 13.08)\ A_w\,h = 8.92\ (\text{kips/in.}^2)\ A_w\,h$; and the moments of curve III, Fig. 26, are $M_{\text{III}} = -\frac{a}{l}\,(8.92)\ (\text{kips/in.}^2)\ A_w\,h$. In Table 6, the ordinates of curve I represent the difference between curves II and III. Curve I, slightly simplified, is shown in Fig. 27. The ordinates smaller than 22 $A_w\,h$ are immaterial, since they do not produce inelastic deformations. All quantities needed in computation are conveniently arranged in Table 7. The data are taken from Table 1(*b*) and Fig. 27.

Fig. 27

The residual deflection of end A, Fig. 26, in relation to the tangent at middle support B is determined by applying Eqs. 21*a*, 21*b*, and 22*a* to the residual conditions. Eq. 22*a* is used for the interval TU, Fig. 27, where the strain is constant. The residual upward deflection is:

$$\delta = 0.1994\,(10^{-3})\,\frac{l^2}{h} \quad \text{.....................} (47)$$

Now apply, elastically, a downward reaction at end A, to bring this end back to its original position. The maximum strain ϵ_e at point B, so induced, is found from the equation $2\,\frac{\epsilon_e}{h}\,\frac{1}{2}\,l\,\frac{2}{3}\,l = 0.1994\,(10^{-3})\,\frac{l^2}{h}$ as follows: $\epsilon_e = 0.2992\,(10^{-3})$.

The residual moment M_r at support B is now found by proportion: $M_r = \frac{0.2992}{1.1}\,22\,A_w\,h = 5.98$ (kips/in.^{2}) $A_w\,h$, instead of 8.92 $A_w\,h$—a discrepancy of $-2.94\,A_w\,h$. Load P has been assumed too small.

Trial 2.—Assume $P = 136.7$ (kips/in.^{2}) $\frac{A_w\,h}{l}$. Repeating the procedure of trial 1, the discrepancy in moments M_r proves to be $+0.40\,\frac{\text{kips}}{\text{in.}^2} \times A_w\,h$, showing that the assumed value of P exceeds the true value. The difference, however, is undoubtedly less than $0.1\,\frac{A_w\,h}{l}$, and a new trial is unnecessary.

A comparison of this solution with the results obtained by the method of limit design and with the results of the limiting elastic condition is given in Table 8.

Some error is involved in this solution because an inscribed polygon has been substituted for the curved line of maximum moments. However, even if the residual deflection found on the basis of this polygonal line may be somewhat in error, the discrepancy in P should be negligible, because only a small change in P is needed to affect the deflection appreciably.

If the conditions of the problem are modified in such a way that the load P is assumed to possess its full capacity value on the first passage, rather than to be built up gradually in the course of previous passages, the problem becomes very laborious, although possible of solution. The magnitude of the capacity load found under those circumstances will be smaller.

17. LIMIT DESIGN

Consider a statically indeterminate structure subjected to flexure, such as one of the beams analyzed in the foregoing examples, and let the loading acting on it increase gradually in intensity. The increase in loading is accompanied by an increase in stresses, and several sections of the beam, one by one, reach the yield point. When the number of such sections at and beyond the yield point, referred to as critical sections, is one larger than the number of static unknowns, the capacity loading is reached, since a small further increase in intensity leads quickly to a large deformation.

In his theory of limit design Professor Van den Broek proposes that the capacity loading be found by assuming that the values of the bending moments at all the critical sections are equal to the value for which the yield stress is just reached. This assumption underestimates, somewhat, the moments at the critical sections reached earlier; but on the whole it is not far from truth, and (what is important) it permits finding the capacity loading by statics alone.

It is conceivable, however, that before the structure yields at the last critical section it may fail at the first critical section, and this vital point must be cleared before the theory of limit design can be accepted. This question can be answered only by an exact theory of bending, such as the one presented in this paper.

In the foregoing examples, the true capacity loadings, together with the accompanying states of stress, have been determined and compared with the limiting elastic loadings and the loadings found by the limit design. Some features of the mechanical behavior of structures, made apparent by these examples, are worthy of notice.

The moment at the first critical section does not remain constant, as the moment at the second section approaches yielding, but it increases. This increase, although relatively slow compared to the elastic stage, must still be sufficient to produce the necessary angle change. In the case of stationary loads, as in Examples 1 and 2, Sections 14 and 15, the strain at the first critical section must almost inevitably extend into the strain-hardening region. This fact can be best illustrated by reference to Fig. 22, assuming, for simplicity, an I-beam consisting mostly of flanges with practically no web. As the positive moment increases, the positive angle change increases also, demanding (by the conditions of restraint) an equal negative angle change at the support; but, as long as the flange stress at the end of the beam remains within the plastic range, the end moment M_B must remain constant, and virtually no increase in the negative angle change is possible, because all yielding is concentrated on an infinitesimal length near the end. If the stress-strain curve of the material of the beam contains no rising part corresponding to strain hardening, the beam must fail at the ends under a load no larger than the one which causes first yielding.

The presence of the web in an I-beam does not modify this condition appreciably, as may be noted from Eq. 13*b* and Table 1(*a*). Eq. 13*b* shows that the angle change occurring on a constant length x_0 of a beam subjected to a triangular moment (Fig. 7) varies as the ratio $\frac{n_0}{m_0}$ corresponding to the stress condition at the end; and this ratio, according to Table 1(*a*), remains nearly constant in the later part of the plastic range, reaching a limit which in case of $\kappa = 1$ is only some 30% higher than the value at the end of the elastic part. In the strain-hardening region, the ratio $\frac{n_0}{m_0}$ again increases quickly, so that its value, required by the conditions of deformation, is soon reached.

An important conclusion can be drawn from this discussion: It is not the plastic part of the stress-strain curve, or at least not this part alone but mostly the strain-hardening part, that makes possible a favorable distribution of moments in the region beyond the elastic stage, as visualized in the theory of limit design.

The steepness and length of the strain-hardening curve, characterized roughly by the ratio of the ultimate stress and the yield-point stress and by the percentage elongation at failure, are very significant. In mild steel these factors are quite favorable, and the strains at the points of critical moments, as a rule, do not extend beyond the very beginning of the strain-hardening range. Even in the extreme case of Example 2, characterized by a great disparity of critical moments in the elastic stage, the strain at the first critical section only reaches the value of 6.2%, which is far short of failure, when the third critical section has just entered the yielding stage. The result may be quite different, however, with some alloy steels and nonferrous metals, possessing a much smaller ratio of the ultimate stress to yield-point stress than the mild steel.

In Example 3, dealing with a movable load, the region of inelastic strain as distinguished from that in the two other examples, is spread over a large length of the span; and, as a result, an ample angle change, relieving the moments in the middle parts of the spans, is produced by only a moderate extension of strain into the plastic region.

Comparison of the capacity loadings found by different methods in the three examples shows that the limit-design values are always on the safe side, which is the direct result of underestimating the moment carried by the beam at the first critical point. This margin of difference is larger with the stationary loads than with the movable loads, and in beams with $\kappa = 1$ it seems to be usually of the order of from 7% to 10%.

The only condition that may require a special investigation in this connection is the case cited in Section 16 when the moving loads are considered to have their full values on the first passage. Limit design can offer no answer to this problem, other than the one assuming a gradual pre-stressing of the beam by smaller loads—an assumption tending to overestimate the capacity load and to make the design unsafe. This tendency is compensated for, however, by an opposite tendency, as explained; and, when appreciable stationary loads occur at the same time as moving loads, the limit design is probably always safe.

Findings of the exact theory are thus very favorable to the theory of limit design when it is applied to mild steel and when the instability failure is not impending.

It is unfortunate that continuous, or fixed-ended, steel beams are rather rare in building construction. This condition limits the practical field of applicability of the flexural theory of limit design. On the other hand, the possibility of the use of this theory in the design of beams provided with the usual web and flange-angle connections, assumed ordinarily in design as simply supported, seems to be worthy of serious study. If the connections of such beams are sufficiently strong, although quite deformable, the end moments will be brought into action eventually, after some yielding at the center, and the design on the basis of end restraints may prove economical, as well as safe. Such an investigation would have to be based on the flexural theory presented herein and on the experimental data pertaining to the strength and rigidity of the end connections.

18. CONCLUSIONS

The material presented in this paper warrants the following conclusions:

1. The proposed flexural theory provides (within the scope of its assumptions) a rigorous method of determining a complete picture of stress and deformation in statically indeterminate or determinate I-beams and channel

beams, irrespective of whether or not the material of the beam obeys Hooke's law. Both the loaded state and the residual state, remaining after the removal of the load, are susceptible to analysis.

2. Favorable redistribution of bending moments, occurring beyond the yield point and taken advantage of in the theory of limit design, is made possible partly by the yielding characteristic of steel, but mostly by its strain-hardening characteristic.

3. Flexural structures of mild steel will not fail at the point of the greatest stress before the capacity load (characterized by approach of large deflections) is reached.

4. Barring the possibility of a failure caused by instability, the value of the capacity load of a flexural structure, found by limit design is on the safe side, with perhaps some rare exceptions when moving loads are involved.

5. Limit design may prove unsafe when applied to alloy steels and nonferrous metals in which the ratio of the ultimate stress to the yield-point stress is comparatively low.

6. The question of applying limit design to steel beams provided with the usual end connections is worthy of study, with a view to placing reliance in design on the end restraints of such beams.

APPENDIX. NOTATION

The following letter symbols, adopted for use in this paper and for the guidance of discussers, conform essentially to American Standard Letter Symbols for Mechanics (ASA—Z10.3—1942), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942. In general, a subscript C denotes "center"; E denotes "end"; e denotes "elastic"; f denotes "flange"; r denotes "residual"; u denotes "ultimate"; w denotes "web"; and Y denotes "yield."

A = area of cross section;

b = breadth, or width;

C = a coefficient with various subscripts before the expressions of different functions determined in the examples of Sections 14, 15, and 16:

$$C_M = M \times \frac{1}{A_w h} \text{ (Eq. 42}a\text{)}; \qquad C_P = P \times \frac{l}{A_w h} \text{ (Eq. 45}a\text{)};$$

$$C_V = V \times \frac{l}{A_w h} \text{ (Eq. 42}c\text{)}; \qquad C_w = w \times \frac{l^2}{A_w h} \text{ (Eq. 42}b\text{)};$$

$$C_\delta = \delta \times \frac{h}{l^2} \text{ (Eq. 42}d\text{)}; \qquad C_\phi = \phi \times \frac{h}{l};$$

d = distance or length; d in Fig. 7 is the distance from the point of zero moment, point A;

E = modulus of elasticity;
h = height, or depth;
l = span length of beam;
M = bending moment;
m = derived moment function of the material of the beam for an I-beam, Eq. 4;
m_1 = derived moment function of the material of the beam for a rectangular beam, Eq. 1;
n = derived slope function of the material of an I-beam, Eq. 10;
P = concentrated load;
q = derived shear function of the material of an I-beam, Eq. 6*b*;
u = derived deflection function of the material of an I-beam, Eq. 17*b*;
V = total shear;
w = load per unit length of span;
x = distances along the longitudinal axis of a beam; dx = an element of length x;
y = distances from the neutral axis;
δ = deflection;
ϵ = unit strain;
κ = ratio $A_f/\frac{1}{2} A_w$;
σ = unit bending and direct stress;
τ = unit shear stress; and
ϕ = angle change.

DISCUSSION

GEORGE WINTER,[6] M. ASCE.—In presenting this comprehensive and realistic solution of the problem of inelastic bending, the author has performed an unusually valuable service to the profession.

In his discussion[7] of the pioneering paper on "Theory of Limit Design" by J. A. Van den Broek, M. ASCE, the writer stated:

> "Any design theory that does not provide the means of determining the deformations corresponding to any given load up to the ultimate one is incomplete and questionable."

It is precisely this problem which is ably solved in this paper. Other attempts in this direction have been made, including the writer's sketchy treatment in the quoted discussion and some work in Great Britain. However, the paper is the first to be, at the same time, complete and practical. The extension to the strain-hardening regions and the discussion of shear stresses are particularly valuable.

From a practical point of view, the method is necessarily rather complex for use in design. The confirmatory evidence it presents for the original, simpler method of limit design is therefore doubly welcome. Although limited in design application, the author's paper should prove particularly valuable in research work in the interpretation of results of tests beyond the elastic range.

The main point of this discussion is to register a sincere request that the complete form of Table 1 be published with the closing discussion. The practical use of these methods is all but impossible without the complete tables. Indeed, as the author notes correctly, Figs. 15 and 16 are not necessarily accurate enough for numerical work. On the other hand, these tables are computed for values of κ not exceeding 1.5. Cases in which κ is larger, however, are frequent in standard wide flange sections. Thus, for example, for a 14 by 16, 426-lb wide flange section, the value of κ is of the order of 3.0. Similar values may also occur in built-up sections.

It would be of great practical value, indeed, if the author agreed to extend his tables to higher values of κ. For general use, the practical value of the paper would be greatly enhanced if it were possible to reproduce the complete and enlarged tables in the author's closing discussion.

D. C. DRUCKER,[8] JUN. ASCE.—The analysis by Professor Hrennikoff is based not only on plane sections remaining plane in the usual sense (that is, longitudinal strain proportional to distance from neutral axis), but also on the applicability of the stress-strain diagram for simple tension (Fig. 1). Unfortunately, the problem is far more complicated than any for which exact solutions of the idealized theory of plasticity have been found. It is the purpose of this discussion to indicate the necessity for a broader stress-strain relationship when vertical shear stresses are large, and to suggest that the elementary approach may seriously overestimate the load carrying capacity of short WF-beams or I-beams especially when fixed ended.

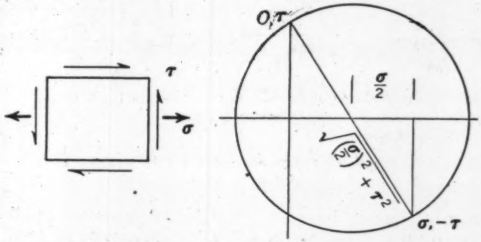
[8] Asst. Prof. of Mechanics, Illinois Inst. of Tech., Chicago, Ill.

In the case of rectangular steel beams or any beam in which the shearing stress is small compared with the bending stress, once the unstable plastic yielding of the outer fibers is complete and the strain-hardening region is reached, the author's careful work undoubtedly will give very useful and accurate information. However, WF-beams and other structural shapes are so proportioned that the vertical shearing stresses are appreciable and, if concentrated loads act near the end of a beam (Fig. 24), may control the design. The larger the ratio of depth to span, h/l, the more important the shear stress becomes.



(*a*) STATE OF STRESS (*b*) MOHR'S CIRCLE

FIG. 28.—STRESS RELATIONS AT JUNCTION OF WEB AND TOP FLANGE NEAR RIGHT END OF BEAM WITH FIXED-ENDED CONDITIONS

An element at the junction of the web and top flange near the right support of a fixed-ended beam will be subject to tensile stress σ, and shearing stress τ, as shown in Fig. 28. A ratio of 20/12 for σ/τ is somewhat low but reasonable for a fixed-ended WF-beam, although usually too low for I-beams. However, it is interesting to note that if $h/l = \frac{1}{12}$ in Example 2, the nominal shearing stress V/A_w is greater than 12 kips per sq in. when the bending stress is 20 kips per sq in. Substituting $\sigma = 20$ kips per sq in., and $\tau = 12$ kips per sq in., the maximum shear stress at the point is $\tau_{\max} = \sqrt{(\sigma/2)^2 + \tau^2} = 15.6$ kips per sq in., ignoring, as is customary, stress concentrations at the fillets and the high stresses actually present near supports or concentrated loads.

Experiments show that the plastic state in structural steel starts when the maximum shear strain energy reaches a limiting value. This criterion is more accurate but not so convenient in nominal stress analysis as the maximum shear stress basis; that is, yielding will occur when $\tau_{\max}$ equals the yield point in shear—approximately 19 kips per sq in. for a tensile yield point of 33 kips per sq in. As all the elastic stresses are proportional to the load, this means that yielding will occur when the bending stress is $20 \times \frac{19}{15.6} = 24.3$ kips per sq in., or only three fourths of the yield point in tension (33 kips per sq in.). The closer the point to the neutral axis, the smaller the ratio of the bending stress to the tension yield point.

The distribution of shear over the cross section of an I-beam or WF-beam, Fig. 29, will often greatly reduce the load required for initial yielding. Although the effect of such local yielding on the main part of the flange can only be guessed, it would be reasonable to expect a decrease in the yield strength.

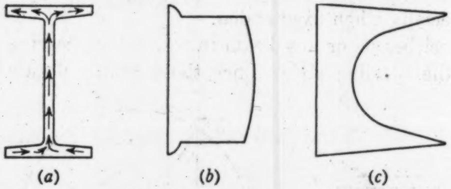


FIG. 29.—DISTRIBUTION OF SHEARING STRESS ON BEAM CROSS SECTION:

(b) NOMINAL, $-\frac{V\,Q}{I\,b}$

(c) ACTUAL, AT FIXED SUPPORTS ALONG CENTER LINE OF WEB

No matter what the ultimate effect on strength, it becomes necessary to think in more general terms than the simple tension test and so Sections 6 and 11 on shear stresses do not seem valid. The resulting shear stress of 24.5 times the average is certainly not a possibility in an I-beam, because yield must occur long before so high a stress is reached (at 19 kips per sq in. or less for the steel of the illustrative examples). As the integral of the shear stresses over the area of the cross section must give the total shearing force, the vertical shearing stresses in the zone of yielding cannot disappear; nor, correspondingly, can the bending stresses at two neighboring sections become equal in the manner shown in Fig. 18. Certainly, the distribution of the bending stresses is not given simply by the stress-strain diagrams for tension alone, but is a function of the shearing stress or strain as well as the bending strain.

BY MICHAEL R. HORNE,[9] ESQ.—

Methods of Stress Analysis Beyond the Elastic Limit.—Professor Hrennikoff's method for dealing with inelastic beams is ingenious, and has the advantage that, once the necessary tables have been compiled, it can be applied to any members of uniform section symmetrical about the plane of bending. However, it suffers from the very serious disadvantage that for complicated problems the application of Eqs. 12 and 21 becomes very involved. Many problems concerned with the elastic bending of beams may be solved quite simply by means of the three-moment theorem, and a similar method may be applied when the bending ceases to be elastic. In effect, it is possible to replace Eqs. 12 and 21 by a single relationship between the bending moments and deflections at three successive points in a beam.

Consider a beam ABC (Fig. 30) in which the bending moments at points A, B, and C are M_A, M_B, and M_C, respectively. It is assumed that between points A and B and between points B and C the bending moment diagram consists of straight lines. Let the length, depth, and web area of span AB be l_1, h_1, and A_{w1}, respectively, and let the corresponding values for span BC be l_2, h_2, and A_{w2}. If m_{AB}, and m_{BA} are the values of the function m at points

---

[9] Research Asst., Dept. of Eng., Univ. of Cambridge, Cambridge, England.

A and B for the length AB, then, from Eq. 5,

$$m_{AB} = \frac{2\,M_A}{h_1\,A_{w1}} \qquad \text{and} \qquad m_{BA} = \frac{2\,M_B}{h_1\,A_{w1}} \qquad \text{(48a)}$$

Similarly, m_{BC} and m_{CB}, the values of the function m at points B and C for the length BC, are

$$m_{BC} = \frac{2\,M_B}{h_2\,A_{w2}} \qquad \text{and} \qquad m_{CB} = \frac{2\,M_C}{h_2\,A_{w2}} \qquad \text{(48b)}$$

Let n_{AB}, u_{AB}, etc., be the values of the functions n and u corresponding to these values of m. Considering the center line of the beam, let δ_1 be the deflection at point B relative to point A, and δ_2, the deflection at point C relative to point B; δ_1 and δ_2 are both measured positive downward. Referring to Fig. 30, A′ BC′ is a straight line tangential to the center line at point B and, from the geometry of the figure,

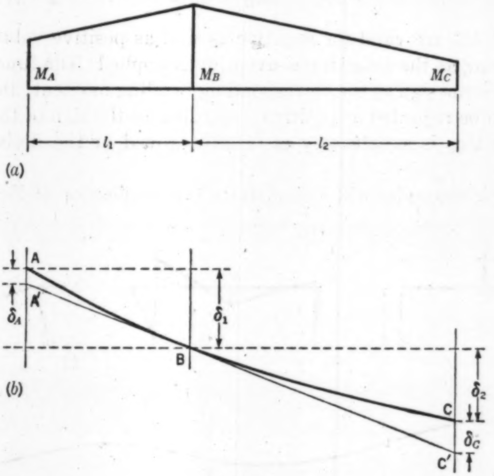

FIG. 30

$$\frac{\delta_1 - \delta_A}{l_1} = \frac{\delta_2 + \delta_C}{l_2} \qquad \text{(49)}$$

Considering span AB, Fig. 30, it is readily proved that

$$\delta_A = \frac{2\,l^2_1}{h_1}\frac{[u_{BA} - u_{AB} - m_{AB}\,(n_{BA} - n_{AB})]}{(m_{BA} - m_{AB})^2} \qquad \text{(50a)}$$

Similarly, for span BC,

$$\delta_C = \frac{2\,l^2_2}{h_2}\frac{[u_{BC} - u_{CB} - m_{CB}\,(n_{BC} - n_{CB})]}{(m_{BC} - m_{CB})^2} \qquad \text{(50b)}$$

Substituting Eqs. 50*a* and 50*b* in Eq. 49,

$$\frac{l_1}{h_1}\frac{[u_{BA} - u_{AB} - m_{AB}(n_{BA} - n_{AB})]}{(m_{BA} - m_{AB})^2} + \frac{l_2}{h_2} \times \frac{[u_{BC} - u_{CB} - m_{CB}(n_{BC} - n_{CB})]}{(m_{BC} - m_{CB})^2} = \tfrac{1}{2}\left(\frac{\delta_1}{l_1} - \frac{\delta_2}{l_2}\right) \quad ..(51a)$$

If the beam ABC is uniform throughout, $h_1 = h_2$ and $m_{BA} = m_{BC}$. Hence, there is no longer any need for the double suffixes, and Eq. 51*a* becomes

$$\frac{l_1[u_B - u_A - m_A(n_B - n_A)]}{(m_B - m_A)^2} + \frac{l_2[u_B - u_C - m_C(n_B - n_C)]}{(m_B - m_C)^2} = \frac{h}{2}\left(\frac{\delta_1}{l_1} - \frac{\delta_2}{l_2}\right) \quad ..(51b)$$

Eqs. 51*a* and 51*b* are valid for negative as well as positive values of M_A, M_B, and M_C, as long as the following convention is applied: The functions m and u are given the same sign as the corresponding bending moment, and the function n is always to be regarded as positive, regardless of the sign of the bending moment. That this is satisfactory is readily proved in the derivation of Eqs. 50*a* and 50*b*.

Two simple examples will demonstrate the application of Eq. 51.

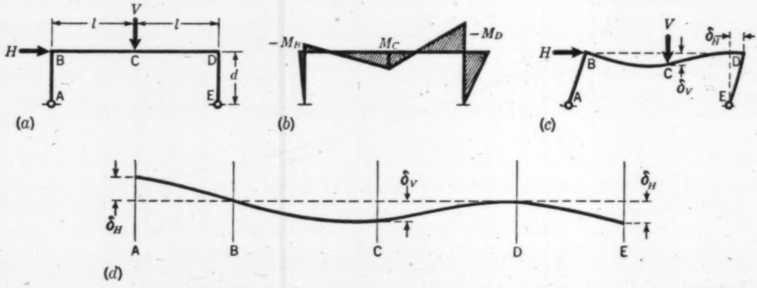

FIG. 31

Example 1.—Consider the portal frame ABDE (Fig. 31(*a*)) of uniform section throughout, supported on pins at points A and E. Let its height be d and its span $2\,l$, and let it carry a vertical load V at point C, the midpoint of span BD, and a horizontal load H applied at beam level. Let M_B, M_C, and M_D be the bending moments at points B, C, and D, respectively (Fig. 31 (*b*)), and let m_B, m_C, m_D be the corresponding values of the function m. Moments are accounted positive when they produce tension in the inner fibers of the frame. It follows from statical considerations that

$$2\,M_C - M_B - M_D = V\,l \quad \ldots\ldots\ldots\ldots\ldots\ldots (52a)$$

and

$$M_B - M_D = H\,d \qquad (52b)$$

If h is the depth of the section, and A_w the web area, then, from Eq. 50*b*,

$$2\,m_C - m_B - m_D = \frac{2\,V\,l}{h\,A_w} \qquad (53a)$$

and

$$m_B - m_D = \frac{2\,H\,d}{h\,A_w} \qquad (53b)$$

For convenience, m_B and m_C can be expressed in terms of the one unknown m_D, and, hence

$$m_B = m_D + \frac{2\,H\,d}{h\,A_w} \qquad (53c)$$

and

$$m_C = 2\,m_D + \frac{2}{h\,A_w}(H\,d + V\,l) \qquad (53d)$$

It will be assumed that all bending that results from axial loads may be neglected, so that Eq. 51*b* is applicable. The vertical deflection at point C will be denoted by δ_V and the sidesway of the frame, by δ_H. Treating the entire frame as a continuous beam (Fig. 31(*d*)), Eq. 51*b* may be applied first to the part ABC, then to the part BCD, and finally to the part CDE, thus obtaining three equations:

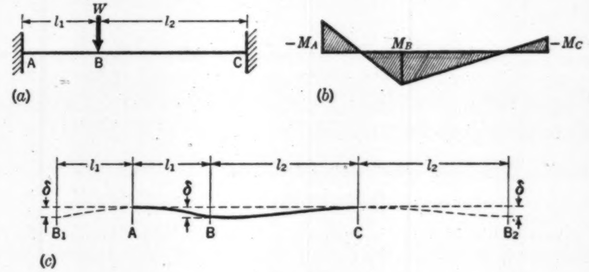

FIG. 32

$$\frac{u_B\,d}{m^2_B} + l\,\frac{[u_B - u_C - m_C\,(n_B - n_C)]}{(m_B - m_C)^2} = \frac{h}{2}\left(\frac{\delta_H}{d} - \frac{\delta_V}{l}\right) \qquad (53e)$$

$$l\,\frac{[u_C - u_B - m_B\,(n_C - n_B)]}{(m_C - m_B)^2} + l\,\frac{[u_C - u_D - m_D\,(n_C - n_D)]}{(m_C - m_D)^2} = \frac{h\,\delta_V}{l} \qquad (53f)$$

$$l\,\frac{[u_D - u_C - m_C\,(n_D - n_C)]}{(m_D - m_C)^2} + \frac{u_D\,d}{m^2_D} = -\frac{h}{2}\left(\frac{\delta_H}{d} + \frac{\delta_V}{l}\right) \qquad (53g)$$

If δ_H and δ_V are eliminated from Eqs. 53*e* to 53*g*, a further relationship is obtained between m_B, m_C, and m_D:

$$d\left(\frac{u_B}{m^2_B} + \frac{u_D}{m^2_D}\right) + l\left(\frac{n_B - n_C}{m_B - m_C} + \frac{n_C - n_D}{m_C - m_D}\right) = 0 \qquad (53h)$$

In obtaining a solution for any given values of V and H it is necessary to assume a value of m_D. Deduce the values of m_B and m_C from Eqs. 53*c* and 53*d*, and then test whether Eq. 53*h* is satisfied. When the correct values of m_B, m_C, and m_D have been obtained, the values of δ_V and δ_H may be found from Eqs. 53*e* and 53*f*.

Example 2.—In Fig. 32, consider beam AC, fixed at points A and C, and subjected to a concentrated load W at a distance of l_1 from point A and l_2 from point C. If the bending moments at points A, B, and C are M_A, M_B, and M_C, respectively, it follows from simple statics that

$$(l_1 + l_2)\, M_B - l_2\, M_A - l_1\, M_C = l_1\, l_2\, W \ldots\ldots\ldots\ldots (54a)$$

If m_A, m_B, and m_C are the corresponding values of the function m, then,

$$(l_1 + l_2)\, m_B - l_2\, m_A - l_1\, m_C = \frac{2\, l_1\, l_2}{h\, A_w}\, W \ldots\ldots\ldots\ldots (54b)$$

If δ is the deflection at point B relative to points A and C, then in applying Eq. 51*b* it is necessary that $\delta_1 = -\,\delta_2 = \delta$. Hence, two equations are available to determine the four unknowns, m_A, m_B, m_C, and δ, and it is necessary to find two more. If span AB is imagined to be reflected about end A into the position AB_1 in Fig. 32(*c*), then Eq. 51*b* may be applied to the length $B_1\,AB$, giving

$$\frac{[u_A - u_B - m_B\,(n_A - n_B)]}{(m_A - m_B)^2} = -\,\frac{h\,\delta}{2\,l^2{}_1} \ldots\ldots\ldots\ldots (55a)$$

Similarly, span BC may be reflected into the position CB_2, and the application of Eq. 51*b* to the length BCB_2 gives

$$\frac{[u_C - u_B - m_B\,(n_C - n_B)]}{(m_C - m_B)^2} = -\,\frac{h\,\delta}{2\,l^2{}_2} \ldots\ldots\ldots\ldots (55b)$$

For any given value of W it is necessary to solve Eqs. 51*b*, 54*b*, 55*a*, and 55*b* by trial and error until suitable values of m_A, m_B, and m_C are found.

The Stress-Strain Relationship of Steel in Bending.—This subject has been treated in a paper by F. G. Eric Peterson,[10] Assoc. M. ASCE, and in the subsequent discussions. As stated by J. F. Baker, Assoc. M. ASCE, and J. W. Roderick in their discussion,[11] the generally accepted theory in England is that the stress distribution is similar to that given by the tensile test when made in an autographic testing machine, care being taken to insure that the applied load is truly axial, but ignoring the effect of strain hardening, as shown in Fig. 33. Under such circumstances mild steel gives a stress-strain relationship in which the upper yield stress f_U may be between 25% and 45% in excess of the lower yield stress f_L. Professors Baker and Roderick also show that the

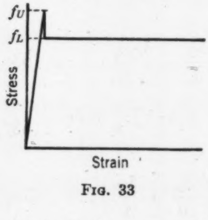

FIG. 33

---

[10] *Transactions*, ASCE, Vol. 112, 1947, p. 1201.

[11] *Ibid.*, p. 1238.

assumption of such a stress distribution accounts very well for the behavior of rectangular mild steel beams in bending. Further work by these writers, at the Engineering Laboratory of Cambridge University at Cambridge, England, in collaboration with the British Welding Research Association, has confirmed these results. The stress-strain relationship assumed by Professor Hrennikoff differs from that assumed by Professors Baker and Roderick in two respects: Professor Hrennikoff ignores the upper yield stress and takes strain hardening into account, assuming that strain hardening occurs in bending in precisely the same way as in a tension test. Most of the work done by Professors Baker and Roderick has been on beams of rectangular cross section, whereas, the paper of Professor Hrennikoff refers also to rolled beams in which local yield due to rolling stresses is certain to occur. Under these circumstances to neglect the upper yield stress is reasonable. However, the assumptions made with respect to strain hardening cannot be justified so readily. The strains at the end of the plastic range are considerable, and under such circumstances it should not be assumed too readily that the strain-hardening effect is the same in bending as in tension. It is interesting to note that the work done at Cambridge indicates that the behavior of both simply supported and continuous beams up to the loads causing large deflections may be explained satisfactorily without reference to strain hardening.

The Importance of Strain Hardening in Limit Design.—Strain hardening, obviously, has an important bearing on attempts to arrive at a design method based on the ultimate capacity of steel structures, but its importance should not be overestimated. In designing ordinary building frames by the usual elastic methods, emphasis is always placed on stresses rather than on deflections. This is because within the elastic range the strains are small. However, when an ultimate load method of design is used, the deflections become as important as the stresses, because of the greatly increased strains within the plastic range. The structure will only be useful up to that load at which the deflections become excessive. The limit method of design justifies itself because the ultimate load calculated according to the principle of equalization of moments must coincide approximately with the load at which excessive deflections first occur. This is because both the equalization of moments and the appearance of large deflections result from the same property of mild steel—its capacity to undergo plastic deformation without increase in stress. The author has now shown that the plastic yield that occurs before strain hardening begins is insufficient to cause a complete equalization of moments. Since the deflections are becoming large, at this stage, however, the ultimate capacity has been reached, so that it becomes pointless to follow the behavior of the structure further. The limit method of design achieves its purpose if it leads to a reasonable estimate of the load at which deflections begin to increase rapidly. Professor Hrennikoff's work is of particular interest since it affords a means of checking the assumption that this is actually the case. The results obtainable in this way may best be illustrated by taking a numerical example.

Example 3.—Consider a portal frame of the type shown in Fig. 31(a), in which $d = l$. Let the cross section of the member be uniform throughout, the web and flange areas being equal so that $k = 1$. Let a vertical load V first be applied so that yield stress in the extreme fibers is just reached in the center of the beam, horizontal load only being applied thereafter. With steel having the properties assumed by Professor Hrennikoff, the value of V just sufficient to produce yield stress at point C is found to be $\frac{2\,V\,l}{h\,A_w} = 140.8$ kips per sq in. The entire frame remains elastic until H has reached a value given by $\frac{2\,H\,l}{h\,A_w} = 35.2$ kips per sq in. when yield stress is just reached in the extreme fibers at point D in Fig. 31(*a*). Thereafter it is necessary to obtain solutions by the use of Eqs. 53*c* to 53*h*. The results are presented in Table 9(*a*). Cols. 2 to 7, Table 9(*a*), give the bending moments at points B, C, and D, and the corresponding extreme fiber strains, and Cols. 8 and 9 give, respectively, the vertical deflection δ_V and the horizontal deflection δ_H at the center of the beam. The bending moment at which strain hardening begins occurs first at point D at a value of $\frac{2\,H\,l}{h\,A_w} = 50.43$ kips per sq in., and subsequently at point C at a value of 58.60 kips per sq in. For the sake of comparison, results are given in Table 9(*b*), based on the assumption that the steel is capable of undergoing indefinite strain without change in stress after the attainment of yield. Where no data are given, the results are the same as in Table 9(*a*). This is equivalent to ig-

noring the effects of overstrain entirely, and complete failure occurs when equal moments sufficient to produce yield stress over the entire section have been reached at points C and D. This occurs when $\frac{2\,M_C}{h\,A_w} = -\,\frac{2\,M_D}{h\,A_w} = 49.50$ kips per sq in. and $\frac{2\,H\,l}{h\,A_w} = 57.20$ kips per sq in. Fig. 34 shows the bending moments at points C and D plotted against the horizontal load; and Fig. 35 shows the horizontal load plotted against the horizontal and vertical deflections at the center of the beam. In all cases the full lines refer to the solution taking account of the effect of strain hardening, the dotted lines indicating what happens when this is ignored. When strain hardening is taken into account the deflections begin to increase rapidly very soon after the value of $\frac{2\,H\,l}{h\,A_w}$ exceeds 57.2 kips per sq in. This represents very nearly the collapse load of the frame. Hence, the collapse load obtained by ignoring strain hardening is very nearly the same as that obtained when it is considered. The percentage differences in the various calculated quantities at $\frac{2\,H\,l}{h\,A_w} = 57.2$ kips per sq in.

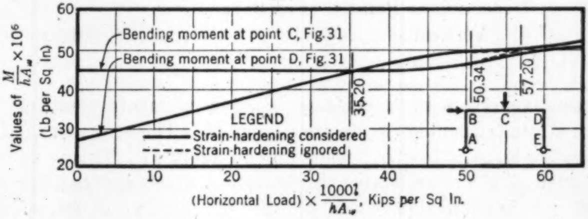

FIG. 34.—EFFECT OF STRAIN HARDENING ON BENDING MOMENTS

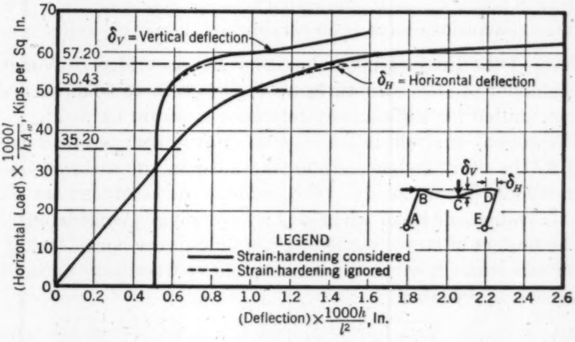

FIG. 35.—EFFECT OF STRAIN HARDENING ON DEFLECTION

are as follows:

Description	Difference (%)
Bending moment at:	
Point C, Fig. 31	1.02
Point D, Fig. 31	−1.00
Deflection at Point C (Fig. 31):	
Vertical	15.56
Horizontal	9.83

The percentage errors in calculating bending moments resulting from the neglect of strain-hardening effects are negligible. The errors in the calculated deflections are large but by no means unreasonably so. This is an interesting result in view of the considerable simplification which results when overstrain is ignored. It is particularly so in the case of a highly redundant framework, the analysis of which would involve the simultaneous solution of a number of formulas of the type of Eq. 51*b*. When overstrain is taken into account, these must all be solved by trial and error, and, obviously, with more than three such equations a solution would be virtually impossible. If overstrain is ignored, however, and if it is desired only to derive the deflections at the point of collapse, the bending moments become statically determinate everywhere, and the equations may be solved directly.

The general complexity of the behavior of rigid structures makes it difficult to draw any conclusions as to the importance of strain hardening in limit design. Three conclusions have been established, however, and are as follows:

(1) Tests at the Engineering Laboratory at Cambridge University indicate that the behavior of steel structures up to the point of collapse may satisfactorily be accounted for without any reference to strain hardening.

(2) Theoretical analysis indicates that, if the collapse load is calculated according to the limit design method, the error in the deduced values of the bending moments is very small. The deflections so deduced are somewhat in excess of the values obtained when strain hardening is considered.

(3) The neglect of strain hardening simplifies, very considerably, the stress analysis of structures beyond the elastic limit, particularly as the theoretical collapse load is approached.

It must be emphasized, however, that these conclusions are tentative. In particular, as Professor Hrennikoff indicates, the presence of semirigid joints may do much to prevent the equalization of moments, and, under such circumstances, the behavior of members in the strain-hardening range may be of considerable importance.

E. P. Popov,[12] Assoc. M. ASCE—A timely study of the theory of inelastic bending, with particular reference to mild steel, is presented in this paper by Professor Hrennikoff. Engineers engaged in the aircraft industry are re-examining the usual criteria of design based on stress and, in certain cases, are attempting to substitute in their place the criteria of excessive deflections, or the ultimate carrying capacity of the flexural members. Historically, it is of interest to note that the early elasticians were not satisfied with the direct proportionality of stress to strain dictated by the Hooke-Mariotte law. B. de Saint Venant,[13] in his notes to M. Navier's book, thus considers a generalized stress-strain relation and obtains the resulting stress distribution. In recent years most engineers are familiar with the assumption of parabolic stress distribution in concrete.[14]

---

[12] Asst. Prof., Civ. Eng., Univ. of California, Berkeley, Calif.

With the demand for rapid analytical solutions, which required simple formulas, straight-line stress distribution became universally adopted and stress became the criterion of design. This probably also followed from researches on fatigue, where stresses and stress concentrations play the major role in determining the serviceability of a member. Gradually, it became apparent that in a large number of cases reversal of loads does not occur. Hence, it is argued, stress is not the best criterion for the selection of a member. This explains the renewed activity in researches in plastic bending, and attempts are made to determine the ultimate carrying capacity of members (limit design).

All problems of plastic bending in earlier and present analyses are based essentially on the Bernoulli-Euler assumption that plane sections, before bending, remain plane after bending. Hence, it follows that strains vary linearly from the neutral axis. This assumption has a reasonable experimental support, as shown by A. Nádai,[15] based on experiments of C. V. Bach, E. Meyer, G. H. McCullough,[16] Joseph Marin, Assoc. M. ASCE, R. L. Cotterman,[17] Jun. ASCE, and others. With this basic assumption the solutions obtained and reported differ merely in form. Professor Hrennikoff chooses certain nomenclature and derives certain expressions, which, in turn, are evaluated for a particular stress-strain diagram.

In 1943 F. P. Cozzone[18] derived formulas and graphs for the plastic-range design of several materials. In his presentation the stress-strain diagram is treated as an equivalent trapezoid, having the same moment about the vertical axis as the actual stress-strain diagram. Earlier, S. Timoshenko,[19] using the conjugate beam method, and utilizing the notion of reduced modulus of elasticity, devised a semigraphical method of determining stresses and deflections. All these schemes are identical in principle and differ only in form. The solutions, obtainable by the use of these methods, should be in substantial agreement. For pure flexure, or for cases where shear is small, it appears that these solutions are in good agreement with previous tests[17,18,20] and may be used with confidence.

To simplify his analytical treatment for I-beams and WF-beams Professor Hrennikoff also introduces a ratio κ, which is defined as a ratio of flange area to one half the area of the web. This simplification also appears reasonable, but the situation differs with shear.

The writer seriously questions whether the simple procedure developed in the paper for shearing stresses in beams is in agreement with known facts about the plastic behavior of ductile materials. Shearing stress concentrations show in Fig. 17 and, again, shearing stress distribution, shown by the dotted line in Fig. 18 of the paper, are excessively high and appear to be strangely localized. Referring to Mr. Cozzone's paper,[18] in which the same basic assumption is utilized, the shearing stress distribution is shown to be

$$\tau = \frac{V\,Q}{I\,b}\left(\frac{1 + R\left(\frac{A\,C}{Q} - 1\right)}{1 + R\,(k - 1)}\right) \ldots\ldots\ldots\ldots\ldots (56)$$

In Eq. 56 τ, V, b, and I have the same meanings as in the paper; A is the area between the fiber in question and the extreme fiber; Q is the first moment of A about the neutral axis; c is the distance to the extreme fiber; k is the section form factor ($1 \leq k \leq 2$); and

$$R = \frac{df_0}{df_m} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

which is the rate of change of intercept stress f_0 with respect to the maximum stress f_m. These latter quantities require some additional comment.

In the Cozzone analysis, in order to avoid algebraic difficulties, the actual stress-strain diagram that corresponds to any maximum stress f_m in a beam is replaced by a trapezoid. The ordinary tension test diagram is used as a basis. Let Oab in Fig. 36 represent such an actual tension test diagram. Then, for a particular moment that a beam carries, if the maximum stress is found to be f_m in the usual way, the stress distribution in that beam will be similar to area Oaf_m. The moment of the area Oaf_mA about the vertical axis through the origin is proportional to the beam's flexural capacity at stress f_m. To simplify further derivations, a trapezoid Of_0f_mA is then found such that its moment around the vertical axis through point O will be equal to the moment previously found. Thus, for a particular value of f_m there is a particular corresponding

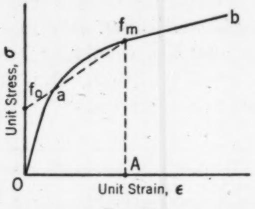

FIG. 36

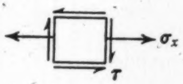

FIG. 37

value of stress intercept f_0. As the applied moment to the beam is increased, f_m increases and f_0 changes correspondingly.

In Eq. 56, R is defined as the rate of change of intercept stress f_0 with respect to the maximum stress f_m. During the plastic stage (that is in the interval between ϵ_{Y1} and ϵ_{Y2} in Fig. 13), f_m remains stationary, whereas f_0 may vary slightly. Thus, Eq. 56 reduces to

$$\tau = \frac{V\,Q}{I\,b} \qquad (58)$$

which is a well-known expression for the shearing stress distribution in the elastic range developed by D. I. Jouravsky[21] in 1855.

Thus, the analyses of Professor Hrennikoff and Mr. Cozzone in the plastic range lead to very different results. It is the writer's opinion that in the plastic range problems concerned with shear cannot be handled in such an elementary way. The flow criterion for ductile materials, such as the steel considered in Fig. 13, is expressed well by the Hencky-Mises-Huber relation.[22] In it the shear distortion energy under a compound state of stress is equated to the shear distortion energy in simple tension at the yield point of the material, σ_{yp}. In bending, with shear, the state of stress on an element in a beam is represented in Fig. 37, and the plastic flow criterion becomes:

$$\sigma_{yp} = \sqrt{\sigma^2_x + 3\,\tau^2} \qquad (59)$$

in which, as will be noted, the yield of the material is dependent on both the normal and the shearing stress.

It appears that at present no complete solution for the problem involving shear is available. However, some studies indicate[23] that, even with shear, the assumption of plane sections remains essentially valid; but shearing stresses contribute to distortion. An attempt to derive a complete solution based on elastico-plastic considerations has been made by Anton Eichinger,[23] based on some earlier work at the Swiss Federal Testing Laboratories.[24] His solution is not in an applicable form to a practical problem, yet it clearly indicates the interdependence of normal and shearing stresses in the plastic range. Thus, the analyst cannot just "rotate" the tension test diagram to obtain stress distribution in the plastic range where shear occurs. The problem involves several variables and hence it is much more complicated than the one indicated by Professor Hrennikoff.

BERNARD A. VALLERGA,[25] JUN. ASCE.—In the "Introduction" Professor Hrennikoff states that "* * * a simpler case of the same problem, involving a rectangular beam, has been treated, in a somewhat different way, by S. Timoshenko.[3]" An analysis of Professor Timoshenko's method of reduced modulus will show that the two methods are identical in so far as the determination of the resisting moment of any section is concerned. Application of the additional simplifying limitation No. 2, as listed by the author, to Professor Timoshenko's more general expression will result in identical equations for bending moment. Hereinafter is a demonstration of the preceding statement for the two cases considered.

Rectangular Section.—Professor Timoshenko shows that, for a material not following Hooke's law, the resisting moment is given by the general expression,

$$M = \frac{E_R\, I}{r} \tag{60}$$

in which E_R is the reduced modulus and r is the radius of curvature of the beam due to the moment M. For a rectangular section,

$$E_R = \frac{12}{\Delta^3} \int_{\epsilon_2}^{\epsilon_1} \sigma\, \epsilon\, d\epsilon \tag{61}$$

in which Δ is the sum of the absolute values of ϵ_1 and ϵ_2. For the case of a mild steel whose compressive stress-strain diagram is assumed to be the same as the tensile stress-strain diagram (limitation No. 2),

$$\epsilon_1 = \epsilon_2 = \epsilon_0 \tag{62a}$$

and

$$\Delta = 2\, \epsilon_0 \tag{62b}$$

Therefore,

$$E_R = \frac{3}{\epsilon^3_0} \int_0^{\epsilon_0} \sigma\, \epsilon\, d\epsilon \tag{63}$$

However,

$$\frac{1}{r} = \frac{2\, \epsilon_0}{h} \tag{64}$$

and

$$I = \frac{b\, h^3}{12} \tag{65}$$

Substitution of Eqs. 63, 64, and 65 in Eq. 60 gives

$$M = \tfrac{1}{2}\, b\, h^2 \frac{1}{\epsilon^2_0} \int_0^{\epsilon_0} \sigma\, \epsilon\, d\epsilon = \tfrac{1}{2}\, m_1\, b\, h^2 \tag{66}$$

I-*Section.*—Professor Timoshenko's method can be expanded to include I-beams. Thus,

$$M = \frac{E_R\, I_w}{r} \tag{67}$$

in which, for an I-section, the general expression for reduced modulus is

$$E_R = \frac{12}{\Delta^3}\left(\int_{\epsilon_2}^{\epsilon_1} \sigma\,\epsilon\,d\epsilon + \frac{b'-b}{b}\int_{\epsilon'_1}^{\epsilon_1} \sigma\,\epsilon\,d\epsilon + \frac{b'-b}{b}\int_{\epsilon'_2}^{\epsilon_2} \sigma\,\epsilon\,d\epsilon\right) \ldots (68)$$

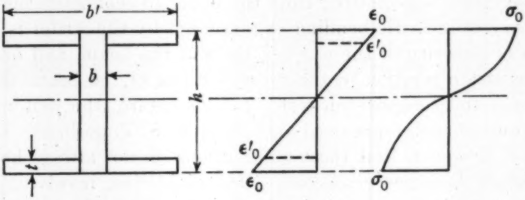

FIG. 38

If limitation No. 2 is applied to this case, together with the additional approximation that the stress does not vary across the flange (see Fig. 38), Eq. 68 becomes

$$E_R = \frac{3}{\epsilon^3_0}\left[\int_0^{\epsilon_0} \sigma\,\epsilon\,d\epsilon + \frac{b'-b}{b}\,\sigma_0\,\frac{\epsilon^2_0 - (\epsilon'_0)^2}{2}\right] \ldots\ldots\ldots (69)$$

From the geometry in Fig. 1 it is evident that

$$\epsilon_0 - \epsilon'_0 = \frac{2\,t}{h}\,\epsilon_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (70)$$

Substituting Eq. 70 in Eq. 9 after factoring the difference of the squares gives:

$$E_R = \frac{3}{\epsilon^3_0}\left[\int_0^{\epsilon_0} \sigma\,\epsilon\,d\epsilon + \frac{(b'-b)t}{\frac{1}{2}\,b\,h}\,\sigma_0\,\epsilon_0\,\frac{\epsilon_0 + \epsilon'_0}{2}\right] \ldots\ldots\ldots (71)$$

Introducing into Eq. 71 the factor κ as defined by Professor Hrennikoff, and making the further approximation,

$$\epsilon_0 + \epsilon'_0 = 2\,\epsilon_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (72)$$

then

$$E_R = \frac{3}{\epsilon^3_0}\left(\int_0^{\epsilon_0} \sigma\,\epsilon\,d\epsilon + \kappa\,\sigma_0\,\epsilon^2_0\right) \ldots\ldots\ldots\ldots\ldots (73)$$

Finally, by substituting Eqs. 64, 65, and 73 in Eq. 67, the bending moment becomes

$$M = \tfrac{1}{2}\,b\,h^2\left(\frac{1}{\epsilon^2_0}\int_0^{\epsilon_0} \sigma\,\epsilon\,d\epsilon + \kappa\,\sigma_0\right) = \tfrac{1}{2}\,m\,A_w\,h \ldots\ldots\ldots (74)$$

which is the same as Eq. 5.

Alexander Hrennikoff,[26] Assoc. M. ASCE.—Although disappointed with the extent of the response to his paper, the writer is grateful to those few who did contribute to the discussion. The writer appreciates the favorable comments of Professor Winter and agrees with him on the need for a complete set of functions of m, n, and u for the interpretation of test results. A large part of these tables was omitted from the paper to economize on space.

The theory of inelastic bending as presented by the writer is based on the assumption of linearity of the cross sections of the beam, and on the identity of the stress-strain relation in the cross sections of the beam with that in a simple tension and compression test. In this regard, the writer has followed in the footsteps of such recognized authorities as S. Timoshenko and A. Nádai. It is possible, however, that these assumptions do not always hold—in which case the theory becomes erroneous. One such case, involving a mild steel beam, with normal stresses in the plastic range, was discussed in the paper.

Professor Drucker in his thought provoking discussion questions the validity of the assumed stress-strain relation in still another case. The core of his discussion, as interpreted by the writer, is as follows: If in a mild steel beam both the normal and the shearing stresses in all parts of the cross section are within the elastic range, but the principal shearing stress reaches or even exceeds the yield value, then a very large shear deformation would tend to take place in the plane of principal shear. This condition would also result in a very large normal deformation in the cross section, for which no allowance has been made in the theory, since the normal stresses still remain within the elastic range. If, however, this large deformation does not materialize (being arrested by continuity with the adjacent material), then some readjustment in the normal stresses and strains in the cross-sectional planes is bound to occur, and the assumed stress-strain relation also becomes incorrect.

Although this reasoning is undoubtedly plausible, the extent of the resultant irregularity is uncertain and may very well be small. The writer feels that Professor Drucker's criticism, in order to be accepted as valid, should be supported by an appropriate quantitative analysis or by experimental evidence.

The objections of Professor Drucker apply only to beams made of material endowed with the property of yielding (for example, mild steel), and only in the range of yielding. For this reason, the writer disagrees with Professor Drucker concerning the validity of Section 6 of the theory presented. This section, dealing with the general theory of shearing stress for any material of the beam, is perfectly valid within the limits of the writer's assumptions.

The absence of any explanation concerning the unusual shape of the shearing stress diagram in Fig. 29(*c*) at the fixed end of an I-beam is regretted. Since the shearing stresses in the cross section of a beam are determined by statics as the difference of the normal stresses in the two adjacent cross sections, the diagram indicates that the normal stresses in flanges increase very fast, and that in the web they decrease toward the fixed support. This condition would suggest that the fixation of the end of the beam has been accomplished by holding the flanges and leaving the web free. If this explanation is correct, the diagram merely reflects the effect of some peculiar end conditions induced artificially in the beam and has no bearing on the theory presented.

---

[26] Prof., Civ. Eng., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

The question of possible incorrectness of the theory when applied to the mild steel beams in the plastic region of stress, as a result of disturbances produced by the shear effects, is also discussed at length by Professor Popov, who makes several references to other investigations along similar lines.

In the reference to the work of F. P. Cozzone, Professor Popov points out a striking disagreement between the expressions for the shearing stresses derived by Mr. Cozzone and the author. Fortunately, the cause of this disagreement is not difficult to find.

In the first place, the general equation (Eq. 56) for the shearing stress in the plastic region does not reduce to Eq. 58. As Professor Popov points out, in this region $df_m = 0$ and df_0 is distinct from zero, which makes R infinity, and thus reduces Eq. 56 to the form:

$$t = \frac{V\,Q}{I\,b}\,\frac{\dfrac{A\,C}{Q} - 1}{k - 1} \quad \text{.....................} (75)$$

This error does not however account for the full extent of the differences considered herein.

All the quantities entering Eq. 75 refer to the geometry of the cross section, the only exception being the term V—the shearing force. Thus, according to this equation, the only characteristic of the loading affecting the shearing stresses in the cross section of the beam is the shearing force. That this conclusion is false in the plastic region of normal stresses in the cross section is evident from Fig. 18. With the normal stresses as indicated in Fig. 18, and quite apart from any particular value of the shearing force present, the conditions of statics demand that there be no shearing stresses on either horizontal or vertical planes in the outer parts of the cross sections, where the normal stresses in the two sides of the element shown are equal, which means that all the shearing stresses must be concentrated near the center of the section. Again by statics these shearing stresses near the center must be the greater, the smaller the region over which they are distributed. Thus, it is not only the shearing force, but also the general state of strain, or, in other words, the bending moment, which determine the state of shearing stress on the vertical and horizontal planes in the plastic region of normal stresses in mild steel I-beams—which is definitely not the conclusion which may be formed from consideration of Eq. 75.

The error of Mr. Cozzone's formula is caused by the crudeness of his assumption of the trapezoidal distribution of normal stresses. The free body diagram, similar to Fig. 18, for an element of beam on the basis of this assumption is shown in Fig. 39. The incorrect manner of distribution of normal stresses on the sides of the element of the beam makes it imperative that there be shearing stresses on the vertical and horizontal planes at all points of the beam, and that these stresses must be independent of any conditions of loading other than the value of the shearing force.

Mr. Cozzone's theory is very crude also in some other respects, and it is totally unsuitable for analysis of statically indeterminate beams stressed beyond the elastic limit.

Although Mr. Cozzone's Eq. 75 is thus unquestionably erroneous, it does not follow that the writer's Eq. 25c and his other equations for the shearing stresses based on this equation are necessarily correct. They are only as correct as the underlying assumption with regard to the normal stresses, and thus the doubts expressed by Professors Drucker and Popov are not unfounded.

In spite of these objections the author still believes that, although the state of strain of a mild steel beam in the plastic region may depart appreciably from the theory presented, the resultant error in stresses is probably small, and the effect of this irregularity on the angle changes, and through them on the statically unknown quantities and the general state of stress and deformation in the statically indeterminate beams, is probably only minor. It should be possible to check this contention by tests.

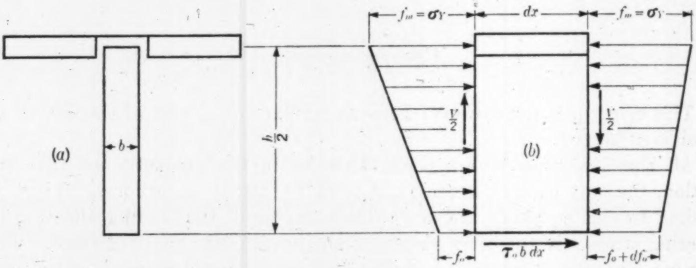

FIG. 39.—THEORY OF INELASTIC BENDING WITH REFERENCE TO LIMIT DESIGN

Mr. Vallerga in his discussion traces the similarity between the method presented by Professor Timoshenko and the writer's theory, thereby raising by implication the question of the originality of the latter. In this connection the writer freely admits that the conception expressed by the symbol m_1 was borrowed from the work of Professor Timoshenko, and the idea expressed by the symbol m represents only a simple elaboration of the former conception, as indeed is shown by Mr. Vallerga. The writer however is not aware of anything in Professor Timoshenko's work, or in any other source, suggesting the equally important ideas implied in the symbols n, u, and q; the extension of the theory into the field of stress recession; and also the general manner of treatment of several problems analyzed by these conceptions—all this comprising at least 90% of the paper.

Mr. Horne has made a thorough study of the theory; he made some further elaboration of it, and solved some additional interesting examples, throwing more light on the behavior of beams beyond the elastic limit. The author, however, disagrees with him on the usefulness of the inelastic version of the three-moment theorem (Eq. 51*b*). In the first place, Mr. Horne is not justified in deriving this formula for a straight beam and then applying it, without further elaboration, to beam ABC (Fig. 31) made of two parts at right angles to each other. Furthermore, Eq. 51*b* merely complicates the matter, instead of making it simpler. Thus, Mr. Horne applies Eq. 51*b* three times, obtaining three cumbersome equations (Eqs. 53*e*, 53*f*, and 53*g*), from which by elimination of the variables Eq. 53*h* is derived, which he uses in the analysis. Mr. Horne overlooks the fact that an equation equivalent to Eq. 53*h* can be written directly without any intermediate steps by the general formulas in Fig. 11. This equation would be different from Eq. 53*h* only in that it would be based on the basic equations (Eqs. 11 and 17*a*) for ϕ and δ. In order to get exactly the same form of the equation as Eq. 53*h* (which by the way is unnecessary), Mr. Horne would have to write first the expressions for ϕ and δ that are equivalent to those assembled in Fig. 11, but that are based on Eqs. 13*b* and 18—rather than on Eqs. 11 and 17*a*.

The writer has been much interested in Mr. Horne's discussion on the theory of limit design and on the effect of ignoring the strain hardening. He is in full agreement with Mr. Horne's general outlook on the subject, and with his conclusion that the load beyond which the deformations begin to increase very fast (which can be looked upon as the failure load) depends only very little on whether the strain hardening is operating or whether the yield stress continues indefinitely on further increase in strain. Thus, in Example 3 the value of the failure load H, allowing for strain hardening, is found to be 58.6, whereas a similar value without the strain hardening is 57.2, indicating a negligible difference.

There is, however, an important aspect of the situation which was emphasized strongly by the writer and which was completely ignored by Mr. Horne, although his data present an admirable commentary on it. Table 9 shows that, when strain hardening is ignored, the local unit strain at point D becomes infinite when the value of load H is only 51.03, which is considerably lower than the failure value, 57.2, previously mentioned. Infinite strain can mean only one thing—actual physical failure of the structure at point D. Thus, if strain hardening is absent, the structure fails long before the equilization of moments at points C and D takes place. That which saves the structure from failure is the strain hardening. Thus, Mr. Horne's conclusion (1) and his several statements—to the effect that the behavior of steel structures up to the point of collapse (he means by collapse, large deflections) may be satisfactorily accounted for without any reference to strain hardening—most certainly is not borne out by the facts. A theory disregarding strain hardening indicates an imminent physical failure at a comparatively low value of the load, and does not explain the most outstanding fact—why this early failure does not actually occur.

Thus, it is only with the knowledge that strain hardening does occur and, in the hope that its extent will be sufficient to prevent an early failure, that it is possible to compute the limiting value of the load and the corresponding deformations without any regard for strain hardening. This hope for beneficial assistance of strain hardening is probably nearly always justified when dealing with mild steel structures, but how true it would be in relation to other materials is questionable. There is strong suspicion that with some aluminium alloys, characterized by a very small and slow rise of stress beyond yielding, the theory of limit design in some cases may prove invalid. In presenting the data to serve as a warning for the too ready and unquestioned acceptance of the theory of limit design, Mr. Horne has rendered a good service to the profession.

Paper No. 2335

REFLECTIONS ON STANDARD SPECIFICATIONS FOR STRUCTURAL DESIGN

By Alfred M. Freudenthal,[1] Assoc. M. ASCE

With Discussion by Messrs. I. Oesterblom, John M. Hayes, and Alfred M. Freudenthal

Synopsis

Standard specifications for structural design determine the effectiveness with which an engineer utilizes his materials; they affect the safety of structures; and they exert considerable influence upon the manufacture of materials. So powerful a tool should be handled in a manner consistent with scientific and engineering progress.

This paper attempts to rationalize the formulation of such standard specifications. It elaborates on their fundamental aspects and advocates the adoption of the scientific method in their preparation. Two examples, dealing with design live loads for highway bridges and with fatigue strength of butt welds, illustrate the arguments and procedure.

Introduction

Rational and scientific methods for designing engineering structures are comparatively new. Until the last one hundred and fifty years of recorded history, engineering was practiced as an art. Up to that time great engineering works were created by artists, whose genius of intuition was guided by sound empirical knowledge acquired through individual experience. For a long time engineering and science progressed at a different level and at a different pace. Scientists of that time, such as Euler, Hooke, Poisson, and others, whose investigations, subsequently, had a most decisive influence upon structural design and analysis, worked on an entirely different level; it took many decades before their theoretical achievements affected the engineer's methods of design. The lag between the progress of science and that of engineering—between research and practice—is a typical phenomenon of technical development; the gradual reduction of this interval indicates the increasingly effective coordination of scientific and technical progress.

Note.—Published in February, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Lecturer on Bridge Eng., Hebrew Inst. of Tech., Haifa, Palestine.

Thus, engineering is being gradually transformed from a profession based on tradition and individual experience to one relying more and more on the methodically selected and classified collective experience provided by that eminently socializing agent, science. However, with this shifting of emphasis, engineering has not become an exact science—it remains a social activity. Evidently, then, it cannot dispense with subjective judgment which, while supplementing the judgment, based on objective evidence and knowledge, must not be allowed to supersede it. Only where the objective approach has not been discerned will it be necessary to rely upon subjective judgment alone.

ORGANIZATION OF ENGINEERING SCIENCE

Knowledge is obtained directly by perception or indirectly by argument. Since such knowledge as is perceived or experienced directly through sensations, by observation or measurement, furnishes the premises of that part derived by argument, experience represents the sole source of knowledge. From the premises of direct experience attempts are made to justify some degree of rational belief about all sorts of inferences and conclusions by perceiving logical relations connecting them. Terms such as "certain" and "probable" describe the different degrees of this belief according to the volume of experience supporting it. The purpose or aim of these inferences and conclusions is to organize, for subsequent application, factual knowledge—using interpretation, generalization, and abstraction—mostly in the form of data or mathematical functions describing the regularities and recurrences of the observed phenomena.

Fundamentally, it makes no difference, however, whether the formulation is mathematical or verbal. There is no particular virtue in mathematical functions or in numbers as such. If they are not really representative, they can be even more misleading than verbal statements; because, psychologically, the number or formula is bound to give the impression of accuracy.

Much engineering knowledge is still descriptive, although its presentation is mathematical. As in the case of the genuinely descriptive marine or foundation engineering, there is always an undisguised, immediate, and real experience as the basis of every generalization. The development toward an exact science by using mathematical abstractions and mathematical language, however, leads occasionally to the ascendency (or domination) of the mathematical form over the real physical content—to an overvaluation of the mathematical exactness inherent in an expression of physical reality and, consequently, to a serious distortion of perspective. To avoid the pitfalls of the mathematical approach to engineering problems, it is essential to realize and to check on its limitations.

The significance attributed to information expressed by numbers or mathematical functions is an indication of the level of scientific organization of experience. At the level of descriptive science, experience is purely qualitative and, therefore, not measurable. Most knowledge has not advanced beyond this stage. A higher level is reached when methods of measuring assumedly relevant, recurrent phenomena have been developed and when the resulting figures and relations are used to devise a quantitative, although empiric, classification of experience. Numerical data have still no absolute significance; they are useful only as far as they are suitable to delimit certain classes of phenomena, and their relative significance is determined by the rigor of the classification which they express. The number or the mathematical function reaches a significance of its own only at the highest level of organization of knowledge—at that of exact science, where the relations between sets of causes and resulting effects have been so reliably established that their expression in mathematical language is justified.

Only a small part of technical science has attained this level; even in structural engineering, the methods of which are relatively exact, data are frequently utilized that do not even belong to the empiric level—as when specifying a definite number for elongation at rupture of structural steel. Although this number may be determined by a well-defined measurement belonging to the sphere of exact physical science, it does not represent more than an arbitrary conventional classification of the material with regard to a desired structural performance, based on the assumption of a vague correlation with such performance. At best it can be used only for purposes of practical designation of the material; it therefore belongs to a stage of descriptive science where measurements of phenomena already play an important part, but where rational although empiric, correlation with essential physical properties is still nonexistent. Such data should not be invested with a meaning beyond what can be justified by the physical reality behind them.

However, even where mathematical presentation is justified, the data or the function can be expected to fit the observed reality only as closely as by the margin of uncertainty inherent in the process of sampling and observation and by the margin of error detectable with the instruments used. Hence, with both the extension of the observational range and the perfection of instruments, the accuracy and reliability of such data and mathematical formulas will undergo continual improvement. Moreover, the regularity and recurrence of physical phenomena, quantities, and constants will never be perfect in a numerical sense. This fact requires the replacement of the conventional concepts of one-valued functional correlation by concepts embodying the uncertainty inherent in any observation, abstraction, or presentation of physical phenomena—where both constants and laws are considered to be of a statistical character and where the closest approach to constancy which a physical quality may attain is understood to be such that it may be represented by a frequency distribution for which all assignable causes of variation have been eliminated.

Ultimately it is of no consequence whether the fluctuations are real, objective, and inherent in the quality considered or are apparent and caused by deficiencies in the procedure of observation or measurement. Thus, for example, the strength of a material, all things being equal, should be a fairly regular and recurrent physical quality. No two samples, however, will show exactly the same test strength, except by pure chance. Fluctuations may result from differences in the quality of the material forming the individual samples and from lack of uniformity within the samples. They may, however, result from the method by which the samples have been taken and prepared; from the procedure of testing; from inaccuracies of observation and measurement; or from a combination of these. The difficulties increase with increasing complexity of the phenomenon or the quality considered or of the sampling and testing procedure. Whereas, for instance, the results of the static tension test of steel are fairly uniform and interpretable, those of fatigue tests display irregularities and frequently become inconclusive. The question, then, is whether such lack of uniformity is an inherent characteristic of the fatigue strength of the material or is the result of the sampling and testing operation.

Generally engineering research is not so much concerned with the behavior of individual specimens of a certain group as with the behavior of the group itself. "Weight" or "strength" are abstractions not intended to represent the real measurable quality of an individual sample, but rather of the "bulk" of the material or of the statistical "universe" of all members of the group—such, for example, as the structural elements or shapes manufactured to one and the same specification in a number of plants. Similarly, "load" in a structural sense refers to the "universe" of states of loading which, for a specified group of structures, may be expected to occur. Since the behavior of a "bulk" or "universe" can be represented only by a distribution curve of statistical frequencies, any law describing the relation of real physical qualities will, to a certain extent, be statistical even if, fundamentally, its character is that of an exact law.

The Standard Specification

These basic aspects of engineering science have a particular bearing on the preparation of standard specifications for structural design. The designer relies on the specifications for all relevant information about the fundamental assumptions and premises of his design. He cannot and should not be expected to ascertain, select, and appraise, for each structure individually, the basic facts and conditions, such as load or permissible stresses, by which both the safety and the economy of the structure will be determined. This is because only in exceptional cases will he command the wide knowledge and experience required for such selection and for the appraisal of all implications. With the increasing complexity of engineering problems he will have to rely increasingly on the organized collective experience of the profession and to substitute the considered objective judgment of the group for his individual opinion.

The standard specification represents this judgment: It is the result of a collective effort of the leading groups within the profession and attempts to convey the quintessence of factual knowledge and engineering experience; it is arrived at by the application of objective methods of research and by rational interpretation of the results. Its purpose is to relieve the designer of the responsibility of selecting the premises and assumptions of the analysis of an individual structure, and to do so by establishing the fundamental relations and conditions pertaining to the design of large groups of structures having certain features in common, such as the material, the type of load, or the structural shape. This procedure has so far been successful: The number of structures designed, rather effectively, by engineers with no more than preliminary experience is considerable.

However, the rapid expansion of the engineer's knowledge and the complexity of his tasks increase the scope and difficulties of the problems to be solved and of the decisions to be reached collectively. The soundness and correctness of these decisions, embodied in and conveyed by the respective standard specifications, is therefore becoming ever more important. Because of the extensive and differentiated knowledge required, the questions arise as to whether the methods by which collective decisions have been reached are sufficiently effective and as to whether subjective judgment and belief, unsupported by adequate objective evidence, are not allowed to play too important a part.

Standard specifications determine the efficiency of the utilization of engineering materials; they decisively affect the safety of structures; and they exert considerable influence upon the manufacture of technical materials. Thus, there is every reason to require that so powerful a tool be handled not merely with judicious care and caution, but in a manner consistent with engineering progress. This is particularly important because the utmost effectiveness in the utilization of basic materials is no longer a matter of individual judgment, but one of national importance.

Among the subjects of fundamental character covered by specifications for structural design are: (1) Design loads; (2) resistance of structural members and shapes and their permissible stresses; and (3) performance, selection, and quality control of structural materials. These are interdependent and must be coordinated. Thus, a specified permissible stress has real meaning only in conjunction with the specification of the design load and the method of structural analysis.[2] The conventional procedure by which standards for design loads, for permissible stresses, and for classifying and selecting materials are devised independently and frequently by different groups—administrative bodies specifying loads; professional societies dealing with matters of structural analysis and strength; and organizations engaged in the testing of manufactured products handling the selection of materials and control requirements—should be replaced by a process coordinating all relevant data and information. Only such a process would result in balanced standard specifications.

A rational approach to any problem requires the appraisal of the meaning of the terms and concepts, since meanings often are not what they appear at first sight. A very effective tool for this purpose is P. W. Bridgman's "operational analysis"[3]—namely, making an analysis of what is actually done when using the concept leads to a real understanding of its meaning. Using this method for the analysis of the concept of "standard specification for design," it is found that the "operation" consists in applying organized fundamental knowledge, derived from past experience and presented in a form most suitable for practical use, to the design of new structures which are expected to serve a definite purpose during a period extending into a more or less distant future. Application of past experience to the design of structures for future service requires prediction of future development (mainly of load and traffic volume), of changes of resistance, and of the state of maintenance and of the deterioration of the structure. These latter are matters for conjecture and represent, therefore, essentially problems for subjective judgment.

---

[2] "The Safety of Structures," by Alfred M. Freudenthal, *Transactions*, ASCE, Vol. 112, 1947, p. 125.

[3] "The Intelligent Individual and Society," by P. W. Bridgman, The Macmillan Co., New York, N. Y. 1938, pp. 74–75.

The "operational" definition shows that the first step in preparing specifications is the collection of past experience. To apply such experience effectively, the salient and recurrent phenomena should be selected and classified to derive from them the relevant relationships either by statistical inference or by induction. Each of the two approaches leads to a different kind of knowledge: Reasoning by induction, justified only if the factual evidence is conclusive, leads to knowledge of principles and to definite functional relationships of general validity; statistical inference, dealing with arguments which are not conclusive, but about which a certain degree of belief may rationally be entertained because it is supported by an appropriate amount of direct evidence, leads to knowledge of facts only and to correlations between certain variables. The reliability of these approaches is determined by the amount of evidence available; the range of validity is restricted to the original range of observation.

It is not always easy to draw a line between the two approaches because of the rôle played by the concept of chance. "Chance" may be subjective as well as objective. Subjective chance is a measure of ignorance of principles, the knowledge of which would enable one to predict the occurrence of certain events. If, however, such events are brought about by a coincidence of causes and circumstances so numerous and so complex that knowledge of principles leading to prediction is altogether out of mental reach, this is defined as objective chance. Because it is often difficult to determine whether the chance happenings entering into experience have a subjective or an objective character, the boundary between logical induction and statistical inference remains indistinct.

"Past Experience" and Experiment

The data that represent "past experience" are obtained either (1) by statistical evaluation of observations of phenomena which bear directly on the quality considered (such as traffic records or wind velocity records for the determination of service loads); (2) by observations of the behavior of existing structures (service records); or (3) by the interpretation of the results of tests or experiments designed to supply the desired information. The testing of full-scale models of structures is mostly impracticable because of their size and the complexity of service conditions—the cost of reproducing which is prohibitive. "Past experience" will, therefore, have to be based upon tests of suitably designed and selected comparatively small specimens. Such tests will be rationally interpretable if they have structural significance—that is, if the specimens tested can be considered as models, having been designed in accordance with the relevant laws of mechanical (not merely geometrical) similitude. Tests will result in the acquisition of relevant factual evidence only if:

(*a*) They can be rationally correlated with the problem under consideration;
(*b*) The characteristics observed are real physical properties, measurable in fundamental units, so as to make the tests easily reproducible and comparable with similar experiments;

(*c*) No oversimplification has been introduced by neglecting or eliminating variables or groups of variables, the relevance of which has not been reliably ascertained; and

(*d*) They have been repeated frequently enough to control the variabilities by statistical methods in order to recognize their physical significance.

Conventional tests are mostly comparative; their structural significance is doubtful or vague, as is their correlation with actual structural performance. With regard to structural materials, modern technological skill in securing specified properties is as yet not equaled by ability to discern, to specify rationally, and to control the properties which are desirable with regard to the contemplated performance in a structure.

Since past experience is to be applied to present construction, the expected behavior of the structure must be predicted on the strength of such experience. This requires the introduction of control: Making sure that what is being done is what is intended following available experience and knowledge. Obviously, such control cannot be performed by direct observation of the relevant characteristics, such as the actual resistance of the structure, but only by observing and recording one or a number of easily measurable qualities which, singly or jointly, can be considered representative. The selection of representative qualities and of adequate testing methods is, therefore, the first step in the establishment of control. The second is the selection of representative samples and the specification of their number and of the manner in which they are to be taken, so as to enable rational conclusions about the quality of the "bulk" or the "universe."

CORRELATION

The possibility of correlating the results of tests of a comparatively small number of samples with the quality of the "bulk" or "universe" is conditional on the imposition of adequate, uniform, and permanent control of the variabilities of the relevant characteristics upon each and every stage of the manufacturing process of the structure, from the production of the raw material to the final process of assembly.

When devising representative control tests, one has to rely on: (1) A strict functional relationship between the relevant characteristic and the observed property, (2) a statistical correlation, or (3) merely an intuitive qualitative correlation. In practical application, the difference between relationships (1) and (2) is one of grade rather than one of principle—a strict functional relationship usually being considered the limit of perfection of a statistical correlation. Also, the number of standard tests based upon a functional relationship between the representative and the represented qualities is surprisingly small, and most tests are based on an intuitive correlation. The general application of statistical methods in analyzing and drawing up standard specifications is one of the conditions of the rational utilization of materials.

Statistical methods have two different functions: One descriptive, concerned with the concise presentation of the variabilities of certain characteristics of observed phenomena; and the other inductive, with the aim of extending and utilizing such description and presentation in the generalization and the prediction of the variabilities in the future. It is essential not to lose sight of the distinction since, frequently, having found a complete and satisfactory method of description, the engineer becomes less careful about the transitional arguments by which he attempts to justify the subsequent use of this description for purposes of generalization and prediction.

The ability to discriminate between the descriptive and the inductive use of statistics, as well as between functional, statistical, and intuitive correlation of phenomena, acquired by frequent and judicious application of statistical methods, is important. The engineer thus acquires not merely the habit of separating assignable causes of variation of a phenomenon from chance variabilities, but also the faculty of discriminating between subjective and objective chance causes, without losing sight of the arbitrary nature and of the expediency involved in all technical applications. He will also learn necessary caution when generalizing from a limited amount of experience. Particularly in the preparation of standard specifications will this intuitive familiarity with the possibilities as well as with the pitfalls of the statistical methods prove important.

As an illustration of the preceding arguments an attempt will be made to establish a rational approach to the drafting of two typical standard specifications for structural design. Since the data on which the examples could be based are not exhaustive, these examples are suggestive of the method applied rather than conclusive with regard to the results.

Example 1. Live Load For Medium and Long-Span Highway Bridges

The design live load for short-span highway bridges or bridge members is represented by the vehicle with the most severe concentration of weight—that is, by a fully loaded truck traveling at high speed. However, for medium and long spans the effect of the individual load concentration is small compared with the effect of the total weight of the traffic properly distributed over the respective influence line; a uniformly distributed design load will therefore represent actual loading conditions. This design load is affected by the character of the traffic; by its distribution, density, and speed; by the number of traffic lanes; by the expected period of service; and by probable changes in the traffic characteristics during the period of service. Information about the heaviest types of vehicles is insufficient, and the fact that the existing specifications convey only this information—apart from a more or less arbitrary impact factor—is a striking illustration of their inadequacy.

The types of vehicles using the modern highway are the passenger car, the passenger bus, the single truck, and the power unit or tractor with semitrailer or trailer. Denoting the loaded weights of the various groups of vehicles by $W_1,\cdots,W_n$, their empty weights by $W'_1,\cdots,W'_n$, the average frequencies of occurrence of the various groups by $F_{V1},\cdots,F_{Vn}$, the average frequencies of occurrence of the loaded vehicles of a certain group by $F_{L1},\cdots,F_{Ln}$, and the total number of vehicles which can be accommodated on all lanes of the bridge by n and their over-all length by L_n, the design live load, (w_{LO}) can be expressed by:

$$\begin{aligned} w_{LO} = \frac{1}{L_n} [F_{V1} F_{L1} W_1 + F_{V1} (1 - F_{L1}) W'_1 + \cdots \\ F_{Vn} F_{Ln} W_n + F_{Vn} (1 - F_{Ln}) W'_n] \ldots\ldots\ldots\ldots\ldots (1) \end{aligned}$$

Every term of this expression is to be considered a frequency distribution. Eq. 1 represents the static weight of the design load, the vehicles being placed along the traffic lanes close to each other. The real traffic load is, however, not static but travels over the structure at a certain speed, exerting dynamic influences in addition to its static weight. At the same time the distances between the consecutive vehicles will increase with their traveling speed, resulting in a reduction of the specific load. If both the load-increasing effects and the load-reducing effects of the traveling speed are combined into one factor, I, for which the conventional term "dynamic increment" may be used, then dynamic design load, $w_L = w_{LO}\,(1 + I)$.

An expression may now be introduced for the load-increasing effects and load-reducing effects as functions of the traveling speed, v^2. Let the impact increment and its range of fluctuation be a function of the number of vehicles n:

$$I'(v) = \bar{I}'(v) \left(1 \pm \frac{1.0}{\sqrt{n}} \right) \dots\dots (2a)$$

in which

$$\bar{I}'(v) = \frac{1.50}{(1 + V_o/3v)\,\sqrt{n}} \dots\dots (2b)$$

Also, average spacing between consecutive vehicles (center to center),

$$l(v) = l_o(v)(1 \pm 0.20) \dots\dots (3a)$$

in which $V_o = 10$ miles per hr; and $L_o = 40$ ft; and

$$l_o(v) = \frac{L_o}{1 - 0.15\,v/V_o} \dots\dots (3b)$$

The chance fluctuations of $l(v)$ about its average $\bar{l}(v)$ can be assumed to reach ±60%, so as to include zero distance between consecutive vehicles as an extreme range.

Hence,

$$(1 + I) = [1 + I'(v)]\,\frac{L_n}{n\,l(v)} \dots\dots (4)$$

In this expression $I'(v)$, L_n, and $l(v)$ are frequency distributions. The quantity $\frac{1 + I'(v)}{l(v)}$, reaches its maximum for $v = 11.5$ miles per hr. This can be considered the critical traveling speed of the design load for bridges, accommodating more than two traveling trucks per lane, corresponding to spans exceeding 75 ft.

The weight distribution diagrams of the principal type of vehicle, the single truck, can be deduced from traffic surveys[4] and studies[5] conducted by the United States Public Roads Administration. These surveys also show that the proportion of trucks of all types (including passenger buses) is normally between 10% and 25% of the total number of vehicles and that the proportion of empty trucks is between 0.35 and 0.40 of the total number of trucks. Studying the relation between the weight and length of trucks, it may be concluded that the ratios of the average weights of single trucks, tractor-semitrailers, and tractor-trailers are approximately 1:1.5:2.5 although the ratios of the respective lengths are about 1:1.5:1.9. Hence, the specific loads of single trucks very nearly equal those of tractor-semitrailer combinations; the tractor-trailer combinations are about one third heavier. The number of these combinations, however, does not exceed an average of 15% of the total number of trucks.

---

[5] "A Study of the Weights and Dimensions of Trucks," *ibid.*, Vol. 16, 1935, pp. 37–52.

Distribution diagrams of the gross weight of both loaded and empty single trucks and of their over-all length have been deduced from the surveys and observations of the Public Roads Administration and are presented in Fig. 1.

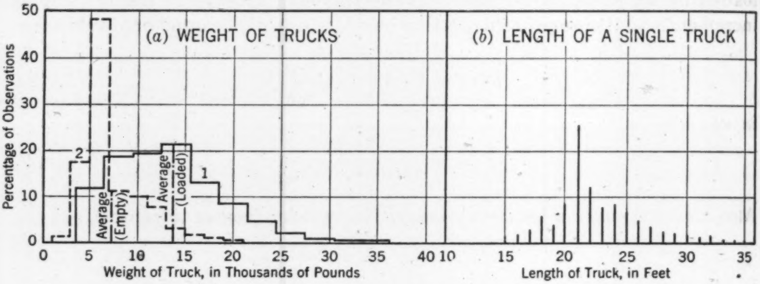

FIG. 1.—CURVES OF FREQUENCY DISTRIBUTION FOR THE PRINCIPAL TRAFFIC CHARACTERISTICS

Computations from the observations including values of σ and k give the following: From frequency distribution of weight (Fig. 1(*a*)):

Symbol	Curve 1 (loaded trucks)	Curve 2 (empty trucks)
$\bar{W}_1$	13,800 lb; $\bar{W}'_1$	7,200 lb
σ (standard deviation)	5,900 lb	3,200 lb
k (skewness)	+0.5	+1.5

$\bar{W}_1$ and W'_1 (maximum range, with a probability of 0.999)—

Computation..... $W_1(\max) = \bar{W}'_1 + 3.5\sigma$ $W'_1(\max) = W'_1 + 3.9\sigma$
Result............. 34,500 lb 19,700 lb

and, from frequency distribution of length (Fig. 1(*b*)):

$$\bar{L} = 22.0 \text{ ft}$$
$$\sigma = 3.6 \text{ ft}$$
$$k = +1.0$$

and the maximum range—

$$L\ (\max) = \bar{L} + 3.7\,\sigma = 35.5 \text{ ft (probability 0.999)}$$

No distribution diagrams are available for weights and lengths of passenger cars; their variations, however, are comparatively small and a specific load of 400 lb per ft of traffic lane with a range of fluctuation of some 25% may be considered as representing actual conditions quite fairly. The average length of passenger cars may be assumed as 15 ft; no difference need be made between loaded and empty cars.

To establish the (average) design load according to Eq. 1, the frequency values in Table 1 should be introduced. These average frequency ratios deduced from observations, have been amended to provide for future development of traffic. The loads of trucks as presented in Fig. 1 are increased by 50% to anticipate rapid development of heavy cargo hauling on highways; likewise, the specific loads of passenger cars are increased by 20%, although even this figure appears excessive in view of the probable increased use of light materials in the construction of cars.

TABLE 1.—VALUES OF FREQUENCY PERCENTAGES OF GROUPS OF VEHICLES

Line	Traffic	F_V[a]	F_L[b]
1	Single trucks, buses, and tractor-semitrailers.....	0.25	0.70
2	Tractor-trailers..........	0.05	0.80

[a] Percentage of the total number (n) of vehicles.
[b] Average percentage of loaded vehicles in a group.

Introducing these modifications and considering the observed frequency distribution of load intensities as the "a priori" probability of the occurrence of these intensities in future—a procedure dating back to Aristotle who stated that "the probable is what for the most part happens"—the static design load w_{LO} and the "dynamic" design load $w_{LO}(1 + I)$ have been evaluated from Eqs. 1 to 4 and the frequency distributions of Fig. 1. The results are presented in Fig. 2. The individual average design values and the ranges of fluctuation pertaining to a probability of 0.001 that values will fall outside this range have

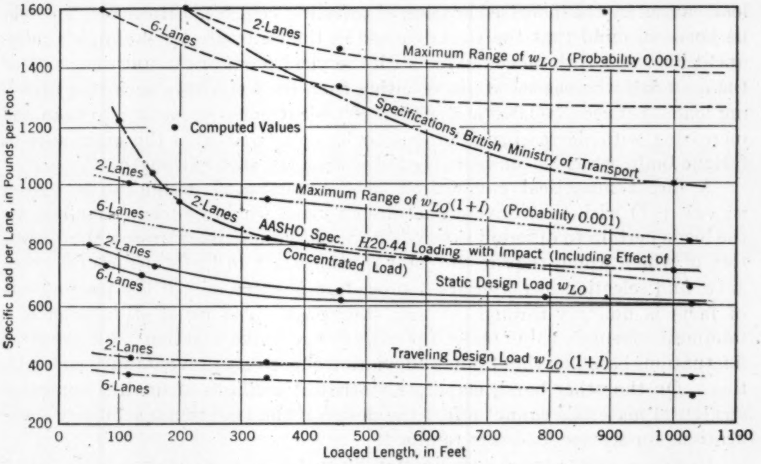

FIG. 2.—DESIGN LIVE LOADS FOR HIGHWAY BRIDGES

been computed for a two-lane structure and a six-lane structure of a length accommodating 3, 9, and 27 vehicles, respectively, per lane.

In establishing the maximum upper range of fluctuations, on which the safety factor pertaining to the design load depends, variations caused by fluctuations of the weight of vehicles according to Fig. 1(*a*), variations caused by fluctuations in the ratio of trucks, and variations caused by fluctuations in the ratio of empty vehicles have been evaluated individually and statistically superimposed. Thus, in the case of eighteen vehicles on the bridge for instance, the static design load w_{LO} comprises one loaded tractor-trailer, four loaded trucks, and one empty truck, and twelve passenger cars, all of average weight; the maximum load due to fluctuations of weight results from the same grouping of vehicles of maximum weight. The maximum variation due to fluctuations of the ratio of trucks results in a group consisting of three loaded tractor-trailers and one empty tractor-trailer, six loaded trucks and two empty trucks, and six passenger cars, all of average weight; the range of variations due to fluctuations in the ratio of empty trucks is determined by replacing the empty truck in the design-load group by a loaded one. Different groupings of vehicles result in varying lengths of the structures accommodating them.

In Fig. 2 it is shown that, contrary to conventional assumptions, the static load w_{LO} considerably exceeds the "dynamic" load $w_{LO}(1 + I)$. This is because the influence of the dynamic load increment is less than the reduction of the load caused by the increased spacing of traveling vehicles. However, it should be borne in mind that the strain caused in the structure by the highly infrequent load w_{LO} is to be compared with the yield point or the static strength of the material, whereas the strain resulting from the frequently occurring traveling load—between 500,000 and 10,000,000 occurrences according to span and increasing with decreasing spans—is to be compared with the endurance or fatigue limit, which is considerably lower than the static strength.

A direct numerical comparison of the computed design loads w_{LO} or $w_{LO}(1 + I)$ with the conventional design loads would be misleading because the loads pertain to different safety factors and permissible stresses, the evaluation of which would require the joint consideration of loads, structural resistance, and selection of material—a procedure possible only if the presentation of facts is uniform throughout and statistical. The usual stipulation of a minimum strength value instead of an average value together with ranges of fluctuations based on the standard deviation effectively prevents such coordination. On the other hand, elaborate statistical methods of quality control of structural materials cannot affect the design if the traditional arbitrary specifications for service loads are retained.

However, even perfect coordination by systematic application of statistical methods will fall short of its purpose if it is one of form only. The importance of analyzing the compatibility of the correlated qualities cannot be emphasized strongly enough. There is as little sense in correlating the strain resulting from a frequently repeated, rapidly moving load with the yield limit of a material, as there is in correlating the strain produced by a steady or very slowly moving load with the fatigue limit.

Even without numerical comparison, however, it appears from Fig. 2 that the conventional values of design loads of highway bridges are substantially higher than could be justified from the factual evidence and a rather unfavorable appraisal of future developments.

EXAMPLE 2. FATIGUE STRENGTH OF BUTT WELDS IN ORDINARY BRIDGE STEEL

To establish the "dependable" fatigue strength of butt welds in ordinary carbon bridge steel, the Committee on Fatigue Testing of the Welding Research Council of the Engineering Foundation has initiated an extensive program of tests of butt-welded specimens, prepared under fairly controlled commercial conditions.[6] From the test results, values are deduced for:

> "*** the unit fatigue strength which may be dependably expected in butt-welded joints commercially produced under standard specifications; to which dependable strength a designer will of course apply whatever factor of safety he deems appropriate for his particular condition."[7]

A study of the test results and of the conclusions shows that, because of the lack of a strictly rational, statistical interpretation of these results, their full implication has been missed, thus partly depriving an otherwise excellent and valuable test series of its merits. In the following independent analysis of the results the full information will be presented. This will lead to the establishment of a rational meaning of the term "dependable," as well as to an estimate of a more objective value of the safety factor than that which the designer "deems appropriate." Contrary to the procedure adopted in the Welding Research Council report, it has not been found necessary to introduce arbitrary criteria for eliminating certain test results only:

> "*** because they would in each case affect the average in a direction for which it is felt that they have too weak a basis in fact as compared with the other data in the same group."[8]

The results of tests on one hundred and eighty-six commercially fabricated, butt-welded specimens—5 in. by $\frac{7}{8}$ in. in critical cross section—are summarized in condensed form in Tables 2, 3 and 4. Data relative to the actual stress divided by the number of load cycles sustained (s_F/N), taken from individual tests have been converted into the approximate fatigue strength s_{FO} at N_o = 100,000 cycles and N_o = 2,000,000 cycles by using the empirical equation:

$$s_{FO} = s_F \left(\frac{N}{N_o} \right)^{\nu} \quad \text{.........................(5)}$$

in a manner similar to that adopted in the report of the Welding Research Council.[6] Exponent ν was derived from tests by establishing the frequency distribution of the number of cycles N endured to failure under various stress

[a] s_{FO} equals the fatigue strength, in pounds per square inch, computed from the applied load and the observed number of load applications sustained prior to failure. A positive sign denotes tension.

amplitudes (see Fig. 3) and computing the value of ν from the averages. This procedure is contrary to that of the Welding Research Council report in which a value of $\nu = 0.13$ was assumed on the basis of previous, and not entirely relevant, tests.

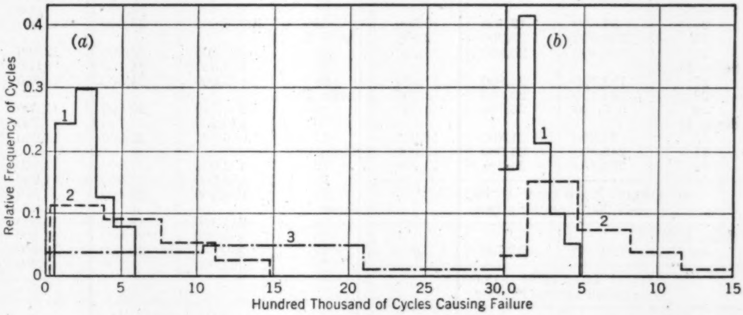

FIG. 3.—FREQUENCY DISTRIBUTION OF THE NUMBER OF CYCLES N REQUIRED TO CAUSE FAILURE

The applied procedure appears fully justified since the apparently inconsistent values of N show a unimodal distribution which, however widespread and skew, is fairly well reproducible by the second approximation of the Normal Law.[9] Thus, with the resulting values of $\nu = 0.235$ for pulsating stresses and $\nu = 0.205$ for reversing stresses, the approximate values of the fatigue strength

s_{FO} have been computed and presented in Tables 2 and 3. Statistical evaluation of the results and presentation of this fatigue strength for $N_o = 100{,}000$ cycles and $N_o = 2{,}000{,}000$ cycles in the form of a frequency distribution both for zero-to-tension amplitudes and for full-stress reversals (Tables 2 and 3 and Fig. 4) give the ranges of variation about the average values $\bar{s}_{FO} \pm C\,\sigma$ where

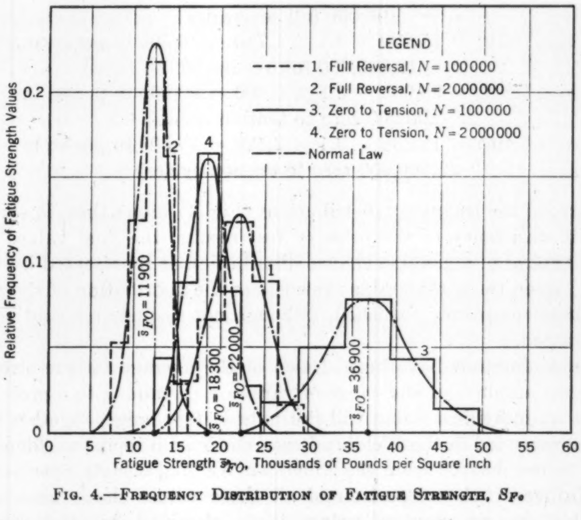

FIG. 4.—FREQUENCY DISTRIBUTION OF FATIGUE STRENGTH, S_{Fo}

C denotes the range constants pertaining to selected probabilities of occurrence of values outside these ranges.

The routine computations have been omitted from Tables 2 and 3, and the following computations will serve as examples to demonstrate the procedure:

The last item of Col. 3, Table 2, is the total of the 106 values of s_{FO} computed from individual tests. The average value then is equal to 3,912,350/106 = 36,900 lb per sq in. A column of differences from the mean is then computed for each test, and another column for squared values. The sum of this last column being $\Sigma(s_{FO} - \bar{s}_{FO})^2 = 2{,}883.8 \times 10^6$, the standard deviation is $\sigma = \sqrt{\dfrac{2{,}883.8 \times 10^6}{106}} = \pm\ 5{,}200$ lb per sq in. To derive values of the skewness of the distribution k a third column $(s_{FO} - \bar{s}_{FO})^3$ is computed for each test and the total $\Sigma(s_{FO} - \bar{s}_{FO})^3$ is found to be $1{,}896.8 \times 10^9$. Thus, $k = \dfrac{(F - \bar{F})^3}{106 \times \sigma^3}$ $= k = \dfrac{1{,}896.8}{106 \times 5.2^3} = +\ 0.13$.

Similarly, for $N_o = 2{,}000{,}000$ cycles in Col. 4, Table 2: $\bar{s}_{FO} = 18{,}300$ lb per sq in., $\sigma = 2{,}500$ lb per sq in., and $k = +\ 0.09$; for $N_o = 100{,}000$ cycles (full reversal) in Col. 3, Table 3, $\bar{s}_{FO} = 22{,}000$ lb per sq in., $\sigma = 3{,}160$ lb per sq in., and $k = -\ 0.21$; and, for $N_o = 2{,}000{,}000$ cycles (full reversal) in Col. 4, Table 3, $s_{FO} = 11{,}900$ lb per sq in., $\sigma = 1{,}740$ lb per sq in., and $k = -\ 0.24$.

Referring to Fig. 4, computations for minimum strength ($C = 3.1$ pertaining to probability 0.001) give:

$$s_{FO1}\,(\text{min}) = 22{,}000 - 3.1 \times 3{,}160 = 12{,}200 \text{ lb per sq in.}$$
$$(100{,}000 \text{ full reversals})$$
$$s_{FO2}\,(\text{min}) = 11{,}900 - 3.1 \times 1{,}740 = 6{,}500 \text{ lb per sq in.}$$
$$(2{,}000{,}000 \text{ full reversals})$$
$$s_{FO3}\,(\text{min}) = 36{,}900 - 3.1 \times 5{,}200 = 20{,}800 \text{ lb per sq in.}$$
$$(100{,}000 \text{ zero to tension cycles})$$
$$s_{FO4}\,(\text{min}) = 18{,}300 - 3.1 \times 2{,}520 = 10{,}500 \text{ lb per sq in.}$$
$$(2{,}000{,}000 \text{ zero to tension cycles})$$

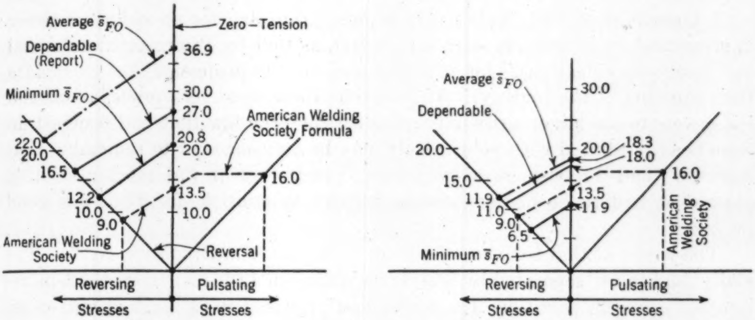
The form of the frequency distributions (Fig. 4) shows that, in spite of the apparent inconsistency of the primary test results, the final values are of a regularity typical of a genuine chance distribution as represented by the Normal Law. Even the considerable skewness of the distribution of the values of N has almost completely vanished, although not a single relevant result has been eliminated.

In Fig. 5 diagrams have been drawn of the average fatigue strength for various stress amplitudes and range of variation pertaining to a probability of 0.001 that an individual value will fall outside this range, together with the values recommended in the Welding Research Council report as "dependable" and with values derived from the American Welding Society Specification for Welded Bridges.[10] A comparison of all these values shows that the term "dependable" is meaningless unless it is classified by the appropriate probability.

To compare the ranges of variation of the fatigue strength of butt welds with those of the static strength s_T of the parent material, this strength has been computed, by statistical evaluation of the data contained in the Welding Research Council report,[6] as $s_T = 61{,}000 \pm 8{,}500 = 61{,}000\,(1 \pm 0.14)$. Expressed in terms of the average static strength the fatigue strength of butt welds has, therefore, the average values given in Table 5.

---

[10] "Specifications for Welded Highways and Railway Bridges," Am. Welding Soc., 1941, p. 18, formula 7.



(a) 100000 CYCLES (b) 2000000 CYCLES

FIG. 5.—FATIGUE STRENGTH AS A FUNCTION OF AMPLITUDE OF STRESS CYCLES, IN KIPS PER SQUARE INCH

TABLE 5.—FATIGUE STRENGTH OF STATIC TENSILE STRENGTH, s_T.

Cycles	$N_e = 100{,}000$	$N_e = 2{,}000{,}000$
Zero to tension....	$0.61\ s_T$	$0.30\ s_T$
Full reversal......	$0.36\ s_T$	$0.195\ s_T$

The statistical difference between the specific maximum ranges of variation of the fatigue strength of butt welds about the average value (which is roughly ± 45%) and of the static strength of the parent material represents the range of variation caused entirely by the effects of welding and of fatigue. This range is therefore $\sqrt{(0.45)^2 - (0.14)^2} = \pm 43\%$. According to the definition of the objective safety factor,[2] it is required that in the design of butt welds in fatigue this factor be $\dfrac{1 - 0.14}{1 - 0.43} = 1.5$ times greater than the factor pertaining to the design of plain sections in static tension—if, all other things being equal, failure is to be prevented in both cases with equal probability.

CONCLUSION

The far-reaching effects of standard specifications in the fields of structural design and of production of engineering materials make it essential that in the preparation of such specifications the barrenness of conventionality and routine be evaded by the scientific attitude to engineering problems, and a spirit of vigorous critical analysis should replace traditional complacency. Nothing must be taken for granted and every relation assumed must be carefully examined by the most appropriate method, be it logical induction or statistical inference. Only thus will the impact of modern scientific development make itself felt in the engineer's everyday work.

DISCUSSION

I. Oesterblom,[11] M. ASCE.—It is most gratifying for an old practitioner in structural engineering to see a paper such as that by Professor Freudenthal on "design specifications," for it shows how far the profession has gone since the beginning of the century. At that time there were very few controls and these were in the larger cities only. Worse yet—the few that had been set up were heavily tainted with politics. It may be amusing now to remember that concrete "had no business aboveground," and when it was most graciously allowed it had to be heavy—always heavier than brick, for that was good politics.

The writer at that time was designing a big stable in Brooklyn, N. Y. The stalls "had to be" separated by 8-in. brick walls—or 12-in. concrete; the 4-in. reinforced concrete partitions the writer had proposed were laughed out of existence. Nothing was mentioned about how the concrete was to be made, however, so that into the walls ultimately went all kinds of refuse salvaged from the lot, including some stable manure.

That time is gone now, seemingly, because the authorities are willing to listen to such excellent rationalization as is presented by the author; and this again raises the very important question: Who were the men that made the most recent codes and to what extent were they governed by the law of probabilities? This is a very pertinent question. Even today one may examine official schedules of permissible live loads, and find that there are great variations even for cities in which they should be the same. Any recent assembly of loads will show variations to 100% where there should have been no variations.

In the light of the present paper, therefore, it is proper to ask: How, and by whom, were the codes made? Were they made by politicians or by practical builders? Were professional engineers also consulted? If engineers were consulted, to what extent were their opinions respected and followed? If they were not consulted, why not? Also what was done to tell the world that engineering judgment should have been included—for the sake of equity and safety for those who "foot the bills."

Bridge builders, as a rule, have been quite free from political interference. Therefore, Example 1 is well chosen; but there should have been another similar example for the common building loads in regard to which more rationalization is sorely needed. Usually there is traffic load on all floors, with people temporarily at rest also included. This load varies for different kinds of service; but it is usually very light. It is the incidental loads of equipment that run the specified loads so high—and keep the code makers in such deep doubt that their guesses seem like a chapter from "Alice in Wonderland." Can it be stated now that the Freudenthal method has given designers the means to combine the light traffic loads with the heavy equipment loads into a rational average—one for each type of building? If this be so, it would be interesting to review the principal classes of building service and study how the rational live loads compare with their political and regional predecessors.

---

[11] Engr., Carbide and Carbon Chemicals Corp., South Charleston, W. Va.

By the way, that problem is also a challenge to the author—of both interesting and practical significance.

Example 2 is not of equal significance in that it deals with permissible stresses for which the variability largely has been eliminated by more definite and better controlled processes of manufacture. This might not yet be true for a butt weld; it certainly will be true soon. If it were not so, one may well ask if the probability method is in order. If a load were assumed too light, it would not be serious, but if a weld strength were too low at a critical point the result might be disastrous—and to include such a weak point in the setup for probability will not save a structure when it is cursed by such an element of possible breakdown.

JOHN M. HAYES,[12] ASSOC. M. ASCE.—Very pointedly, this paper emphasizes the importance of standard specifications for structural design and clearly advocates the adoption "of the scientific method in their preparation." Too often design practice, as reflected in standard specifications, has lagged behind research, theory, and the study of the action of existing structures. There seems always to be somewhat of a constant conflict between theory and practice. This is futile, since only an integral fusion of both will produce successful results. The great English statesman, Benjamin Disraeli, has stated, "A practical man is a man who practices the errors of his forefathers."

Normally, theory precedes practice. However, this is not to belittle practice. Hardy Cross, M. ASCE, has written:[13]

> "* * * a designer of engineering structures upon which the integrity of property values and the safety of human life depend has no right to accept theoretical results unless he finds for them some support in experience or in common sense."

This seems paradoxical, but it only emphasizes the complexity of the problem.

Specifications for structural design should reflect practices based on sound thinking, thoroughly blended with theory and experience. This experience should be tempered with information derived from a complete study of structures in service. Every engineer should recognize his obligation to gather data on the actions of structures in service at every opportunity and disseminate this information to the profession. In common with practitioners in every field, the structural designer must rely on authentic information from other engineers and related workers. This necessitates complete cooperation and coordination of all fields of engineering.

A structural designer must not only be able to interpret standard specifications and apply them to routine design problems, but must also have a working understanding of the theory and practice on which they are based. He must be thoroughly conversant with their limitations, and, therefore, should be able to cope with special problems that arise in design. Too often, specifications reflect personal prejudice and blind admiration for past practice.

[13] "Limitations and Application of Structural Analysis," by Hardy Cross, *Engineering News-Record*, October 17, 1935, p. 535.

The writer can do no more than to lend emphasis to the author's closing statement:

> "Nothing must be taken for granted and every relation assumed must be carefully examined by the most appropriate method, be it logical induction or statistical inference. Only thus will the impact of modern scientific development make itself felt in the engineer's everyday work."

Alfred M. Freudenthal,[14] M. ASCE.—In discussing a previous paper by the writer,[2] to which the present paper might be considered a sequel, one of the participants pointed to the surprising lack of interest among engineers in the fundamentals of their profession. That there appears to be no reason to revise this statement is obvious by the reluctance to discuss, and thus help to solve, one of the most fundamental problems facing the structural designer—that of the design specification.

This classification of the problem is hardly an exaggeration; there is no single problem of greater importance or of greater consequence in the daily work of the individual structural designer than that of being able to work on the basis of rational and sound design specifications, which are devised to help him to use the material at his disposal with the maximum efficiency consistent with adequate safety, without, at the same time, affecting the expediency of his design procedure by the introduction of cumbersome and time consuming methods of analysis. The average designer, however, is ready to discuss in greatest detail, and apparently without ever tiring, every possible aspect of the analysis of elastic structures. He does not spare his time in attempting to eliminate whatever inaccuracy still remains in his methods of analysis by devising procedures of higher precision.

Nevertheless, he invariably turns away whenever it is pointed out to him that the stage in his analysis that could bear some investigation is that which follows moment computation. This is the stage in which, after having obtained statical characteristics such as, for instance, the bending moment for a unit load (by rigorous application of methods of analysis devised on the bases of the best scientific and engineering thought of the last two centuries), he (*a*) multiplies the moment by the specification load, a value generally arrived at by the guessing of one or a number of administrators, and then, in order to obtain the required section, he (*b*) divides the result by the permissible stress. This stress value usually represents a rather elusive compromise between the tendency to improve the utilization of the material and the conflicting tendencies to do this without affecting the existing manufacturing processes of the material—without changing established design practices and without, in general, giving the matter too much thought as a fundamental engineering problem.

The question might be asked whether such a procedure constitutes adequate design. However, it appears that this is a rather inappropriate question to ask and, apparently, not many engineers care enough to reply. Why this is so is hard to understand; but there is undoubtedly an intrinsic fascination in playing with numbers, and considerably less fascination in getting behind the numbers to find out how they were arrived at, what they mean, or if they mean anything at all.

---

[14] Visiting Prof. of Theoretical and Applied Mechanics, Graduate School, Univ. of Illinois, Urbana, Ill.

It is gratifying to find such wholehearted endorsement of a proposed line of thought as that expressed by Messrs. Oesterblom and Hayes in their comments. In connection with Mr. Oesterblom's very thoughtful discussion, one particularly interesting aspect of the problem emerges. There appears to be one point at which even the most rational engineering mind becomes reluctant to face the consequences of his own way of thinking—this is, when the mechanical strength or the permissible stress of materials is being discussed. Mr. Oesterblom considers Example 2 of the paper, dealing with strength of butt welds, to be of less significance

> "* * * in that it deals with permissible stresses for which the variability largely has been eliminated by more definite and better controlled processes of manufacture. This might not yet be true for a butt weld; it certainly will be true soon. If it were not so, one may well ask if the probability method is in order. If a load were assumed too light, it would not be serious, but if a weld strength were too low at a critical point the result might be disastrous—and to include such a weak point in the setup for probability will not save a structure when it is cursed by such an element of possible breakdown."

This is an admirably concise expression of the (apparently subconscious) apprehension when considering comparative effects of "overload" and "understrength." The variability of the load, leading to a possible overload, is accepted as an indisputable fact. However, if the variability of strength is mentioned, some cord of subconscious fear of "possible breakdown" is struck. Mr. Oesterblom's is not an isolated reaction, but one shared by almost every member of the profession with whom the writer has had the privilege to discuss his views on structural safety.

In his previous paper[2] the writer tried, apparently without great success, to argue the following points:

a. The safety factor is a factor of correlation of "load" and "resistance" (or "strength").

b. By correlation of these two design characteristics, the safety factor automatically compensates for the effects of both ignorance and uncertainty; even if, for the sake of argument, it were considered possible to eliminate "ignorance" (both subjective and objective), the objective uncertainty inherent in all—even the most carefully planned and performed—human activities and observations remains ineliminable. This applies to both load and strength.

c. It is, therefore, equally impossible to predict an absolute minimum of strength, even if the highest level of control were imposed on the manufacturing process of the material or to predict an absolute maximum load. Thus the only rational specification of either load or strength is to specify a value of relatively high frequency of occurrence, with such a range of extreme fluctuation that the probability of occurrence of values outside this range is negligibly small, considering the expected number of loads during the period of service of the structure.

d. It is the probability method that makes it at all possible to correlate an extremely improbable "overload" with an extremely improbable "understrength," by computing, instead of arbitrarily selecting, a safety factor in such a manner that a coincidence of both extreme conditions becomes practically impossible.

e. In view of the preceding arguments design loads and permissible stresses are closely interrelated; thus, in establishing design specifications they must not be considered except in conjunction, precisely because both load and strength can only be specified in the form of statistical frequency distributions. That in this respect there is no difference in principle between the strength of a butt weld and that of a steel section manufactured and rolled under the usual controlled conditions becomes evident by comparing Fig. 4 of the paper under discussion with Fig. 3 of the writer's previously published paper on safety.[15]

There is no alternative approach which can give the designer some confidence that, by rationally specifying an overload not to be exceeded more frequently than once in 10,000 loading cycles, and a minimum strength value to be attained in at least 9,999 of 10,000 tests, the probability of coincidence of extremes leading to disastrous breakdown has been reduced to less than 1 in 100,000,000. It is a chance which, considering the total number of load cycles in civil engineering structures, is beyond any practical range. The writer is particularly grateful to Mr. Oesterblom for having raised the point and thus provided an opportunity for its renewed consideration.

There is no doubt that, as Mr. Hayes points out, the problem is too complex to be solved by the exclusive application of rational methods. It is in this light that the cited remarks by Hardy Cross, Hon. M. ASCE, are very much to the point. So far, however, it is rather the reverse—that is, rational methods have only been admitted in stress analysis. In devising the procedure of how to apply the results of this analysis to the design of real structures, the reliance is mostly on subjective judgment, "experience," and "common sense." It is to plead for the admission, on at least equal terms with subjective judgment and prejudice, of rational analysis in this stage of design—the stage of drawing up of standard specifications—that the writer has presented his arguments in a manner that may appear to place too little emphasis on the existing and very real limitations of the rational approach in engineering.

THIN-SHELLED DOMES LOADED ECCENTRICALLY

BY WALTER C. VOSS,[1] ASSOC. M. ASCE, DEAN PEABODY, JR.,[2] M. ASCE, AND HOWARD R. STALEY[3] AND ALBERT G. H. DIETZ,[4] ASSOC. MEMBERS, ASCE

SYNOPSIS

A shallow thin-shelled model dome of plaster of Paris was subjected to a concentrated load successively placed between the springing and the crown. Strains were measured at near-by and distant stations on the upper surface. Compression and transverse tests of the plaster gave data concerning moduli of elasticity and Poisson's ratio whereby stresses were computed from the recorded strains. Sand loads were distributed uniformly over an eighth segment and over a quarter segment to study the transition from a concentrated load to a uniformly distributed load over the entire surface.

A mathematical analysis was made to determine the stresses caused by a concentrated load applied at the crown of a shallow thin-shelled spherical dome. Stresses of any magnitude are essentially local ones, so this analysis applies approximately to an eccentric load applied at some distance from the springing or any hole in the dome. As far as the test of one model dome can authorize, this series of tests seems to justify the use of the mathematical analysis to compute maximum stresses in a shallow dome.

INTRODUCTION

The absence of information on the effects of eccentric concentrated loads on thin-shelled domes with small rise prompted these tests. Domes of this type were already in existence and were being built without accurate data in regard to the stresses carried by load concentrations.

NOTE.—Published in October, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[3] Asst. Prof., Dept. of Bldg. Eng. and Constr., Mass. Inst. Tech., Cambridge, Mass.

[4] Asst. Prof., Dept. of Bldg. Eng. and Constr., Mass. Inst. Tech., Cambridge Mass.

To check laboratory and theoretical studies against loading data from actual structures, it was decided to build a plaster model of a large dome, actually erected, to a scale of one to eight. The base of the spherical dome was 8 ft in diameter; its rise was 1 ft ($\frac{1}{8}$ d); and the thickness of the shell was 0.25 in. The radius of the sphere was 8.5 ft.

This exploratory test was made in 1941, before the mathematical analysis had been initiated; and it was not considered wise at that time to assume that an eccentric concentrated load would produce measurable strains only in the surface close to the area of load application. Consequently, sixty-four gage stations were located on the dome surface with two wires connected to each station. The assumption was made that the axes of principal strains for highly strained stations would be at, or near, the meridional and circumferential axes of the dome. A mathematical analysis by Eric Reissner[5] confirms this assumption (see Appendix I) and indicates that any divergence in test data would probably be slight. It would be necessary to add sixty-four more wired connections to obtain a third strain at each station to complete a rosette.

The inner form of the dome was not dropped far enough to permit strain readings on the under surface. An attempt was made to read deflections to 0.001 in. with a transit, but no deflections of this magnitude were recorded. If subsequent tests are made, it is desirable that the number of stations be reduced so that three strains at each station may be taken to complete a rosette, that stations be located on both the upper and lower surfaces near the area of load application, and that accurate measurement of deflections be attempted near the load application.

Strains were measured in the meridional and circumferential directions at each station. After the completion of the concentrated load tests, the distributed sand load tests were made, the sand load remaining several days on the dome while the time effect on the strains was measured. Finally, the dome was tested to failure by a concentrated load applied about three tenths of the meridian length from the springing.

Notation.—The letter symbols used in this paper are defined as they occur, and are assembled for convenience of reference in Appendix II.

PART I. EXPERIMENTAL DETERMINATION OF STRAINS

GENERAL

Objective.—The objective of these tests was to study the effect of concentrated loads on a spherical dome. Test data on models or full-sized domes are lacking for such loads, especially for loads that are not applied at the central axis. As nearly as can be determined, theoretical analyses were not in existence prior to the work done by Mr. Reissner.[5] Test data for eccentric loadings will be valuable for establishing the extent of the surface strained and the comparative magnitude of these strains, and for a comparison with the mathematical analysis.

Eccentric distributed loading is desirable to supply the transition from an eccentric concentrated load to a symmetrical uniformly distributed load.

---

[5] "Stresses and Small Displacements of Shallow Spherical Shells," by Eric Reissner, *Journal of Mathematics and Physics*, February, 1946, p. 80.

Construction of the Model.—A rigid wooden ring was mounted in a frame in an even plane. A recess left on the top inner part of this ring acted as a support and also took the reaction of the model when loaded. The bottom of this recess acted as a guide for the templet during the operation of fabricating the base mold on which the dome shell was cast. The top of the recess was used as a guide for forming the dome shell. The base mold and dome shell were formed by rotating a metal templet about a central shaft. The shell was cast with the usual heavier ring, or haunch. Before testing, the base mold was lowered by jacks.

Strain Gages.—Electrical resistance wire gages of the type developed by Professors A. C. Ruge, Assoc. M. ASCE, and A. V. deForest of the Massachusetts Institute of Technology at Cambridge were adopted as best meeting the requirement for precision over a short gage length. Gages were placed at the sixty-four stations shown in Fig. 1. At each station, strains were measured in the circumferential and meridional directions. The 128 gages were connected to a central selector panel which allowed any one gage to be read at will. For the initial tests, the gages were straight wires, approximately 3 in. long, and were cemented to the surface, as shown in Fig. 2. Subsequently, hairpin gages were used at, or near, the loaded stations. These hairpin gages measured the strain for a 1.5-in. length. In the autumn of 1940 the shorter gages, now in use, were not on sale.

(c) 135° AND 315° LINES

FIG. 1.—LOCATION OF STRAIN GAGE STATIONS ON THE DOME

LOADING PROCEDURE

Concentrated Loads.—For most of these tests a concentrated load of 40 lb was used. Lead blocks, 4 in. square, rested on four soft rubber pads, each $\frac{1}{8}$ in. thick and $1\frac{1}{4}$ in. square. The pads were separated by $\frac{1}{2}$-in. clearance, so that it was 3 in. out-to-out for the pads, whereas the actual loaded area was 6.25 sq in. The loads were applied on the 0° meridian or at other points between the 45° and 315° meridians.

The test to failure was made by applying a concentrated load at Station 5,6 on the 0° meridian (see Fig. 1). In this case, a lever system was employed which consisted of an arm swinging about a pivot through the center of the

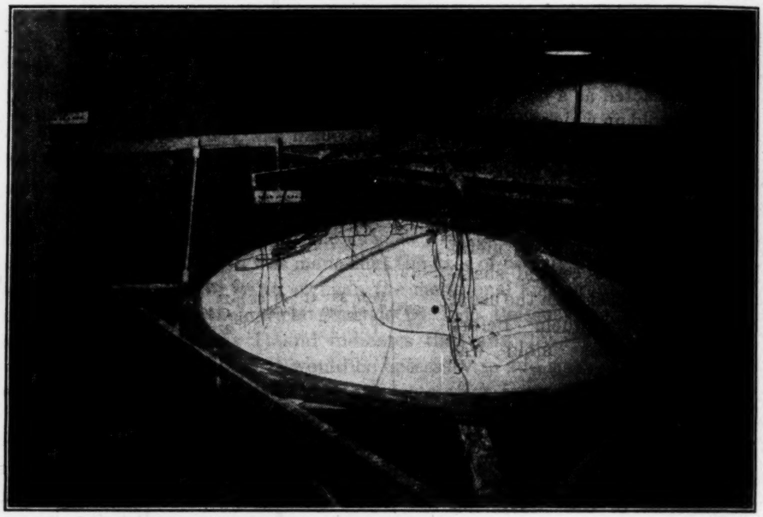

FIG. 2.—TEST TO FAILURE

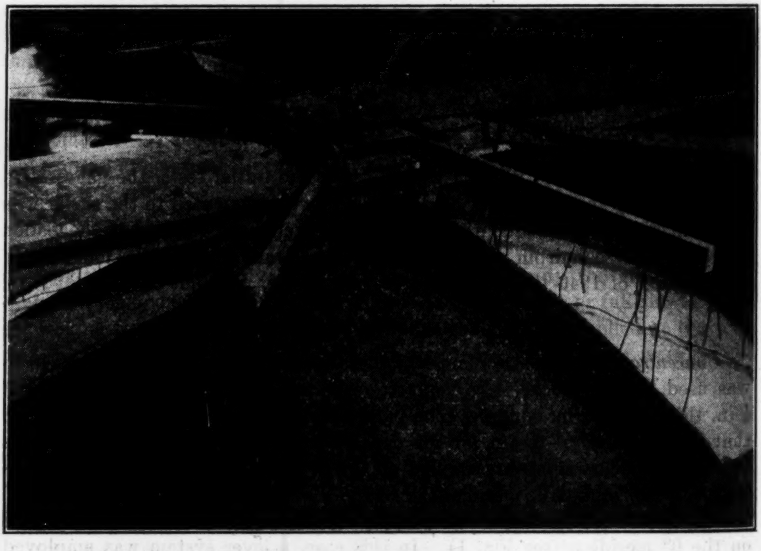

FIG. 3.—DISTRIBUTED LOAD OVER ONE QUARTER OF THE SURFACE

dome. This arm had a load platform at the far end, and rested on a leg bearing on a shoe placed on the rubber pads (Fig. 2).

Sand Loads.—A form of plywood and sheet metal rested on the dome shell and confined the sand to a definite area (Fig. 3). Dry sand was spread uniformly over the segment until the desired weight was obtained.

Poisson's Ratio and the Modulus of Elasticity

Compression tests were made on plaster cylinders, 2 in. in diameter and 4 in. high. Gages similar to those used on the dome were installed to give longitudinal and circumferential strains. From the data, the modulus of elasticity and Poisson's ratio were computed.

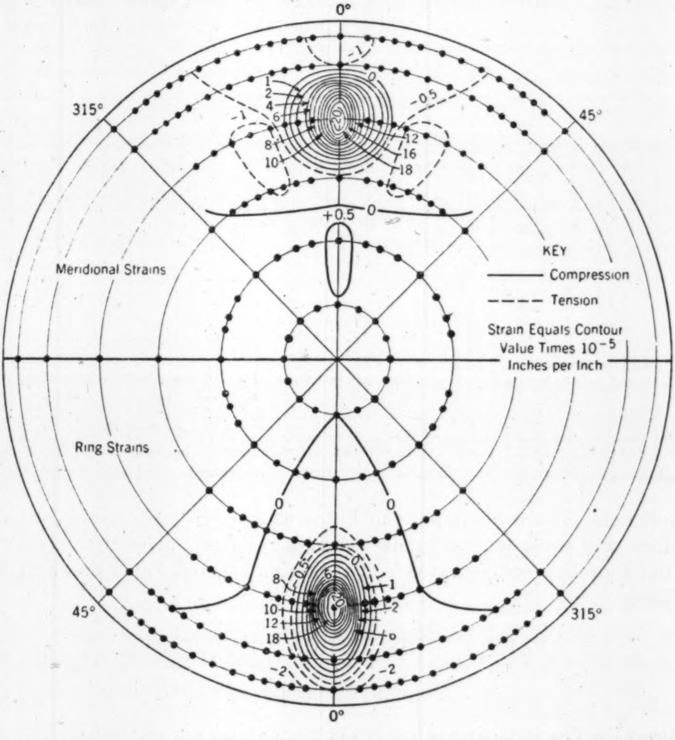

Fig. 4.—Strain Contours for a Concentrated Load of 40 Lb at Station 5,6

Transverse tests were also made on small pieces of the broken dome. Assuming uniformly varying stresses and strains, fiber stresses and the modulus of rupture were computed, as well as the modulus of elasticity. For each specimen a plot of the load-strain data can be represented by two straight lines at slightly different slopes. However, the comparison of moduli of elasticity with the compression moduli (presented subsequently in Table 6) has been made as the stress varies by tenths of the ultimate.

EXPERIMENTAL DATA AND RESULTS

The complete report on which this paper is based (including Mr. Reissner's complete mathematical treatment, which is reported briefly in Appendix I) can be consulted at Engineering Societies Library as well as at the library of the Massachusetts Institute of Technology.

Concentrated Loads.—The strains measured for a given position of the concentrated load were assembled in tables such as Tables 1(*a*) and 1(*b*). These strain data were plotted to show the variation along a meridian and along circumferences. The contour plots in Fig. 4 show equal compression strain by full lines, and equal tension by dashed lines. Table 2 gives the data for the test to failure by a concentrated load at Station 5,6, and Fig. 2 shows the type of failure.

PART II. DISCUSSION OF RESULTS

CONCENTRATED LOADS

Strains.—The strains were measured on the upper surface of the dome for various concentrated loads applied at a gage station, or applied at measured distances on a circumference through the gage station. Thus, it was possible to record, with a minimum of stations, the strains at definite distances from the loading point. For certain loadings several tests were made on the same circumference. In these cases the readings have been averaged. Most of the loads were constant at 40 lb, but in certain cases loads of 20 lb, 55.0 lb, 55.1 lb, and 56.1 lb were used. The corresponding strain data were revised to a common base load of 40 lb, assuming strains to vary directly with the low loads used.

It was not feasible to locate gage points on the under surface of the dome because the form was dropped only a few inches and only the gage stations near the outer haunch could have been reached.

The averaged strain data are also shown on the contour plots, using contour lines to connect points of the same strain value. These contours (see Fig. 4) were located by scaling the plotted strain values. Of necessity many of these contour lines were sketched in to connect rather widely dispersed points of equal strain. However, close to the loaded areas, they are accurate.

Col. 3 are the strain readings in Col. 2 revised to a common base corresponding to a 40-lb load. [d] The strains at age of the two.

The common characteristic of these plots is the large compressive strain immediately under the loaded area in both meridional and circumferential directions. The strains decrease rapidly outside the loaded area; farther away small tensile strains usually occur, often followed by equally small compressive strains. The deformations suggest those observed if one presses a finger against the surface of an inflated toy balloon. Except for the area close to the loaded point, the magnitude of the strains is very small. Near the loaded area, the meridional contours are approximately circular whereas the circumferential contours are elliptical. The reader should note that "meridional" and "circumferential" refer to the central dome axis and not to an axis through the center of the load.

The strains are comparatively small for a load applied at Station 1,2 near the outer ring, or haunch (see Fig. 5). The stiffer haunch influences the strain distribution. As the position of application of the 40-lb load is moved up the meridian toward the crown of the dome, the strains increase to a maximum at

Station 21,22, which was the station nearest to the hole at the crown, the increase being about 40% more than the maxima at Station 3,4. The numerical values of the maximum strains in the meridional and circumferential directions at the same station are approximately equal.

Stresses.—The stress-strain plots of the compression and transverse tests indicate that the plaster behaves as an elastic material for stresses of less than 700 lb per sq in. To convert strain data to stresses, average values of the modulus of elasticity E (1,770,000 lb per sq in.) and of Poisson's ratio μ (0.20) are used. Knowing the meridional strain ϵ_m and the circumferential strain ϵ_c, under the load, the corresponding stresses σ_m and σ_c can be computed by the elastic relations:

$$\sigma_m = \frac{E}{1 - \mu^2} (\epsilon_m + \mu \, \epsilon_c) = 1{,}844{,}000 \, (\epsilon_m + 0.2 \, \epsilon_c) \ldots\ldots\ldots (1a)$$

and

$$\sigma_c = \frac{E}{1 - \mu^2} (\epsilon_c + \mu \, \epsilon_m) = 1{,}844{,}000 \, (\epsilon_c + 0.2 \, \epsilon_m) \ldots\ldots\ldots\ldots (1b)$$

[b] Load, in pounds. [c] Values in Col. 3 are the strain readings in Col. 2 revised to a common base corresponding to a 40-lb load.

Using the averaged maximum strains under the load, the maximum stresses for a 40-lb load applied at the successive gage stations are given in Table 3. These maximum stresses increase as the load is applied nearer the crown of the dome. At any given station, the maximum meridional and circumferential stresses may be regarded as equal. The computed stresses at Station 21,22 are about 16% of the compressive strength of the plaster cylinders tested in compression (3,850 lb per sq in.).

Stress Comparison with the Mathematical Analysis.—Equations for the normal stress in a thin shell of a shallow dome, due to a concentrated load applied over a small circular area at the crown, are presented in Appendix I. The assumption is made that the load is applied relatively distant from any boundary or hole in the shell. Eqs. 6 in Appendix I give the values of the

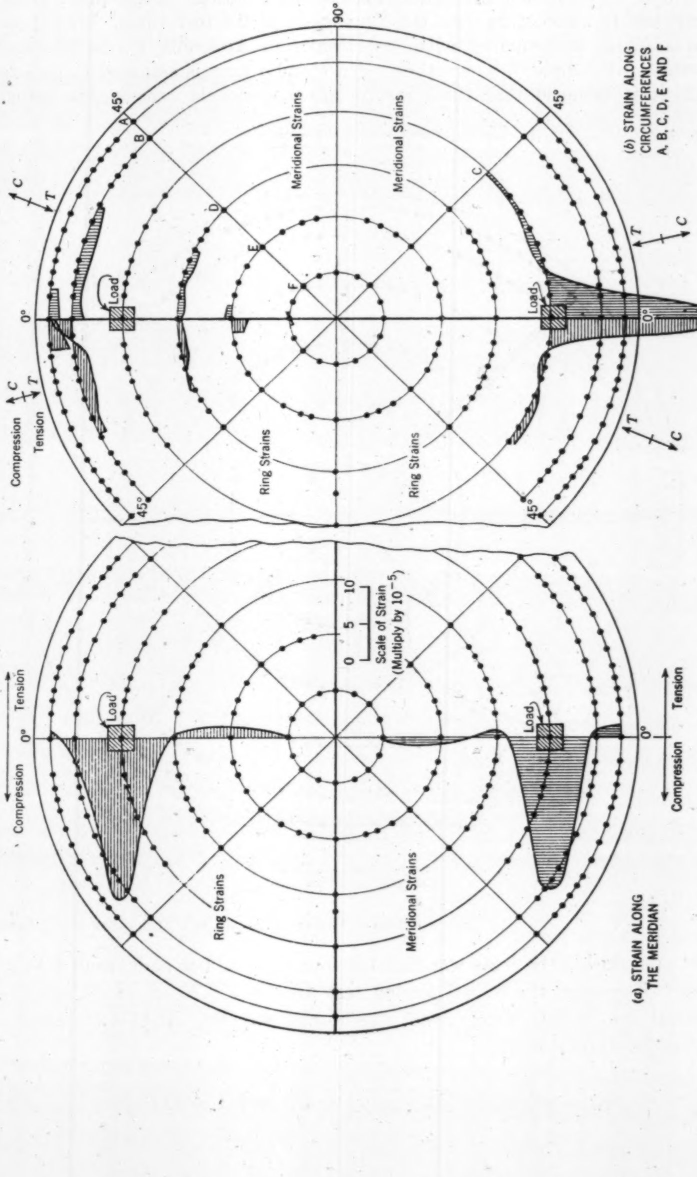

FIG. 5.—ANALYSIS OF STRAIN VARIATION FOR A CONCENTRATED LOAD OF 40 LB AT STATION 5,6

normal stresses in the meridional and circumferential directions at the upper and lower surfaces of the shell due to direct stress and bending. The equations are then applied to a structure with the dimensions of the test dome. The theoretical analysis is compared with test results in Appendix I (see heading, "Illustrative Example"), where the loaded circular area is assumed to be 6.25 sq in. It is believed that these results are comparable because the actual loaded area during the tests was through four thin rubber pads, each 1.25 in. square. Therefore, the actual loaded test area was 6.25 sq in. Using the numerical results thus determined, the normal stresses, direct and bending, at the upper surface equal:

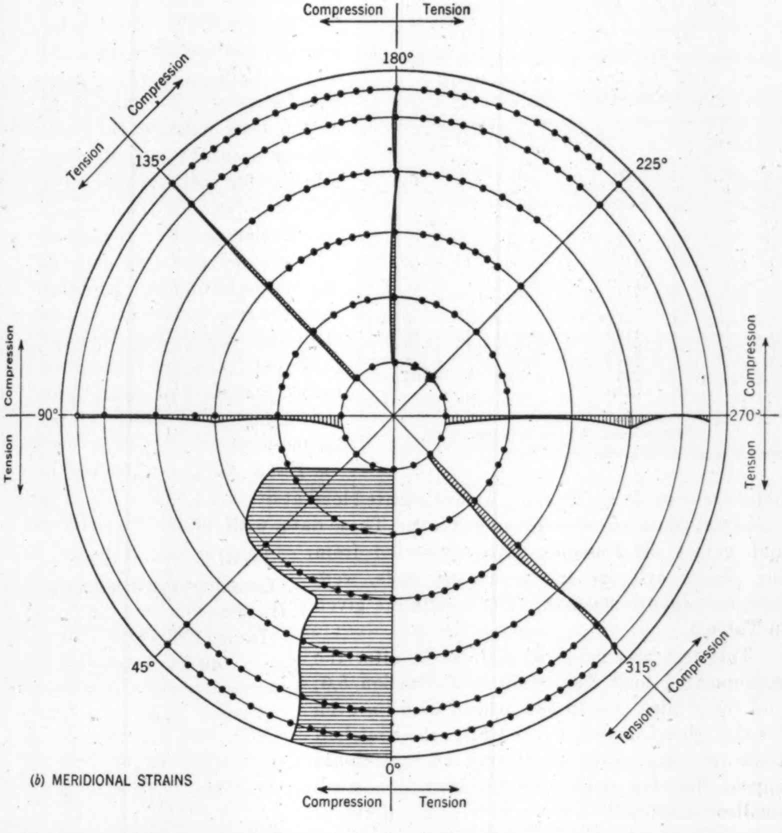
and

$$\sigma_c = \frac{P}{\pi\, \xi^2_c\, h^2}\left[\sqrt{3(1-\mu^2)}(1-C_1) + 3(1+\mu)\, C_2\right] \ldots\ldots\ldots (2b)$$

in which $\xi_c = 0.5146$, $C_1 = 0.9050$, and $C_2 = 0.1728$. By computation:

$$\sigma_m = \sigma_c = (0.1938 + 0.7477)\,\frac{P}{h^2} = \frac{(0.9415)\,P}{(0.25)^2} \ldots\ldots\ldots\ldots (3)$$



(*b*) MERIDIONAL STRAINS

of 267 Lb on an Eighth Segment Centered about the 0° Meridian

If $P = 40$ lb, $\sigma_m = \sigma_c = 124 + 479 = 603$ lb per sq in. (compression). This value is close to the average of the test stresses at Station 21,22. The stresses on the upper surface are larger than the resultant stresses on the under surface. It appears that the theoretical analysis approximates closely the maximum stresses given by the test data, even though Station 21,22 is about 6.5 in. from the edge of a hole, approximately 2 in. in diameter, at the crown of the test dome. The results from only one test dome are not conclusive, but they establish the possibility that the theoretical analysis may be used with safety to design shallow domes subjected to a concentrated load.

If Fig. 7(*a*), presented subsequently, is examined, it will be noted that the curves of stress variation are similar to the plots of strain variation from the test data. Measuring along the meridian the theoretical stresses should equal zero about 4.95 in. out from the center of the loaded area, for meridional stresses, and about 7.15 in. out, for circumferential stresses. The strain data of the tests indicate that zero stresses occur, in general, about 8 in. out for both stresses. The difference between the theoretical circular area and the actual four squares probably explains the nonconformance. In either case, the compressive stresses on the upper surface have reduced to zero at a distance beyond the loaded boundary of about twice the diameter, or width, of the loaded area.

[a] Load release. [b] Load at failure.

Test to Failure.—The test to failure was made by applying a concentrated load at Station 5,6 (Fig. 1). The load-strain data are recorded in Table 2. These data, with moduli of elasticity and values of Poisson's ratio estimated from the plaster cylinder and transverse tests, were used to compute stresses. The results are given in Table 4.

TABLE 3.—MAXIMUM COMPRESSIVE STRESSES (IN POUNDS PER SQUARE INCH) CREATED BY A 40-LB LOAD

9,10	545[a]	545[a]
21,22	596	631

[a] Strains assumed to be equal in meridional and circumferential directions.

This test was made several weeks after the concentrated load test of 40 lb at Station 5,6; and the strains due to the load of 37.6 lb, even for the reloading (see Table 4(*b*)), are about half those recorded earlier at Station 5,6. It would appear that the strains for the lower loads are smaller than would be expected from the previous tests. During the period of testing, the plaster had dried thoroughly. However, with the greatest load applied (293 lb), the computed stresses approach the compressive strength of the moist cylinders, giving about 94% of the cylinder strength for a load that was 91% of the load at failure.

The stresses computed by the mathematical analysis in Appendix I approximated the stresses obtained from the measured strains only for the load applied at Station 21,22. For the 40-lb load applied at Station 5,6, the average stress from the strain data was 469 lb per sq in., or 77.8% of the theoretical stress of 603 lb per sq in. Using this percentage reduction of the theoretical stress applied to the second loading, a comparison is afforded by Table 4(*b*) of the stresses from strain data (Col. 6) and the corrected theoretical stresses.

[a] Pounds per square inch. [b] By Eq. 4*a* (see text). [c] Col. 6 $\times \frac{1}{3,850}$. [d] Col. 1 $\times \frac{1}{322}$.

The values in Col. 7 were computed by the formula:

$$\sigma = 0.778 \frac{0.9415}{0.25^2} P \qquad (4a)$$

The theoretical stress of 441 lb per sq in. for a load of 37.6 lb is the value that would be expected from the strain data of the initial tests at Station 5,6. As the dome approached failure this same ratio (0.778) of test data to theoretical analysis was approached for the strain data of Table 2. The dome failed close to the load predicted by stress computations for the upper surface.

However, the computed stresses for the lower surface are tensile and

$$\sigma_m = \sigma_c = (0.7477 - 0.1938) \frac{P}{h^2} \qquad (4b)$$

For a load of $P = 293$ lb, this tensile stress equals $\sigma_m = \sigma_c = 0.778 \times 0.5539 \times 16 \times 293 = 2,020$ lb per sq in., as compared with the compressive value of 3,440 lb per sq in. on the upper surface (Col. 7, Table 4(*b*)). The transverse tests of Table 5 indicate a modulus of rupture for the plaster of about 750 lb per sq in., the failure being tensile. It would seem that the effect of shrinkage and plastic flow is such that the computed tensile stresses on the under surface are not realized. Until greater experience is gained, the high computed tensile stresses are an added incentive to use conservative allowable stresses and to disregard such stress reduction factors for position of the load as the value 0.778 used in Eq. 4*a*. Tests to observe variations in modulus of elasticity are presented in Table 6.

[a] Specimen 2 broke at a load of 22.05 lb. [b] Specimen 3 broke at a load of 17.64 lb.

Continued Loading.—A time-load test was made with 40 lb applied at Station 7,8 for 5 days. During this interval the compressive strains directly under the loaded area gave increased values. The strains at the other stations tended to become tensile, this effect being most marked from 1 day to 5 days. Between the initial and the 24-hour readings, the maximum increase in compressive strain occurred at Station 7,8, followed by a slight steady decrease for the next 4 days. From 0 days to 1 day a few of the other stations also showed an increase of compressive strain which was overcome by the decrease for the next 4 days.

Summary.—Concentrated loads about one eighth of the ultimate load were applied at stations on a meridian varying in position from close to the outer haunch to close to the central hole. In every test the greatest stresses occur at the upper surface of the shell directly under the load, and they increase as the load is moved toward the crown. The stresses for a load close to the crown check closely those obtained by mathematical analysis (see Appendix I). The compressive stresses on particles in the upper surface decrease rapidly as the distance increases away from the loaded area. The stresses located twice the width of the loaded area from the loaded boundary have ceased to be compressive. Beyond this perimeter all stresses are comparatively small in magnitude. A concentrated load has only a local effect as far as stress intensities are concerned.

If a concentrated load remains in place for several days, the strains increase about 15% under the load during the first day. Thereafter, there is a slow decrease; at 5 days the strains are about 5% greater than the initial readings. Elsewhere in the dome the strains showed small elongations due to plastic flow.

DISTRIBUTED LOADS

Eighth Segment Loaded.—The sand load of 267 lb on an eighth segment corresponds to an intensity of 40 lb per sq ft, or 0.278 lb per sq in., as compared with the concentrated load of 40 lb on 6.25 sq in. or 6.4 lb per sq in. Table 7 gives strain data at the time of load application for continued loading to 1.7 days. Fig. 6 shows the plotted strain data at the time of load application. The sand load was centered on the 0° meridian, and all other recorded stations were outside the loaded area. The initial circumferential strains (Fig. 6(*a*)) were relatively large along the 0° meridian with maximum values at Stations 3 and 5 of about the magnitude of those recorded for the concentrated load of 40 lb at Station 21,22. Elsewhere in the dome the circumferential strains were of small tensile magnitudes, except for the innermost Station 47 on the 90° meridian and three stations on the 315° meridian. The meridional strains (Fig. 6(*b*)) were also compressive on the 0° meridian, but the maximum values occurred nearer the crown of the dome at Stations 10 and 22. Elsewhere the strains were very low tensile values. Using these strain data, with a modulus of elasticity of 1.77×10^6 lb per sq in., and a Poisson ratio $\mu = 0.20$, the computed stresses along the 0° meridian are given in Table 8(*a*).

None of these stresses, caused by a load of 267 lb, exceed those obtained

by the concentrated load of 40 lb at Station 21,22. If the meridional stress, σ_m, at each station is plotted according to its position on the meridian, the individual values do not deviate greatly from their average. This is not true for the circumferential stresses, σ_c, which greatly exceed their average from a location close to Station 1,2 (and the haunch) to a position about halfway up the meridian; beyond this point the circumferential stresses are much lower than their average.

Continued loading for 0.85 day gives a marked decrease in compressive strains along the central 0° meridian. The amount of depression had decreased but the general shape was unchanged, since the stations of greater strain had proportionately greater reductions. Elsewhere in the dome there was an increase in tensile strains, with the changes again proportional to the magnitude of the initial strain. It appears that the depression under the load was reduced, whereas elsewhere the dome shell bulged outward.

In the interval from 0.85 to 1.7 days there was further readjustment. The circumferential compressive strains on the 0° meridian again decreased roughly in proportion to the strain value, whereas the meridional strains increased at Stations 10 and 22 with a considerable decrease at Stations 2 and 4 near the haunch. Elsewhere in the dome, outside the loaded area, the change in strain was largely a reduction of tensile strain, so that about half of the final strains were compressive. It appears that the depression under the load was again reduced; elsewhere the previous bulge was also decreased.

The total effect of continued loading from 0 to 1.7 days was to reduce the compressive strains under the load on the 0° meridian. The circumferential strains were reduced from 38% to 94%; and the meridional, from 20% to 68%. The greater strains had the greater percentage reduction so that the strains at 1.7 days tended to approach a common value more closely. The stations outside the loaded area, for the most part, had net shortenings so that compressive strains were increased and tensile strains were reduced. Of the twenty-five circumferential stations outside the loaded area, twenty one recorded small initial tensile strains of less than 1.55×10^{-5} upon application of the load. The other four were close to the hole at the crown of the dome. At the end of 1.7 days eleven had tensile, twelve compressive, and two zero strains, compared with the unloaded dome. Similarly, for the twenty-six meridional stations outside the loaded area, the initial strains were: Nineteen tensile, six compressive, and one zero. Four of the compressive strains were on the 180° meridian, the other two were near the haunch. At the end of 1.7 days these twenty-six stations divided into twelve with tensile, thirteen with compressive, and one with zero, strains.

The effect of plastic flow on this plaster dome appears to be a readjustment by which the strains on the upper surface under the loaded area are markedly reduced, with a tendency to approach more uniform values. Stations outside the loaded area show an increase in tension from 0 day to 0.85 day and then a greater decrease, so that the general net result is a decrease in the original tensile values. However, stations on the circumference including Station 3,4 have final stresses indicating that the restraint of the near-by haunch causes bending.

The foregoing statement covers the observed readings on the upper surface. A complete knowledge of the effect of plastic flow cannot be obtained unless data in regard to the strains on the under surface and the change of deflection are also known. The area under the load is in bending as well as direct stress and the plastic readjustment is complex. It is possible that the dome is no longer a perfect spheroid elsewhere, and has been displaced horizontally as well as vertically.

Quarter Segment Loaded.—The load of 534 lb also corresponded to an intensity of 40 lb per sq ft, or 0.278 lb per sq in. The sand load centered on the 0° meridian, and its boundaries were the 45° and 315° meridians. Compared with eighth-segment loading, the initial strains were much reduced. Using a modulus of elasticity of 1.77×10^6 lb per sq in. and a Poisson ratio of 0.2, the computed stresses along the 0° meridian are given in Table 8(*b*).

At the boundary on the 315° meridian the circumferential strains on the top surface were tensile and the meridional strains were compressive. Outside the loaded area the strains were all of small magnitude, whereas their reversals suggested wave action in the shell.

This sand load remained in place for 5 days. Strain readings to measure plastic flow were taken at approximately 1, 2, 3, and 5 days. The readings varied considerably from day to day with many reversals of strain from compression to tension and vice versa. Many readings were as small as the probable error of reading. On the center line of the loaded area (0° meridian), the circumferential strains indicated that proximity to the haunch affected Station 1 and the hole at the crown may have affected Stations 9 and 21. The haunch apparently affected the meridional strains as far out as Station 6. Neglecting the readings at Station 1,2, at the end of 2.8 days the average circumferential strain was $+ 3.8 \times 10^{-5}$ and the individual values were fairly uniform; at 4.8 days the average strain was $+ 2.2 \times 10^{-5}$, but the values at Stations 9 and 21 departed considerably from this average. Similarly, the meridional strains averaged $+ 3.5 \times 10^{-5}$ at 2.8 days and $+ 3.2 \times 10^{-5}$ at 4.8 days.

At the boundary of the sand load on the 315° meridian, the circumferential strain curve preserved its general shape as time passed but steadily shifted to the compression side, so that initial strains that were wholly tensile by 2.8 days became wholly compressive. The 4.8-day readings were slightly lower. The meridional strains were wholly compressive for the initial readings (except for those at Station 50) with the greatest strain recorded for all stations at Station 56 near the crown (11.95×10^{-5}). There was a marked shift at 0.8 day so that all strains were tensile, except those at Station 52 near the haunch.

Thereafter the general pattern was preserved but the shift was toward small compressive strains.

The general effect of plastic flow on the upper surface of the shell along the center line meridian of the loaded area was to produce fairly uniform compressive strains which oscillate above and below $+ 3 \times 10^{-5}$ between 1.8 days and 4.8 days, except for the station close to the haunch. These strains were usually greater than the initial strains. At the boundary of the sand load (315° meridian) the strains reversed, the circumferential strain becoming compressive, whereas the meridional strain became tensile at 0.8 day, and then the strains slowly returned to low compressive values.

Outside the loaded area the initial strains had low values, some compressive, some tensile. From 0.8 day to 2.8 days they all shifted toward greater tensile values, remaining fairly constant during this time interval. At 4.8 days the strains all tended to approach zero strain: Seventeen with final compressive values (maximum $= + 3.0 \times 10^{-5}$), twenty four with final tensile values (maximum $= - 2.95 \times 10^{-5}$), and two with zero strain.

Uniform Load on Entire Dome Surface.—The tendency for the stresses to decrease as a larger area is loaded is reasonable. If the same sand load of 40 lb per sq ft is assumed to be spread over the entire surface, the circumferential and meridional stresses can be computed, assuming the shell to be a membrane.[6] In the part of the shell close to the haunch, the circumferential stress equals 40 lb per sq in.; and the meridional stress, 60 lb per sq in. No allowance was made for bending stresses caused by the proximity to the larger and more rigid haunch; but a load four times that on the quarter segment produced direct stresses of the general magnitude of those computed in Table 8(*b*) for the quarter segment.

GENERAL SUMMARY

The distributed load tests were made to clarify the transition from an eccentric concentrated load to a uniformly distributed load. They emphasize the fact that progressive concentration causes increasingly larger strains under the loaded area.

The discussion of concentrated loads is based on a load of 40 lb bearing on an area of 6.25 sq in. The distributed loads were 6⅔ × 40 on an eighth segment and 13⅓ × 40 on a quarter segment. The maximum stresses for the eighth-segment loading were comparable to those obtained for the concentrated load in the position producing the greatest recorded strains. The maximum stresses for a quarter-segment loading were about a sixth as much. The part of the dome well outside the loaded area had negligible stresses.

The readjustments due to plastic flow tended to reduce the strains in the upper surface of the loaded area. Elsewhere, the strains tended to become tensile in the first day of quiescent loading. Thereafter the strains outside the loaded area tended to approach zero. During these adjustments the restraining effect of the haunch was noticed at near-by stations.

ACKNOWLEDGMENT

This investigation was planned and executed for the Preload Company. The test was made on a plaster model to a reduced scale of a large dome designed and erected by this company.

APPENDIX I. MATHEMATICAL ANALYSIS

BY ERIC REISSNER

To facilitate the analysis of the test data of the model dome, theoretical equations were derived[5] for the direct stresses and bending stresses as components of the total normal stress in a shallow spherical dome treated as a thin shell. The equations apply to a total load P distributed uniformly over a circular area with its center at the apex of the dome. Let "ber," "bei," "ker," and "kei" be used to designate tabular functions. Also let $\xi_v = x/l$ and $\xi_c = r_o/l$ denote a dimensionless variable and a dimensionless constant, respectively (see Fig. 7). For small values of ξ_v:

$$\operatorname{ber} \xi_v \approx 1 - \frac{\xi^4_v}{64} \qquad \text{(5a)}$$

$$\operatorname{bei} \xi_v \approx \frac{\xi^2_v}{4} - \frac{\xi^6_v}{64 \times 36} \qquad \text{(5b)}$$

$$\operatorname{ker} \xi_v \approx -\log_e \xi_v + 0.1159 + \frac{\pi}{16} \xi^2_v \qquad \text{(5c)}$$

and

$$\operatorname{kei} \xi_v \approx -\frac{\xi^2_v}{4} \log_e \xi_v - \frac{\pi}{4} + (0.1159 + 1) \frac{\xi^2_v}{4} \qquad \text{(5d)}$$

Equations for maximum stresses, σ, are: Direct—

$$\sigma_m (0) = \sigma_c (0) = \frac{P}{h^2} \frac{\sqrt{3(1 - \mu^2)}}{\pi \xi^2_c} (1 - C_1) \qquad \text{(6a)}$$

and bending—

$$\sigma_m (0) = \sigma_c (0) = \pm \frac{P}{h^2} \frac{3(1 + \mu)}{\pi \xi^2_c} C_2 \qquad \text{(6b)}$$

TABLE 9.—FORMULAS FOR THE DETERMINATION OF ARBITRARY DESIGN CONSTANTS

C_1	C_2	D_3	D_4	Value
ber ξ_c	bei ξ_c	−ker ξ_c	−kei ξ_c	1
−bei ξ_c	ber ξ_c	kei ξ_c	−ker ξ_c	0
ber′ ξ_c	bei′ ξ_c	−ker′ ξ_c	−kei′ ξ_c	0
−bei′ ξ_c	ber′ ξ_c	kei′ ξ_c	−ker′ ξ_c	0

in which subscript m denotes "meridional"; and subscript c denotes "circumferential." To use Eqs. 5 and 6, the following data must be known: The concentrated load P; the radius r_s of the spherical dome shell; the thickness h of the shell; the radius r_c of the circular loaded area, equal to the actual loaded area; and Poisson's ratio μ. For concrete $\mu = 0.20$ is a reasonable value. The arbitrary constants C_1 and C_2 in Eqs. 6 are determined by solving the equations in Table 9.

The procedure consists in first determining the values of the arbitrary constant $\xi_e = r_e/l$, the length parameter l being defined as:

$$l = \frac{\sqrt{h\,r_s}}{\sqrt[4]{12(1-\mu^2)}} \qquad \text{(7)}$$

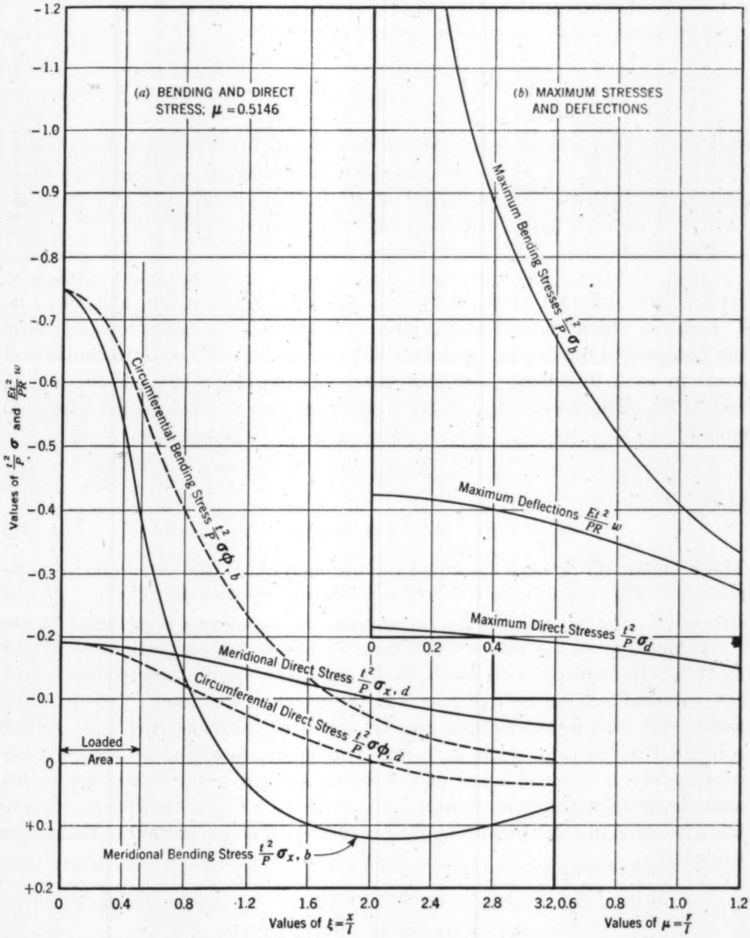

FIG. 7.—DESIGN VALUES OF DIMENSIONLESS FACTORS ξ_v AND ξ_e

With this value of ξ_e enter Fig. 7(a) and read the maximum bending stress σ_b and the maximum direct stress σ_d. Fig. 7(a) is not applicable for $\xi_e < 0.2$ or $\xi_e > 1.3$; but Eqs. 5 can be solved directly or by interpolation in Table 10.

Illustrative Example.—A numerical example was solved and discussed in detail in the original analytical report.[5] For this study the dimensions of the model were used—namely: $r_s = 102$ in.; $h = 0.25$ in.; and $\mu = 0.20$. By Eq. 7, then, $l = 2.7410$; and $\xi_v = x/l = 0.3648\,x$. The load was assumed to act on three different areas—$\pi\, r^2_c = 1.5625$ sq in., 6.25 sq in., and 16 sq in. The case in which the loaded circular area equals 6.25 sq in. approaches closely the test case of 6.25 sq in. composed of four squares with outer boundaries of 3 in. in each direction. For this case: $\xi_c = 0.5146$; $C_1 = 0.9050$; and $C_2 = 0.1728$. The maximum combined stress at the upper surface of the shell equals:

TABLE 10.—VALUES OF FUNCTIONS OCCURRING IN THE SOLUTION OF THE EQUATIONS OF THE FLAT SPHERICAL DOME PROBLEM

x	ber x	bei x	ker x	kei x	$\frac{\text{ber}' x}{x}$	$\frac{\text{bei}' x}{x}$	$\frac{\text{ker}' x}{x}$	$\frac{\text{kei}' x}{x}$

1.0	0.9844	0.2496	0.2867	−0.4950	−0.06245	0.4974	−0.6946	0.3524
1.5	0.9211	0.5576	0.05294	−0.3314	−0.1400	0.4868	−0.1961	0.1971
2.0	0.7517	0.9723	−0.04164	−0.2024	−0.2465	0.4585	−0.05330	0.1099
3.0	−0.2214	1.9376	−0.06703	−0.05115	−0.5233	0.2935	+0.00716	0.03068
5.0	−6.2301	0.1160	−0.01148	+0.01118	−0.7691	−0.8708	0.00344	−0.00016

$$\sigma_m = \sigma_{m,d} + \sigma_{m,b} \quad \text{(8a)}$$

and

$$\sigma_c = \sigma_{c,d} + \sigma_{c,b} \quad \text{(8b)}$$

These maximum stresses are equal for the meridional and circumferential directions. Fig. 7 shows, not only the maximum stresses, but the variation of stress over, and beyond, the loaded area as the loaded area is increased in size. Table 10 gives the values of the functions used in the equations of Table 9 to obtain the constants C_1 and C_2. These stress equations are derived for a concentrated load on a circular area at the crown of the dome. The fact that the loaded area is not circular can be neglected, provided the area is small compared to the total dome surface. The equations can also be applied approximately, if the load is not at the crown, as long as the loaded area is not near the springing, a hole, or other discontinuity. These results are approximate because an eccentrically applied gravity load is not normal to the surface loaded.

APPENDIX II. NOTATION

The following letter symbols, adopted for use in the paper, and in its discussion, conform essentially to American Standard Letter Symbols for Mechanics (ASA—Z10.3—1942), prepared by a Committee of the American

Standards Association, with Society participation, and approved by the Association in 1942:

C = an arbitrary constant; formulas for the determination of C_1, C_2, D_2, and D_4 are listed in Table 9;
c = subscript denoting "circumferential";
D = an arbitrary constant, such as D_2 and D_4 in Table 9;
d = diameter;
E = modulus of elasticity;
h = thickness of shell;
l = a length parameter defined by Eq. 7;
m = subscript denoting "meridional";
P = a concentrated point load, or the resultant of a distributed load assumed to be acting at the centroid of pressure;
r = radius, with subscript c to denote radius of area of concentrated loading, with subscript s to denote radius of spherical shell;
x = perpendicular distance from the axis of symmetry of a spherical shell;
ϵ = strain, with subscripts m and c to denote "meridional" and "circumferential," respectively;
μ = Poisson's ratio;
ξ = dimensionless quantity, with subscripts c and v to denote a "dimensionless constant" and "dimensionless variable," respectively; and
σ = unit stress, with subscripts b and d to denote "bending" and "direct" stress, respectively, and subscripts m and c to denote "meridional" and "circumferential," respectively.

The various tabular functions "ber," "bei," "ker," and "kei" are defined by Eqs. 5. These operators primed denote first differentials.

UNDERGROUND CONDUITS—AN APPRAISAL OF MODERN RESEARCH

By M. G. Spangler,[1] M. ASCE

With Discussion by Messrs. Wilson V. Binger, Jacob Feld, Zdeněk Bažant, Jr., Anson Marston, George E. Shafer, E. F. Kelley, Bailey Tremper, and M. G. Spangler.

Synopsis

The increasingly successful application of scientific principles of mechanics to the analysis of soil has characterized engineering development during the first twoscore years of the twentieth century. A number of problems that involve the soil as an integral part of the finished structure and which a generation or two ago were considered by many to be too complex to be subject to orderly classification and solution are yielding to the onslaught of organized research.

One notable example of problems in this category concerns the design of underground structures such as conduits, sewers, drains, culverts, water mains, and gas lines. Conduits of this general type have been used by mankind for at least 3,000 years, being found among the earliest examples of the practice of the engineering arts; but not until about 1910 was serious effort directed toward the development of a rational method for determining the magnitude and character of the loads to which underground conduits were subjected in service due to the earth overburden and other load sources. In those early days, Anson Marston, Past-President and Hon. M. ASCE, then director of the Engineering Experiment Station at Iowa State College in Ames, inaugurated a research program which has been continuously active under his direction. The purpose of this paper is to review Dean Marston's theory of loads on, and supporting strengths of, underground conduits and to record the experimental background, together with working values of many of the constants required for the practical application of the theory.

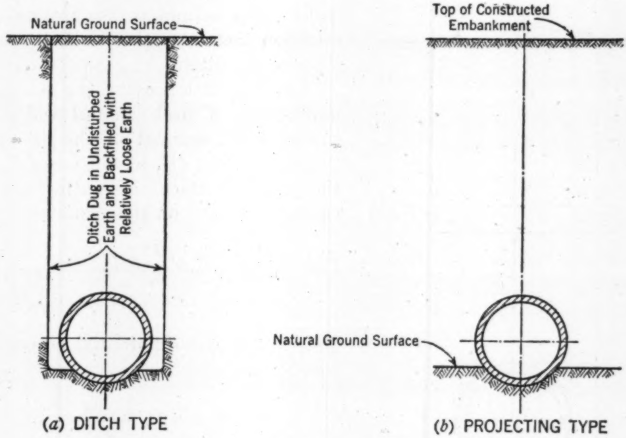
Note.—Published in June, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Research Associate Prof., Civ. Eng. Dept., Iowa Eng. Experiment Station, Iowa State College, Ames, Iowa.

Load Classification of Underground Conduits

Underground conduits, in general, may be divided into two main classes on the basis of construction conditions under which they are installed—that is (1) ditch conduits and (2) projecting conduits.

(1) "Ditch conduits" are structures installed and completely buried in narrow ditches in relatively passive or undisturbed soil. Examples of this class of conduits are sewers, drains, and water mains (see Fig. 1(*a*)).



Natural Ground Surface
Ditch Dug in Undisturbed Earth and Backfilled with Relatively Loose Earth
Top of Constructed Embankment
Natural Ground Surface

(*a*) DITCH TYPE (*b*) PROJECTING TYPE

Fig. 1.—Essential Elements of Typical Conduits

(2) "Projecting Conduits" are structures installed in shallow bedding with the top of the conduit projecting above the surface of the natural ground, and then covered with an embankment, as shown in Fig. 1(*b*). Railway and highway culverts are good illustrations of this class of conduits. Conduits installed in ditches wider than about two or three times their maximum horizontal breadth may also be treated as projecting conduits.

Notation

The letter symbols in this paper are defined where they first appear, in text or by illustration, and are assembled for reference in Appendix I. Discussers are requested to conform to this usage.

Loads on Ditch Conduits

When a conduit is placed in a ditch not wider than about two or three times its outside breadth, and covered with earth, the backfill will tend to settle downward. This downward movement or tendency for movement of the soil in the ditch above the pipe produces vertical frictional forces or shearing stresses along the sides of the ditch which act upward on the prism of soil within the ditch and help to support the backfill material. Assuming the cohesion between the backfill material and the sides of the ditch to be negligible, the magnitude of these vertical shearing stresses is equal to the active lateral pressure exerted by the earth backfill against the sides of the ditch, multiplied by the tangent of the angle of friction between the two materials. This assumption of negligible cohesion is justified because: (*a*) Even when the ditch is dug in, and backfilled with, cohesive material, considerable time must elapse before effective cohesion between the backfill material and the sides of the ditch can develop after backfilling; and (*b*) the assumption of no cohesion yields the maximum probable load on the conduit. The maximum load may develop at any time during the life of the conduit due to heavy rainfall or other causes which may eliminate or greatly reduce cohesion between the backfill and the sides of the ditch.

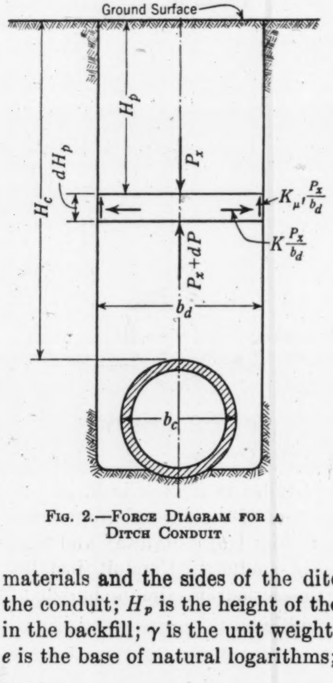


FIG. 2.—FORCE DIAGRAM FOR A DITCH CONDUIT

Let Fig. 2 represent the section of a unit length of ditch conduit and consider a horizontal element of the fill material having a height dH_p at a distance H_p below the ground surface. Equating[2] the vertical forces acting on this element:

$$P + dP + 2\,K\,\mu' \frac{P}{b_d}\,dH_p = P + \gamma\, b_d\, dH_p \,..\,(1a)$$

This is a linear differential equation, the solution for which is

$$P = \gamma\, b^2_d \frac{1 - e^{-\alpha H_p}}{2\,K\,\mu'}\,\ldots\ldots(1b)$$

in which P equals the total vertical pressure on a horizontal plane in the backfill, in pounds per linear foot; μ' is the coefficient of sliding friction between the fill materials and the sides of the ditch; b_d is the width of ditch at the top of the conduit; H_p is the height of the ground surface above any horizontal plane in the backfill; γ is the unit weight of filling material, in pounds per cubic foot; e is the base of natural logarithms; and, to simplify typography:

$$\alpha = \frac{2\,K\,\mu'}{b_d}\,\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2a)$$

The ratio K of active lateral pressure to vertical pressure, is defined as

$$K = \frac{\sqrt{\mu^2 + 1} - \mu}{\sqrt{\mu^2 + 1} + \mu}\,\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2b)$$

in which μ is the coefficient of internal friction of the filling material. The coefficient μ' may be equal to or less than μ, but it cannot be greater.

When $H_p = H_c$, Eq. 1*b* gives the total vertical pressure within the ditch at the level of the top of the pipe. The proportion of this total pressure that will be carried by the conduit will depend upon the relative rigidity of the conduit and of the fill material between the sides of the conduit and the sides of the ditch. In the case of very rigid pipes, such as burned clay, concrete, or heavy cast-iron pipe, the side fills may be relatively compressible and the pipe itself will carry practically all the load, P. On the other hand, if the pipe is a relatively flexible, thin-walled pipe and the side fills are thoroughly tamped in at the sides of the pipe, the stiffness of the side fills may approach that of the conduit and the load on the structure will be reduced by the amount of load the side fills are capable of carrying.

---

[2] "The Theory of Loads on Pipes in Ditches and Tests of Cement and Clay Drain Tile and Sewer Pipe," by A. Marston and A. O. Anderson, *Bulletin No. 31*, Iowa Eng. Experiment Station, Ames, Iowa, 1913, p. 32.

For the case of rigid ditch conduits with relatively compressible side fills, the load will be:

$$W_c = C_d\,\gamma\,b^2_d \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

For the case of flexible pipes and thoroughly compacted side fills having the same degree of stiffness as the pipes, the load will be:

$$W_c = C_d\,\gamma\,b_c\,b_d \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

in which W_c is the total load on the conduit, and:

$$C_d = \frac{1 - e^{-\alpha H_c}}{2\,K\,\mu'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3c)$$

Eq. 3*a* has been verified many times by experiment and by observation of the performance of actual sewers and drains. The results of two of Dean Marston's early load experiments on rigid pipes are shown in Fig. 3, together with loads calculated by Eq. 3*a*.

Evaluation of Eqs. 3*a* and 3*b* may be simplified by the use of Fig. 4 in which values of C_d for various values of H_c/b_d have been plotted for several kinds of filling materials having different coefficients of internal friction.

The width of ditch, b_d, is the actual width of a normal, parallel-sided ditch. In case the ditch is constructed with sloping sides, or the conduit is placed in a subditch at the bottom of a wider trench, experiments[3] have shown that the width of ditch at or slightly below the top of the pipe is the proper width to use when determining the load.

These ditch conduit formulas (Eqs. 3*a* and 3*b*), with proper selection of the physical factors involved, give the maximum loads to which any particular conduit may be subjected in service. On the other hand, because of the development of cohesion, any particular conduit may escape the maximum load for a long time, sometimes until its removal for other causes than load failure. Experiments and field observations show that the load on a conduit at the time the fill is completed is usually less than it will be at some later time. This condition accounts for the fact that sewers and other conduits which have been observed to be structurally sound immediately upon completion are sometimes found to be cracked some months or years later.

[3] "Loads on Pipe in Wide Ditches," by W. J. Schlick, *Bulletin No. 108*, Iowa Eng. Experiment Station, Ames, Iowa, 1932.

LOADS ON PROJECTING CONDUITS

Projecting conduits, as defined and as the name implies, are placed with their tops projecting some distance above the natural ground surface. They may be of any shape, such as circular, rectangular, or elliptical; may be made of any material, such as concrete, burned clay, cast iron, corrugated metal, or wood; and may possess any degree of rigidity from the very rigid concrete pipes and monolithic box culverts to the very flexible, lightweight corrugated metal pipes.

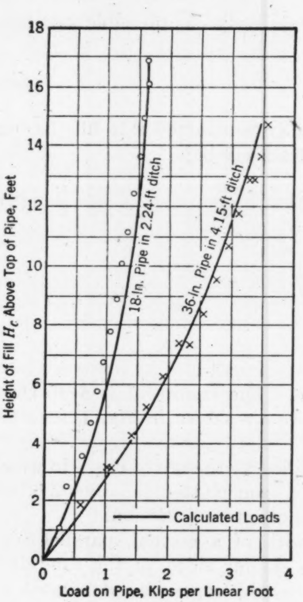

FIG. 3.—MEASURED LOADS ON DITCH CONDUITS

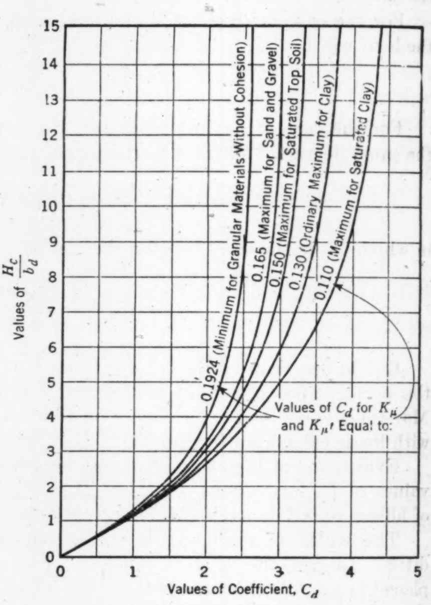

FIG. 4.—COMPUTATION DIAGRAM FOR DITCH CONDUITS

As a basic case for studying the action of an embankment over this type of conduit, consider first a rigid structure resting on an earth foundation which settles under the load the same amount as the natural ground adjacent to the structure (see Fig. 5). Then in the embankment built over the conduit, there are three masses or prisms of soil, one of which, called the "interior prism," is directly over the conduit between the vertical planes tangent to the sides. The other two masses of soil, called the "exterior prisms," are those on each side of the structure adjacent to the tangent vertical planes.

It is evident that the height of the interior prism will be less than that of the exterior prisms by the amount which the conduit projects above the natural ground. In accordance with the well-known phenomenon that a high prism of soil will settle more than a lower prism, there is a tendency for the exterior prism to settle more than the interior prism and for friction forces or shearing stresses to be exerted along the tangent vertical planes bounding the interior prism. These shearing stresses are transmitted to the conduit, making the load on the structure greater than the weight of the interior prism of soil. The magnitude of the shearing stresses (again neglecting cohesion) is assumed to be equal to the active lateral pressure at these planes, multiplied by the coefficient of internal friction of the fill material. It is recognized that definite shearing planes between the interior and exterior prisms of soil do not actually exist in an earth embankment and that, in all probability, the shearing stresses are transferred from one prism to another through more or less narrow zones of the filling material. Nevertheless, actual vertical shearing planes are assumed for convenience in developing the theory, and load measuring experiments indicate that the assumption is valid.

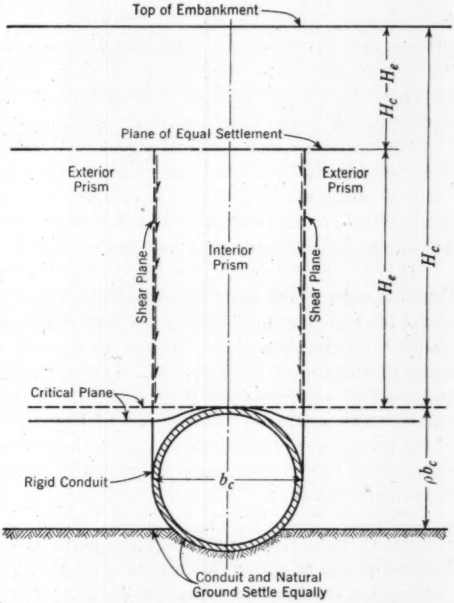

FIG. 5.—BASIC CASE FOR CONSIDERING THE ACTION OF AN EMBANKMENT OVER A PROJECTING CONDUIT

If the embankment is not very high, these shearing stresses may extend upward from the conduit completely to the top of the embankment. In the case of higher fills, the shearing stresses will not extend to the surface, but will terminate at some horizontal plane between the top of the conduit and the top of the embankment, known as the "plane of equal settlement." The distance between the top of the conduit and this plane is called the "height of equal settlement, H_e."

The plane of equal settlement is defined as the horizontal plane in the embankment at and above which the settlements of the interior and exterior prisms of soil are equal. Above the plane of equal settlement there is no tendency for relative movement between the three adjacent prisms and no shearing stresses are generated along the boundaries of the interior prism above this plane, whereas, below it, relative movements do have a tendency to occur and shearing stresses are developed.

A plane of equal settlement in this basic case results from the transfer of pressure, by shear, from the exterior prisms to the interior prism. Since the vertical deformation of a prism of material due to its own weight is a function of the height as well as characteristic of the material, normally the summation of deformations from the bottom of a prism upward will be at a greater rate in a high prism than in a lower one if the prisms act independently of one another. In the case of projecting conduits, however, the exterior prisms of soil transfer a part of their vertical pressure to the interior prism and the rate of summation of vertical deformations will be reduced in the exterior prisms and increased in the interior prism because of this stress transfer. Therefore, the total summation of deformations in the interior prism will approach that in the exterior prisms, and the height at which the deformations become equal is the height of equal settlement.

The existence of a plane of equal settlement was first announced by Dean Marston in 1922[4] on the basis of pure mathematical reasoning and a formula for evaluating its height was developed at that time. Since then the actual existence of such a plane has been demonstrated by measurements of the settlements and of the loads on a number of experimental conduits.

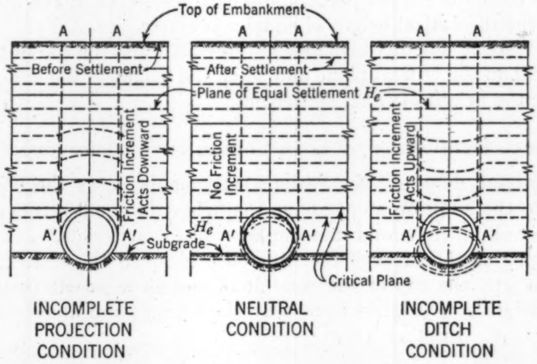
This basic settlement situation is practically always modified by two additional factors which must be considered in the development of a general theory of fill loads. The first of these is the settlement of the undisturbed subgrade under the exterior prisms adjacent to the conduit; and the second, the settlement of the top of the conduit. The settlement of the subgrade adjacent to the conduit augments the downward movement of the two exterior prisms of earth. The settlement of the top of the conduit (which is equal to the sum of the settlement of its foundation and the distortion or shortening of its vertical dimension) has the tendency to neutralize this action by reducing the relative movement between the interior and exterior prisms. Indeed, if the conduit is sufficiently flexible, if it is placed on a very yielding foundation, or if both conditions hold true, the top of the conduit may settle enough to permit the interior prism to move downward a greater amount than the exterior prisms. When this occurs, the direction of the induced shearing stresses is reversed and the stresses are subtractive from the weight of the prism of earth over the conduit. The rate of summation of settlements in relation to height above the conduit for the interior prism is less than that in the exterior prisms due to the reduced pressure. Nevertheless, there still may be a plane of equal settlement, even if the direction of relative movements is reversed, because the total settlement is augmented by the settlement of the top of the conduit, which causes the entire interior prism to move downward.

In this connection it is convenient to define a "critical plane" which is the horizontal plane in the fill material at the level of the top of the conduit at the beginning of construction of the embankment and before settlements have begun to develop. With this definition in mind, the aforementioned facts concerning direction of the induced shearing stresses may be simplified by stating that, when the critical plane settles more than the top of the conduit, the shearing stresses act downward on the interior prism and that, when it settles less, they act upward.

---

[4] "Second Progress Report to the Joint Concrete Culvert Pipe Committee," by Anson Marston, April 7, 1922 (mimeographed).

A neutral or transition case occurs when the top of the conduit settles downward an amount just equal to the settlement of the critical plane. When this case occurs, the plane of equal settlement is right at the top of the conduit and coincident with the critical plane; the interior and exterior prisms of soil move downward equally throughout their full height and no shearing stresses are induced, with the result that the load on the structure is equal to the weight of the prism of soil directly over it. Some typical settlement situations affecting loads on projecting conduits are illustrated in Fig. 6. (The solid horizontal lines represent imaginary planes of embankment before settlement. The broken lines represent the same planes after settlement.[5])



INCOMPLETE PROJECTION CONDITION

NEUTRAL CONDITION

INCOMPLETE DITCH CONDITION

FIG. 6.—TYPICAL SETTLEMENT CONDITIONS AFFECTING LOADS ON PROJECTING CONDUITS

In the mathematical analysis of loads on projecting conduits, the net effect of all these settlement factors, both as to magnitude and direction of the relative movements of the three prisms of soil, is combined into an abstract ratio known as the "settlement ratio," which is defined as the ratio of the difference between the settlement of the critical plane and the top of the conduit, to the deformation of the fill material adjacent to the conduit within the vertical distance between the top of the conduit and the natural ground line. Dean Marston defined this ratio on the basis of the settlements of the various elements which are produced by that section of the fill above the plane of equal settlement.

For purposes of calculating the external vertical loads on projecting conduits, the field conditions affecting the loads are conveniently grouped into four subclassifications based on the magnitude of the settlement of the interior prism relative to that of the exterior prisms and, therefore, the direction of the shearing stresses, and the height of the embankment in relation to the height of equal settlement. These four conditions are: (1) The complete projection condition, (2) the incomplete projection condition, (3) the complete ditch condition, and (4) the incomplete ditch condition.

---

[5] "Investigation of Loads on Three Cast Iron Pipe Culverts Under Rock Fills," by M. G. Spangler, *Bulletin No. 104*, Iowa Eng. Experiment Station, Ames, Iowa, 1931, p. 26, Fig. 11.

They are defined as follows:

(1) The "complete projection condition" prevails when the top of the conduit settles less than the critical plane and when the height of the embankment is less than the theoretical height of equal settlement.

(2) The "incomplete projection condition" prevails when the top of the conduit settles less than the critical plane and when the height of the embankment is greater than the height of equal settlement.

(3) The "complete ditch condition" prevails when the top of the conduit settles more than the critical plane and when the height of the embankment is less than the theoretical height of equal settlement.

(4) The "incomplete ditch condition" prevails when the top of the conduit settles more than the critical plane and when the height of the embankment is greater than the height of equal settlement.

MATHEMATICAL DERIVATION OF LOAD FORMULAS FOR PROJECTING CONDUITS

Dean Marston defines[4,6] the various settlements, y, as the "* * * increments due to the addition at or above the height of equal settlement of any [the same for all] incremental uniform layer of fill materials." A settlement ratio is defined as the ratio of the difference between the settlement of the critical plane and the top of the conduit of the fill adjacent to the conduit within the height $\rho\, b_c$ (Fig. 5) caused by the fill material above the plane of equal settlement. In other words:

$$\delta = \frac{(y_m + y_g) - (y_f + y_c)}{y_m} \qquad \text{(4a)}$$

in which y_g is the settlement of the embankment subgrade adjacent to the conduit, in feet; y_f is the settlement of the flow line of the conduit; y_c is the deflection of the conduit—that is, the shortening of its vertical dimension; and y_m is the deformation of the filling material adjacent to the conduit within the height $\rho\, b_c$ in feet—that is:

$$y_m = \frac{(H_c - H_e)\,\gamma}{E_f}\,\rho\, b_c \qquad \text{(4b)}$$

in which E_f is the modulus of deformation of the filling material. The settlement of the "critical plane," in this notation is $y_m + y_g$ and the settlement of the top of the conduit is $y_f + y_c$. In Eq. 4*a*, δ is negative for the "incomplete" ditch condition and positive for the "incomplete" projection condition.

Considering first the complete ditch and projection conditions (Fig. 7(*a*)), in which $H_c < H_e$, the vertical forces on any thin horizontal element of the interior prism may be equated as follows:

$$P + dP = P + \gamma\, b_c\, dH_p \pm 2\, K\, \mu\, \frac{H_p}{b_c}\, dH_p \qquad \text{(5a)}$$

---

[6] "The Theory of External Loads on Closed Conduits in the Light of the Latest Experiments," by Anson Marston, *Bulletin No. 96*, Iowa Eng. Experiment Station, Ames, Iowa, 1930.

The solution of this equation is

$$P = \gamma\, b_c^2 \frac{e^{\pm \beta H_p} - 1}{\pm\, 2\, K\, \mu} \ldots\ldots\ldots\ldots\ldots\ldots (5b)$$

in which μ is the coefficient of internal friction of the filling material, and to simplify typography (compare Eq. 2a):

$$\beta = \frac{2\, K\, \mu}{b_c} \ldots\ldots\ldots\ldots\ldots\ldots (5c)$$

At the top of the conduit, $P = W_c$ and $H_p = H_c$; therefore:

$$W_c = C_c\, \gamma\, b_c^2 \ldots\ldots\ldots\ldots\ldots\ldots (6a)$$

in which the load coefficient for projecting conduits is represented by:

$$C_c = \frac{e^{\pm \beta H_c} - 1}{\pm\, 2\, K\, \mu} \ldots\ldots\ldots\ldots\ldots\ldots (6b)$$

in which H_c is the height above the top of a conduit. In Eq. 6b the plus signs are used for the complete projection condition and the minus signs for the complete ditch condition.

(a) COMPLETE PROJECTION CONDITION (b) INCOMPLETE PROJECTION CONDITION

FIG. 7.—FORCES ACTING ON A PROJECTING CONDUIT

Considering the incomplete ditch and the incomplete projection conditions (Fig. 7(b)), in which $H_c > H_e$, and again equating the vertical forces on a thin horizontal element:

$$P + dP = P + \gamma\, b_c\, dH_p \pm 2\, K\, \mu \frac{P}{b_c} dH_p \ldots\ldots\ldots\ldots (7a)$$

When $H_p = 0$, $P = (H_c - H_e)\,\gamma\,b_c$ and the solution of this differential equation (Eq. 7*a*) is:

$$P = \frac{\gamma\,b^2_c}{2\,K\,\mu} \pm \frac{\gamma\,b^2_c}{2\,K\,\mu}\,e^{\pm\beta H_p} + (H_c - H_e)\,\gamma\,b_c\,e^{\pm\beta H_p} \quad \text{(7b)}$$

At the top of the conduit, $P = W_c$ and $H_p = H_e$; therefore, in Eq. 6*a*, the load coefficient C_c becomes:

$$C_c = \frac{e^{\pm\beta H_e} - 1}{\pm\,2\,K\,\mu} + \left(\frac{H_c}{b_c} - \frac{H_e}{b_c}\right) e^{\pm\beta H_e} \quad \text{(8)}$$

As before, the plus signs are applicable to the incomplete projection condition and the minus signs apply to the incomplete ditch condition.

To derive an expression for evaluating H_e, the following two conditions are assumed:

a. The internal friction in the embankment materials distributes the infinitely small increments or decrements of pressure from shear into the interior prism below the plane of equal settlement in such manner that their effect on settlement may be assumed to be substantially the same as for uniform vertical pressure; and

b. The internal friction in the embankment materials distributes the infinitely small decrements or increments of pressure from shear into the exterior prisms so completely that their effect on settlement may be neglected.

Equating the settlements in the exterior prisms and the settlements in the interior prism caused by the fill material above the plane of equal settlement:

$$\frac{(H_c - H_e)\,\gamma}{E_f}\,H_e + y_m + y_g = \int_0^{H_e} \frac{(H_c - H_e)\,\gamma}{E_f}\,e^{\pm\beta H_p}\,dH_p + y_f + y_c \quad \text{(9)}$$

In Eq. 9, using Eqs. 4:

$$e^{\pm\beta H_e} \mp 2\,K\,\mu\,\frac{H_e}{b_c} = \pm\,2\,K\,\mu\,\delta\,\rho + 1 \quad \text{(10)}$$

In the three quantities of Eq. 10 the +, −, and + signs are used for the projection condition; and the −, +, and − signs, respectively, are used for the ditch condition.

Eq. 10 must be solved by trial, since it contains H_e as an exponent of *e*, the base of natural logarithms (see Eq. 5*c*).

As in the case of ditch conduits, the solution of these various expressions for loads on projecting conduits is made easy by the construction of a load coefficient diagram,[7,8] as shown in Fig. 8. For selected values of the "settlement" ratio and the "projection" ratio ($\delta\,\rho$) and given values of H_c/b_c the proper value of the coefficient C_c is read from the curves and substituted in Eq. 6*a*. Comparisons between actual weighed loads in carefully conducted experiments and loads computed by Dean Marston's load theory are shown in Fig. 9.

---

[7] "The Theory of External Loads on Closed Conduits in the Light of the Latest Experiments," by Anson Marston, *Bulletin No. 96*, Iowa Eng. Experiment Station, Ames, Iowa, 1930, p. 14, Fig. 3.

[8] "The Supporting Strength of Rigid Pipe Culverts," by M. G. Spangler, *Bulletin No. 112*, Iowa Eng. Experiment Station, Ames, Iowa, 1933, p. 46, Fig. 18.

Several alternate methods of determining the value of H_e have been investigated, including an analysis in which the settlement ratio was based on the total settlements of the various elements of the fill and of the conduit caused by the total height of embankment. The loads obtained by this alternate analysis were nearly the same as those obtained by Dean Marston's original analysis, being somewhat less for high values of $\frac{H_e}{b_e}$ and $\delta\,\rho$.

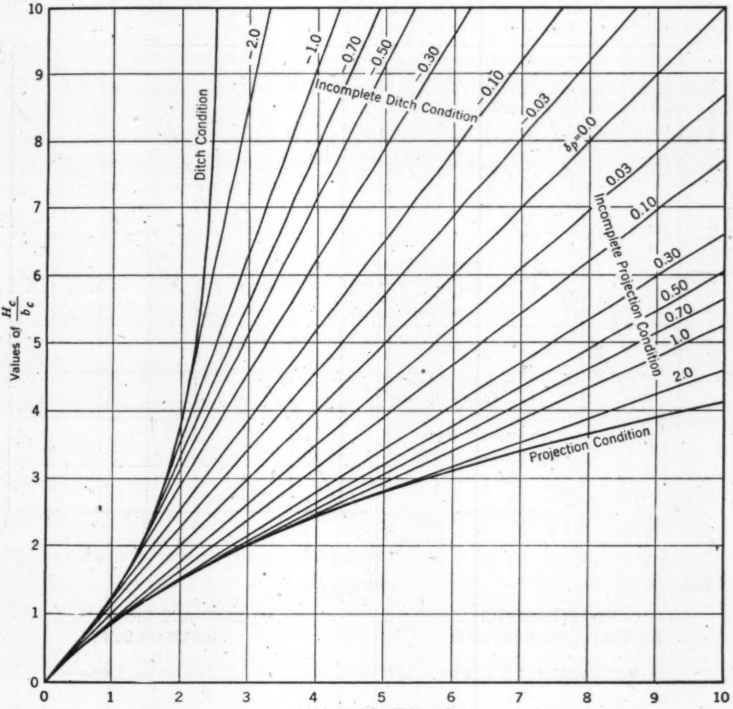

FIG. 8.—COMPUTATION DIAGRAM FOR EXTERNAL LOADS ON CONDUITS ($K\,\mu$ = 0.1924)

Working values of μ, the coefficient of internal friction of the embankment material, may be determined by soil tests in a particular case. However, Dean Marston has shown that the variation in load on a projecting conduit is relatively small for wide variations of the coefficient of internal friction. For example, when this coefficient varies from about 0.3 to 1.0, corresponding to angles of friction from about 17° to 45°, the product $K\,\mu$ varies from about 0.17 to 0.1924 and back to 0.17. Since the load is dependent upon the product $K\mu$ and not on μ alone, a value of $K\mu = 0.19$ may reasonably be chosen as a safe working value for most cases of projecting conduit loads.

TIME EFFECT ON LOADS

To study the effect of time on the loads produced on culverts by earth embankments, three test culverts supported on weighing devices were built and loaded with a 15-ft embankment late in the fall of 1927, and observations of the loads on these structures have been made periodically since that date. This load history shows that the maximum load was reached in April of the following spring after the fill was completed, after which the load fell off somewhat, reaching a low point about 10% below the maximum in the following October and November. Since that date, the load has fluctuated between these approximate limits, reaching the maximum for each year early in the spring and the minimum late in the fall.

(b) SAND AND GRAVEL FILL
126.5 Lb per Cu Ft

FIG. 9.—COMPARISON BETWEEN ACTUAL WEIGHED LOADS ON PROJECTING CONDUITS

Eq. 10 for H_e has been derived for the assumed case in which the fill material has a uniform modulus of deformation throughout; and it is emphasized that the value of H_e is independent of the value of this modulus. In other words, even if the fill material is thoroughly compacted during placement and a high value of the compression modulus is attained, the direction of the relative settlements of the interior and exterior prisms and the height of equal settlement will not be affected thereby.

The settlement ratio is wholly rational in the theoretical analysis of loads on projecting conduits. However, except in unusual cases it will not be practicable to predict the value to use in the design of a given structure on the basis of individual study and analysis of the soil at a proposed site. It has been deemed advisable and appropriate, therefore, to consider the settlement ratio as a semi-empirical factor and to determine proper design values on the basis of the observed performance of projecting conduits in service.

Rather extensive field measurements of the settlement characteristics of some actual culverts under the highways of Iowa and southern Minnesota, which have been conducted by the Iowa Engineering Experiment Station in cooperation with the Public Roads Administration, Federal Works Agency, tentatively indicate the following working values for the settlement ratio—for rigid culverts on:

Foundation material	δ
Rock or other unyielding material............	+ 1.0
Ordinary earth.................................	+ 0.5 to + 0.8

Observations of the settlement ratio have been made on a few flexible type culverts in actual service, but the number of specimens is limited. These measured values ranged from 0 to + 0.7 and they varied directly with the values of the modulus of passive pressure of the side-fill materials. It appears, therefore, that high quality densification of the side fills around a flexible pipe, for the purpose of increasing the modulus of passive pressure, tends to increase the load on the pipe. However, the ultimate deflection of the pipe is decreased by this practice, since the increase in supporting strength of the pipe more than offsets the effect of the increased load.

Unusual installation conditions may cause exceptional values of the settlement ratio and of the load to develop. For example, a case has come to the writer's attention where a highway fill was built across a salt marsh underlain with stiff clay at about 10 ft or 12 ft below the surface. A concrete pipe culvert was built prior to construction of the fill. To reduce the expected settlement of the culvert and to increase its supporting strength, the pipes were laid in a well-designed concrete cradle, which in turn was supported on piles driven into the clay stratum. Shortly after the fill was completed this culvert collapsed, even though it was constructed of excellent reinforced concrete pipe. Although no settlement data are available, it seems probable that the fill material at the sides (the "exterior prisms") settled a very large amount due to the soft spongy character of the marsh bed, whereas the culvert resting on piles driven to the stiff clay could not settle. Under these conditions the critical plane probably settled much more than the top of the culvert, causing a very high positive value of the settlement ratio and a very high load to develop.

IMPERFECT DITCH CONDUITS

In the early days of Dean Marston's researches on conduit loads, he was impressed by the very high loads that may develop on projecting conduits when the conditions are such that large shearing forces add to the weight of the prism of soil directly over the conduit, and he strove to devise a method of construction that would reduce or eliminate these shearing forces, or would possibly reverse their direction so that they would act benevolently as in the case of ditch conduits. With this objective in mind, he developed the imperfect ditch method of construction in which the soil on both sides and above the conduit for some distance above its top is thoroughly compacted by rolling, tamping, or any other suitable method. Then a ditch is constructed in this compacted fill by removing the prism of material directly over the conduit. The ditch is refilled with very loose compressible material, after which the embankment is completed in a normal manner.

The purpose of this method of construction is accomplished by creating a condition wherein it is certain that the prism of material directly over the conduit will settle more than the adjacent prism; the ditch in the artificially compacted material must be deep enough and the refilling material must be loose enough to insure this action. Straw or other highly compressible material may be used as part of the ditch backfill to augment the settlement of the interior prism. The efficacy of this method of construction was demonstrated by a series of experiments conducted by Dean Marston from 1919 to 1921, in which the load on a conduit was measured, first, when the fill was constructed in the ordinary manner for a projecting conduit, and, second, when the fill was constructed by the imperfect ditch method. The loads measured in these experiments are shown in Fig. 9(*a*).

SURFACE LOADS

In addition to external loads imposed by the filling material around and above underground conduits, these structures are also subjected to loads resulting from highway, railway, or airplane traffic or from other types of loads applied at the surface and transmitted through the soil to the underground structure. Such loads are of major importance when a conduit is placed under a trafficway with a relatively shallow covering of earth.

John H. Griffith, M. ASCE, was among the first to suggest the applicability of the Boussinesq solution[9] for the distribution of stress in a semi-infinite elastic solid to various problems of stress distribution in soils in a report prepared for a subcommittee on soils of the United States Bureau of Standards of which he was chairman. Extensive experiments[10,11] on both ditch and projecting conduits subsequent to this suggestion have shown that a concentrated surface load, such as a truck wheel, is transmitted through the soil covering to the underground structure substantially in accord with the Boussinesq solution.

[10] "The Causes of Structural Failures of Sewers," by Anson Marston and M. G. Spangler, *Proceedings*, Am. Soc. of Municipal Engrs., Vol. 38, 1933, p. 236.

[11] "Experimental Determinations of Static and Impact Loads Transmitted to Culverts," by M. G. Spangler, Clyde Mason, and Robley Winfrey, *Bulletin No. 79*, Iowa Eng. Experiment Station, Ames, Iowa, 1926.

From these facts, the load on an underground conduit due to a concentrated surface load may be expressed as:

$$W_P = \frac{1}{L} F_i \, C_t \, P_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which W_P is the average load on an underground conduit due to a concentrated surface load, in pounds per linear foot; P_0 is a concentrated surface load, in pounds; F_i is an impact factor; L is the length of the conduit, in feet; and C_t is a coefficient for load on an underground conduit due to a concentrated surface load.

The coefficient C_t may be calculated by dividing the area of the top of the conduit or its horizontal projection, $L\,b_c$, into a number of small areas as illustrated in Fig. 10, and summing up the total pressure on all these small areas, according to the formula:

$$C_t = a \sum \frac{3}{2\,\pi} \frac{H^3_c}{H^5_s} \ldots (12a)$$

in which a is the area of an element, in square feet; H_c is the vertical height from the top of the conduit to the embankment surface, in feet; and H_s is the slant height, in feet, from the center of each element to the point of application of the load; that is: $H_s = \sqrt{x^2 + y^2 + z^2}$, in feet.

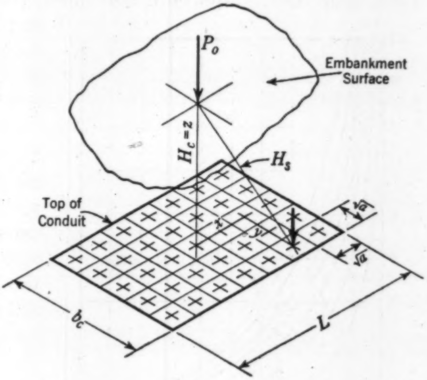

FIG. 10.—COMPUTATION OF THE CONCENTRATED SURFACE LOAD TRANSMITTED TO AN UNDERGROUND CONDUIT

Early in 1929 D. L. Holl integrated this expression for C_t and obtained:

$$C_t = 1 - \frac{2}{\pi} \left\{ \left[\sin^{-1} H_c \sqrt{\frac{\dfrac{L^2}{4} + \dfrac{b^2_c}{4} + H^2_c}{\left(\dfrac{L^2}{4} + H^2_c\right)\left(\dfrac{b^2_c}{4} + H^2_c\right)}} \right] - \frac{\dfrac{L\,b_c\,H_c}{4}}{\sqrt{\dfrac{L^2}{4} + \dfrac{b^2_c}{4} + H^2_c}} \left(\frac{1}{\dfrac{L^2}{4} + H^2_c} + \frac{1}{\dfrac{b^2_c}{4} + H^2_c} \right) \right\} \ldots\ldots\ldots (12b)$$

Eq. 12*b* can be evaluated[12] readily by the table prepared by N. M. Newmark,[13] M.ASCE, for determining stresses in the soil beneath uniformly loaded rectangular foundations.

---

[12] "A Method of Computing Live Loads Transmitted to Underground Conduits," by M. G. Spangler and Richard L. Hennessy, *Proceedings*, Highway Research Board, National Research Council, Vol. 26, 1946, p. 179.

[13] "Simplified Computation of Vertical Pressures in Elastic Foundations," by Nathan M. Newmark, *Circular No. 24*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill., 1935.

Values of C_t for conduits 3 ft long of various widths, b_c, are shown[14] in Fig. 11 for various heights of fill up to 10 ft. When fill loads and surface loads are combined to obtain the design load on an underground conduit, the minimum load will be found to occur when the height of fill is relatively low over the top of the structure.

The impact factor, F_i, is equal to unity when the surface load is static. When it is moving, as in the case of truck or airplane wheels, the value of F_i may vary widely depending on speed of the vehicle, vibratory action, wing uplift, and most important, on roughness characteristics of the roadway surface. Experiments[9] have indicated design values of F_i ranging from 1.5 to 2.0 for highway traffic on an unsurfaced roadway.

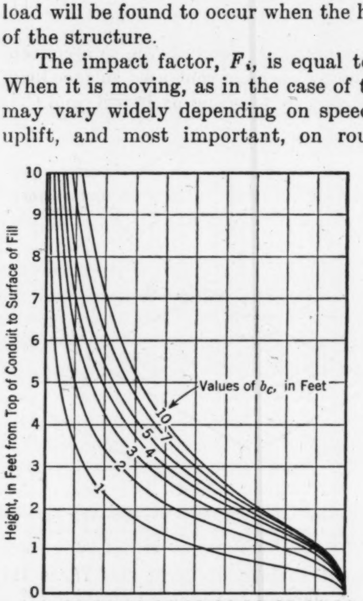

FIG. 11.—CONCENTRATED SURFACE LOAD COEFFICIENTS FOR UNDERGROUND (L = 3 Ft)

Professor Griffith gave extensive consideration to problems of the transmission of stress through soils and the applicability of the Boussinesq classical solution to them. In 1929 he developed a generalized expression[15] for the intensity of vertical pressure in a soil mass due to a concentrated surface load in the form:

$$P_z = \frac{\nu}{2\pi} P_0 \frac{\cos^{\nu+2}\theta}{z^2} \quad \ldots . (13)$$

in which P_z is the intensity of pressure at a point in the soil mass; P_0 is the concentrated load applied at a point on the surface; θ is the angle formed with the vertical by the radius vector from the point of application of the surface load to the point considered; z is the vertical distance from the surface to the point; and ν is a disposable parameter, often referred to as the "concentration" factor or "dispersion" factor.

Professor Holl[16] has utilized Eq. 13 in the solution of a number of problems dealing with the transmission of surface loads through soil masses.

THE SUPPORTING STRENGTH OF UNDERGROUND CONDUITS

Underground conduits are constructed in a wide variety of shapes and of many different structural materials. In general, the load on a conduit is independent of its shape and the material of which it is made. In contrast, the supporting strength of a conduit is intimately dependent upon its shape and the kind and quality of material of which it is made. The remainder of this paper will be devoted to a discussion of the supporting strength of a number of commonly used types of conduits.

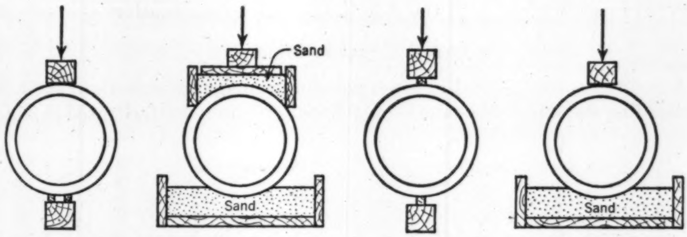
[16] "Stress Transmission in Earths," by D. L. Holl, *Proceedings*, Highway Research Board, National Research Council, Vol. 20, 1940, p. 709.

Monolithic Arch and Box Culverts or Sewers.—These monolithic types of reinforced concrete structures may be designed satisfactorily by any current procedures for analysis of rigid frame structures. Numerous measurements of the distribution of the vertical load on both rectangular and circular shaped culverts due to the earth overburden have indicated that it is essentially uniformly distributed over the width of the conduit and may be so considered for design purposes. Culverts may or may not be subjected to active lateral pressure on all or part of their side-wall areas, depending on the local situation.

Some laboratory experiments[17] on the supporting strength of monolithic box culverts indicate that the actual supporting strength exceeds the calculated strength until the concrete of the top slab cracks, after which the actual strength very closely approximates the calculated strength.

Rigid Circular Pipes.—Rigid circular pipes, which are usually pre-cast of such materials as burned clay, plain or reinforced concrete, or cast iron, are difficult to analyze by principles of mechanics; and, since they are usually relatively small structures, their supporting strength can be most easily determined by testing a representative group of specimens in the laboratory. Several methods of testing short sections of circular pipes have been devised[18] —the two-edge bearing, the three-edge bearing, the sand bearing, and the Minnesota bearing tests—the details of which are shown in Fig. 12. Of these, the three-edge bearing test (Fig. 12(*a*)) is the simplest and most easily performed. At the same time it gives accurate and uniform results, and for these reasons it is widely used in tests to determine the strength of pipes, although some engineers prefer the sand bearing test (Fig. 12(*b*)) because of the wider distribution of both the applied load and reaction.



(*a*) THREE-EDGE BEARING (*b*) SAND BEARING (*c*) TWO-EDGE BEARING (*d*) MINNESOTA BEARING

Fig. 12.—Typical Bearings for Laboratory Tests of Pipes

The test load and reaction on the pipe are distributed differently in each of these types of tests and the ultimate load or supporting strength will likewise be different. It is convenient to express the supporting strength of a pipe in terms of its strength when tested by the three-edged bearing method, taken as unity, by a load factor or strength ratio which is defined as the ratio of the strength of a pipe under any stated condition of loading to its three-edge bearing test strength. The following values of load factor or strength ratio for the other three test methods shown in Fig. 12 are applicable:

---

[17] "The Supporting Strength of Reinforced Concrete Box Culverts," by George C. Pagels, thesis presented to Iowa State College, Ames, Iowa, in 1935 in partial fulfilment of the requirements for the degree of Master of Science.

[18] "The Supporting Strength of Rigid Pipe Culverts," by M. G. Spangler, *Bulletin No. 112*, Iowa Eng. Experiment Station, Ames, Iowa, 1933, p. 13, Fig. 5.

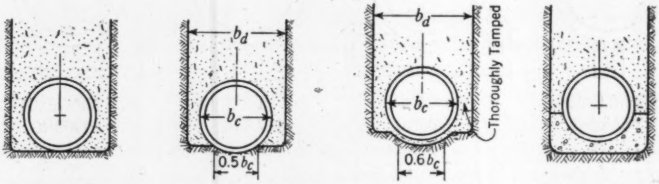
Test	Load factor
Sand bearing	1.5
Two-edge bearing	1.0
Minnesota bearing	1.1

Likewise when a pipe is placed and loaded in an actual field installation, the loads and reactions will be distributed much differently than in the test loading; and, in certain cases, lateral pressures will be exerted against the sides of the pipe thereby increasing its ability to support vertical loads.

A wide variety of bedding conditions affecting the load and reaction distribution and the lateral pressure situation may be encountered in sewerage, water works, and culvert construction practice; and a wide variety of supporting strengths of a given conduit may be obtained simply by varying the installation conditions. It is feasible to establish and define classifications of bedding conditions covering a range of practical attainments and determine a load factor for each classification which, when multiplied by the three-edge bearing laboratory strength of the pipe, will give the safe supporting strength for pipes installed in accordance with the definition of that classification.

DITCH CONDUIT BEDDINGS

For ditch conduits used in sewerage and drainage construction, the following bedding classifications have been defined[19,20,21] and are illustrated in Fig. 13.



(*a*) NOT PERMISSIBLE (*b*) ORDINARY (*c*) FIRST CLASS (*d*) CONCRETE CRADLE

FIG. 13.—TYPICAL BEDDING SPECIFICATIONS FOR SEWERS AND OTHER DITCH CONDUITS

Bedding conditions for cast-iron pipe in water works construction will be discussed subsequently.

[21] "Concrete Cradles for Large Pipe Conduits," by W. J. Schlick and James W. Johnson, *Bulletin No. 80*, Iowa Eng. Experiment Station, Ames, Iowa, 1926.

1. "Impermissible" bedding (Fig. 13(*a*)) is that method of bedding ditch conduits in which little or no care is exercised to shape the foundation to fit the lower part of the conduit exterior and to refill all spaces under and around the conduit.

2. "Ordinary" bedding (Fig. 13(*b*)) is that method of bedding ditch conduits in which the conduit is placed with "ordinary" care in an earth foundation shaped to fit the lower part of the conduit exterior with reasonable closeness for a width of at least 50% of the conduit breadth. The remainder of the conduit is surrounded to a height of at least 0.5 ft above its top by granular materials, shovel placed and shovel tamped to fill completely all spaces under and adjacent to the conduit—all under the general direction of a competent engineer.

3. "First-class" bedding (Fig. 13(*c*)) is that method of bedding ditch conduits in which the conduit is set on fine granular materials in an earth foundation carefully shaped to fit the lower part of the conduit exterior for a width of at least 60% of the conduit breadth. The remainder of the conduit is entirely surrounded to a height of at least 1.0 ft above its top by granular materials carefully placed by hand to fill, completely, all spaces under and adjacent to the conduit. The fill is tamped thoroughly on each side and under the conduit as far as practicable in layers not exceeding 0.5 ft thick—all under the direction of a competent engineer represented by a competent inspector constantly present during the operation.

4. "Concrete-cradle" bedding is that method of bedding conduits in which the lower part of the conduit exterior is set in plain or reinforced concrete, of suitable thickness, under the lowest part of the conduit exterior and extending upward on each side of the conduit for a greater or less proportion of its height.

The load factor for each of these bedding classifications has been determined experimentally to be:

Figure No.	Bedding	Load factor
13(*a*)	Impermissible	1.1
13(*b*)	Ordinary	1.5
13(*c*)	First class	1.9
13(*d*)	Concrete cradle	2.2 to 3.4

PROJECTING CONDUIT BEDDINGS

In culvert construction practice, rigid pipes are often installed as projecting conduits and the fill material may exert an active lateral pressure against the sides of the pipes, which tends to increase the supporting strength of the structure. The supporting strength of a projecting conduit, therefore, is a function of both the distribution of the vertical load and the reaction on the pipe, and the magnitude and distribution of the active lateral pressure on sides which are exposed to the embankment filling material.

Because of the large number of possible combinations of reaction distributions and effective lateral pressure distributions, the experimental determination of load factors for projecting conduits has been supplemented by analytical studies of the stress situation in pipe rings under various combinations of loads and lateral pressures.[22] By definition, the load factor is

$$F_p = \frac{R_c}{R_{eb}} \qquad (14a)$$

in which F_p is the load factor; R_c is the supporting strength of the pipe in any stated loading condition; and R_{eb} is the three-edge bearing supporting strength of the pipe.

Except for the normal variations in physical properties of the material of which culvert pipes are made, it is sufficiently accurate to assume that the outer fiber stress at the point and at the time of rupture will be the same whether the pipe is loaded in a testing machine or in an actual embankment. Therefore, the thin ring elastic theory and the flexure formula may be used to express the outer fiber stress in terms of the loads on the pipe in the field and laboratory loadings; and, by equating these expressions, the load factor is readily determined. When the field loading situation is such that the pipe cracks first at the bottom, this process leads to the formula:

$$F_p = \frac{1.431}{X_P - X_A \kappa_t} \qquad (14b)$$

in which X_P is a parameter which is a function of the distribution of the vertical load and vertical reaction; X_A is a parameter which is a function of the area of the vertical projection of the pipe on which the active lateral pressure of the fill material acts; and κ_t is the ratio of the total lateral pressure to the total vertical load.

When the load and reaction situation causes the pipe to crack first at the top (which is usually the case when pipes are bedded in concrete cradle), X'_P and X'_A should be substituted for X_P and X_A in Eq. 14*b*. Values of the parameters X_A and X'_A for various projection ratios are as follows:

Projection ratio, p	Values of X_A	Values of X'_A
0	0	0.150
0.3	0.217	0.743
0.5	0.423	0.856
0.7	0.549	0.811
0.9	0.655	0.678
1.0	0.638	0.638

As in the case of ditch conduits, it is convenient to name and define several classes of bedding conditions for projecting conduits and to determine a value of X_P or X'_P for each class. These classes of bedding are defined as follows:[23]

1. "Impermissible projection bedding" is that method of bedding projecting conduits in which little or no care is exercised either to shape the foundation surface to fit the lower part of the conduit exterior or to fill all spaces under and around the conduit with granular materials. This type of bedding also includes the case of conduits on rock foundations in which an earth cushion is

---

[22] "The Supporting Strength of Rigid Pipe Culverts," by M. G. Spangler, *Bulletin No. 112*, Iowa Eng. Experiment Station, Ames, Iowa, 1933.

[23] *Ibid.*, p. 15, Fig. 6.

provided under the conduit, but is so shallow that the conduit, as it settles under the influence of vertical load, approaches contact with the rock.

2. "Ordinary projection bedding" is that method of bedding projecting conduits under embankments in which the conduit is bedded with "ordinary" care in an earth foundation shaped to fit the lower part of the conduit exterior with reasonable closeness for at least 10% of its over-all height. The remainder of the conduit is surrounded by granular materials, placed by shovel to fill all spaces completely under and adjacent to the conduit—all under the general direction of a competent engineer. In the case of rock foundations, the pipes are bedded on an earth cushion, having a thickness under the pipe of not less than 0.5 in. per foot of height of fill, with a minimum allowable thickness of 8 in.

3. "First-class projection bedding" is that method of bedding projecting conduits, having a projection ratio not greater than 0.70, in which the conduit is carefully bedded on fine granular materials in an earth foundation carefully shaped to fit the lower part of the conduit exterior for at least 10% of its over-all height. The earth filling material is thoroughly rammed and tamped, in layers not more than 6 in. deep, around the conduit for the remainder of the lower 30% of its height—all under the direction of a competent engineer, represented by a competent inspector constantly present during the operation. In the case of rock foundations, the pipes are bedded in an earth cushion having a depth as provided under ordinary projection bedding.

4. "Concrete-cradle projection bedding" is that method of bedding conduits in which the lower part of the conduit exterior is bedded in a cradle, constructed of 2,000-lb concrete, or better, having a minimum thickness under the pipe of one fourth of the nominal internal diameter and extending up the sides of the pipe for a height equal to one fourth of the outside diameter. The values of X_P for these bedding classes are as follows:

Type of projection bedding	Value of X_P
Impermissible	1.310
Ordinary	0.840
First class	0.707
Concrete cradle (X'_P)	0.505

Working values of the load factor F_P, computed for rigid culvert pipes installed as projecting conduits on ordinary, first-class, and concrete-cradle beddings, with various projection ratios and a value of the settlement ratio of 0.7 are shown in Fig. 14. The general correctness of the foregoing analytical method of determining load factors has been established by a series of experiments in which ten pipe culverts of four kinds of material—plain concrete, reinforced concrete, burned clay, and cast iron—were loaded by earth embankments and their supporting strengths determined. Then samples of pipes representative of each of the ten culverts were tested in the laboratory by the three-edge bearing test and the ratios of the field and laboratory strengths were obtained.[24]

CONCRETE-INCASED CLAY PIPE

Circumstances may arise under which an engineer may wish to increase the strength of clay pipes by incasing them in concrete. Some extensive experiments[25] in which commercial vitrified salt-glazed clay pipe was incased in plain concrete and the combined structure tested in both sand and three-edge bearings have indicated that the test strength is only slightly greater than the sum of the individual supporting strengths of the clay pipe and of the incasement. The action of the incased pipe was very nearly that of two independent but concentric rings—the supporting strength of the combined structure being very much less than if the two materials had acted as a unit in resisting the stresses due to the test load. As a result of these experiments, computations have been made of the three-edge bearing supporting strength of A.S.T.M. (American Society for Testing Materials) standard sewer pipe when incased in concrete of various thicknesses. The results of these computations are shown in Fig. 15.

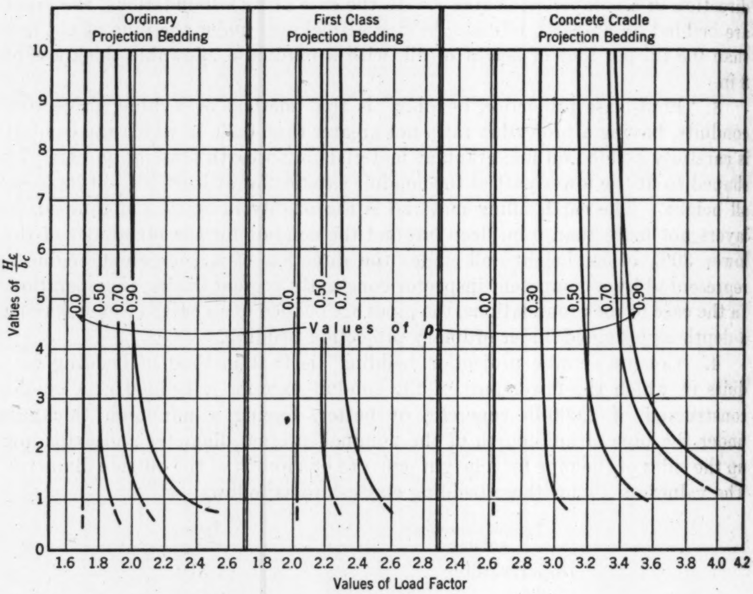

FIG. 14.—WORKING VALUES OF THE LOAD FACTOR FOR PROJECTING CONDUITS ($\delta = 0.70$)

THE SUPPORTING STRENGTH OF CAST-IRON PIPE WHEN SUBJECTED TO INTERNAL PRESSURE

When used for the transportation of water, gas, or other fluids, cast-iron pipe conduits not only are subjected to the ring stresses produced by the external loads due to backfilling and surface loads, but in addition must resist the stresses produced by the internal fluid pressure as well. Since 1939 completed studies[26, 27, 28] on the supporting strength of this kind of pipe under combined loads and pressures indicated an approximately parabolic relationship between the magnitude of the external load and the internal pressure which is required to cause failure of the pipe. The external loads may be those for any loading condition, although usually it will be most convenient to test the pipe in three-edge bearings and then apply the proper strength ratio or load factor to calculate the equivalent supporting strength under any particular field condition of installation.

[25] "Supporting Strength of Concrete-Incased Clay Pipe," by W. J. Schlick, *Bulletin No. 93*, Iowa Eng. Experiment Station, Ames, Iowa, 1929.

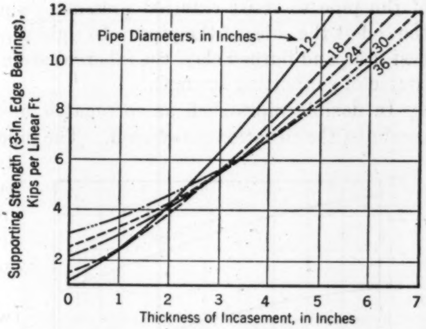

FIG. 15.—SUPPORTING STRENGTHS (AT 70° F) OF STANDARD A.S.T.M. SEWER PIPE, INCASED IN 3,000-LB CONCERTE

Safe design values of the strength ratio have been determined for cast-iron pit-cast pipes installed under six different field conditions, as follows:

Condition	Trench	Backfill
A	Flat bottom	Untamped
B	Flat bottom	Firmly tamped under and around pipe
C	Pipe laid on blocks	Untamped
D	Pipe laid on blocks	Firmly tamped under and around pipe
E	Shaped bottom	Untamped
F	Shaped bottom	Firmly tamped under and around pipe

Quoting W. J. Schlick,[29] M. ASCE:

> "The safe design values of the strength ratio for these field conditions are shown for nominal pipe diameters from 4″ to 60″ [in Fig. 16]. The values shown in this figure have been adopted by Sectional Committee A21 of the American Standards Association, with whom this research work was conducted on a cooperative basis. They are based directly upon the experimental results although those adopted for conditions B and F have been reduced from the experimental values in the belief that the tamped earth beddings in the laboratory tests were more carefully made and therefore more effective than is safe to assume for field conditions."

Flexible Pipes

In general, it may be stated that underground conduits derive their capacity to support the earth above them from two sources: First, the inherent strength of the pipe to resist external pressures; and, second, the lateral pressure of the soil at the sides of the pipe. In rigid pipes such as those made of concrete, cast iron, and burned clay, the inherent strength of the pipe is the predominant source of supporting strength.

In flexible pipes such as corrugated metal culverts and thin-walled steel conduits, the situation is reversed. The pipe itself has relatively little inherent strength, and a large part of its capability of supporting vertical load must be derived from the passive pressures induced as the sides move outward against the soil.

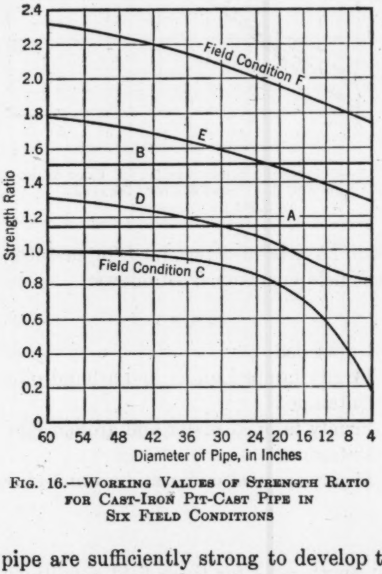

Fig. 16.—Working Values of Strength Ratio for Cast-Iron Pit-Cast Pipe in Six Field Conditions

Another major difference between the rigid types of conduits and the flexible types is that the latter fail by deflection rather than by rupture of the pipe walls, as do the former. The action of a flexible pipe under embankment loading is one of large deflection change unaccompanied by rupture of the pipe wall; and, for this reason, the design of the flexible types of conduits should be based upon the deflection of the ring rather than upon stress in the side walls as in the case of the rigid types. This statement is predicated on the assumption that the longitudinal joints in the flexible pipe are sufficiently strong to develop the pipe wall as a continuous ring.

Laboratory tests[30] of short sections of corrugated metal culvert pipes of various diameters and gages of metal have indicated that the elastic theory of flexure as applied to thin rings by Claude W. L. Filkins and Edwin J. Fort,[31] M. ASCE, is applicable to these flexible conduits, even if the deflections and changes in radius of the elastic ring are relatively very large. Therefore, if the loads and pressures acting on a flexible pipe are known or can be assumed confidently, the deflection of the pipe can be determined by this theory within the elastic limit of the pipe material. Typical results of laboratory measurements of diameter changes under three-edge loading conditions are shown in Fig. 17.

[30] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Iowa Eng. Experiment Station, Ames, Iowa, 1941.

[31] "Stresses and Deflections in Circular Rings Under Various Conditions of Loading," by Claude W. L. Filkins and Edwin J. Fort, *Transactions*, Assn. of Civ. Engrs. of Cornell Univ., Ithaca, N. Y., Vol. IV, 1896, pp. 99–112.

A number of field loading experiments on corrugated metal pipe culverts, in which the vertical and lateral pressures and the deflections of the pipes were measured have led to the following conclusions regarding soil pressures and deflections of flexible conduits:

1. The vertical load may be determined by Dean Marston's theory of loads on conduits; it is distributed approximately uniformly over the breadth of the pipe.

2. The vertical reaction is equal to the vertical load and is distributed approximately uniformly over the width of bedding of the pipe.

3. The horizontal pressure on each side of the pipe is distributed parabolically over the middle of 100° of the pipe, and the maximum unit pressure (which occurs at the ends of the horizontal diameter of the pipe) is equal to the modulus of passive resistance of the fill material multiplied by one half of the horizontal deflection of the pipe.

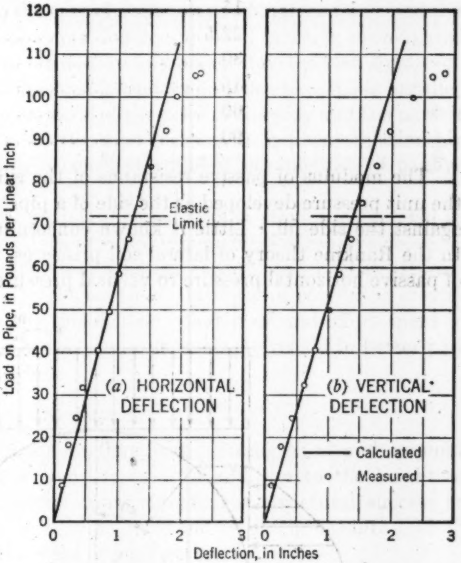

FIG. 17.—LOAD-DEFLECTION DIAGRAMS FOR A 42-IN. CORRUGATED CULVERT PIPE ON THREE-EDGE BEARINGS

4. The pipe may continue to deform for some period of time after the maximum fill load has developed, due to continuing deformation of the side fills under lateral pressure. The assumed loading is shown graphically[32] in Fig. 18. The expression for horizontal deflection resulting from these hypotheses is:

$$\Delta = F_d \frac{F_k W_c r^3}{E I + 0.061 \epsilon r^4} \quad \dots\dots\dots\dots\dots\dots (15)$$

in which Δ is the horizontal deflection of the pipe, in inches; F_d is the deflection lag factor; F_k is a bedding constant, depending upon the bedding angle; W_c is the vertical load per unit length of the pipe, in pounds per inch; r is the mean radius of the pipe, in inches; E is the modulus of elasticity of the pipe material, in inches; I is the moment of inertia per unit length of cross section of pipe wall, in inches^4 per inch; and ϵ is the modulus of passive resistance of the enveloping soil, in pounds per square inch per inch.

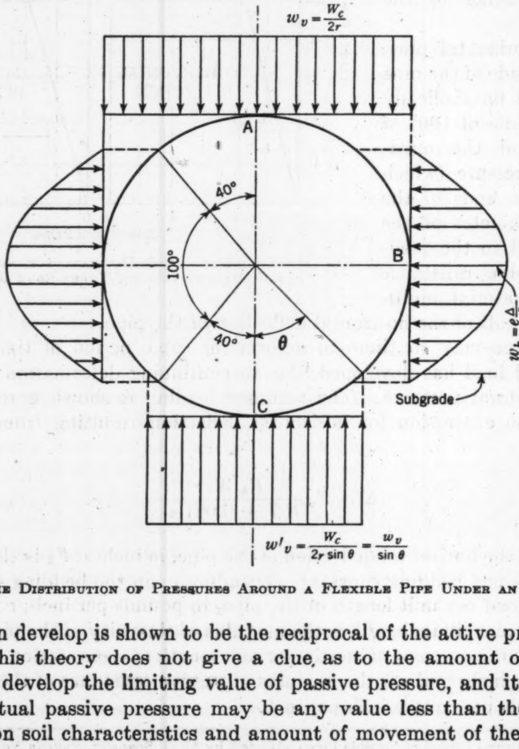
---

[32] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Iowa Eng. Experiment Station, Ames, Iowa, 1941, p. 26, Fig. 17.

Values of the bedding constant, F_k, for various values of the bedding angle are:

Degrees	Bedding constant, F_k
0	0.110
15	0.108
22.5	0.105
30	0.102
45	0.096
60	0.090
90	0.083

The modulus of passive resistance of the side filling material is defined as the unit pressure developed as the side of a pipe moves outward a unit distance against the side fill. Little is known concerning the nature of this modulus. In the Rankine theory of lateral soil pressures, the limiting value of the ratio of passive horizontal pressure to vertical pressure which a granular soil without cohesion can develop is shown to be the reciprocal of the active pressure ratio. However, this theory does not give a clue as to the amount of movement required to develop the limiting value of passive pressure, and it would seem that the actual passive pressure may be any value less than the maximum, depending on soil characteristics and amount of movement of the sides of the pipe.



$w_v = \frac{W_c}{2r}$

FIG. 18.—THE DISTRIBUTION OF PRESSURES AROUND A FLEXIBLE PIPE UNDER AN EARTH FILL

Several facts concerning the value of the modulus of passive resistance of side fills adjacent to experimental flexible culvert pipes have been observed. First, this modulus varies widely with soil characteristics. Measurements have indicated a value for a gravel material approximately three times as great as for a loam material. Also in the case of a silty clay soil material, the modulus of passive resistance was approximately doubled by hand tamping as compared to the value for the same material in a relatively loose, shovel-placed condition. The second fact that has been observed is that when a flexible pipe is installed without struts the horizontal movement of the sides of the pipe and the passive resistance pressure at the sides of the pipe increase in a linear relationship with the height of fill, indicating a constant value of the modulus of passive resistance pressure as the height of fill is built up.

Field observations of several flexible pipe culverts in service, completed in 1946, have indicated that the settlement ratio, the modulus of passive pressure, and the deflection lag factor are all intimately interrelated. These studies also indicate that the structural performance of this type of conduit is greatly influenced by the character of the side fills and that time and effort spent in compacting the soil at the sides of the pipe will be amply repaid in better performance of the structure as a whole.

SUMMARY

Dean Marston's theory of loads and supporting strengths of underground conduits serves to highlight the many factors, in addition to the height of fill and the conduit strength, which contribute to the structural success or failure of such structures. It is a guide to sound design procedure and to good construction practice in this field of engineering.

For example, the theoretical analysis of ditch conduits indicates that the width of ditch has a marked effect upon the load which the conduit must carry and field observations tend to verify this indication. Good practice, therefore, requires that the design width of ditch be held to a practical minimum value and that this design width be adhered to in construction.

In the case of projecting conduits, such factors as the projection ratio and the settlement ratio have an important bearing on the load which the soil overburden produces on the structure, and knowledge of the characteristics of the site which influence these ratios is necessary before an accurate load analysis can be made. These characteristics are concealed to a very great extent when an embankment is built so that it is usually not possible to determine the load on a projecting conduit after it is completed merely by observing the height of fill and the character of the soil covering. Likewise, the bedding characteristics of a conduit, and the conditions governing the development of lateral earth pressures on the structure, both of which influence its field supporting strength, cannot be determined readily after construction is completed. It is not feasible, therefore, to base one's judgment of the safe height of fill which can be constructed over a given type of conduit in one location, on the height of fill which the same type of conduit may be successfully supporting in another location, unless it is known that all factors which influence load and supporting strength are the same in both locations.

APPENDIX. NOTATION

The following letter symbols, adopted for use in this paper and in its discussion, conform essentially with ASCE *Manual of Engineering Practice No. 22*, "Soil Mechanics Nomenclature":

a = an area element (see Fig. 10);
b = horizontal breadth or width, with subscripts denoting:
    c = conduit;
    d = width of ditch at top of conduit;
C = load coefficient, with subscripts denoting:
    c = projecting conduits;
    d = ditch conduits;
    t = load on the underground conduit transmitted by concentrated load on the surface;
E = modulus of elasticity of the pipe material; Young's modulus;
E_f = modulus of deformation of the filling material;
e = base of natural logarithms;
F = factor, with subscripts denoting:
    d = deflection lag;
    i = impact;
    k = bedding constant;
    p = load;
H = height of fill, with subscripts denoting:
    c = height to ground surface above top of conduit;
    e = height to the plane of equal settlement from the top of a pipe; this is the "height of equal settlement";
    p = height to top of backfill from any horizontal plane;
    s = slant height from the center of an elementary area in Fig. 10 to the point of application of a load;
I = moment of inertia per unit length of cross section of pipe wall;
K = ratio of lateral pressure at a point to vertical pressure; hydrostatic pressure ratio;
L = longitudinal length of the conduit;
P = total vertical pressure on a horizontal plane in the backfill, or within the interior prism:
    P_0 = the pressure of a concentrated load at the surface;
    P_z = total at any point distant z from the surface;
R = supporting strength or resistance of a pipe, with subscripts denoting:
    c = strength in any stated loading condition;
    eb = strength for the case of three-edge bearing;
r = mean radius of the pipe;
W = weight or total load, with subscripts denoting:
    c = load on an underground conduit;
    P = load transmitted by a concentrated surface force;
w = load per unit area, with subscripts denoting:

h = horizontal unit load;

v = vertical unit load;

X = a parameter symbol, denoting by subscripts a function of:

A = the area of the vertical projection of the pipe on which the active lateral pressure of the fill material acts;

P = the distribution of the vertical load and vertical reaction; When the load and reaction situation (Eq. 14*b*) causes the pipe to crack first at the top the parameter symbol is primed, thus: X';

y = vertical deflection or vertical settlement, corresponding to Δ = horizontal deflection, the subscripts denoting:

c = deflection of the conduit or the shortening of its vertical dimension;

f = settlement of the flow line of the conduit;

g = settlement of embankment subgrade adjacent to the conduit;

m = deformation of the filling material adjacent to the conduit within the height $\rho\, b_e$;

z = distances along the z-axis, also vertical distance from the surface to a given point;

α = a substitution symbol involving b_d introduced to simplify typography (see Eq. 2*a*);

β = a substitution symbol involving b_c introduced to simplify typography (see Eq. 5*c*);

γ = unit weight of filling material;

Δ = horizontal deflection;

δ = a settlement ratio defined by Eq. 4*a*;

ϵ = modulus of passive resistance of the enveloping soil;

θ = angle formed with the vertical by the radius vector from the point of application of the surface load to the point considered (Eq. 13), also the angle to the intersection of a pipe trench with the ground surface (Fig. 18);

κ_t = ratio of total lateral pressure to total vertical load;

μ = coefficient of internal friction between fill materials; μ' = coefficient of sliding friction between the fill materials and the sides of the ditch;

ν = concentration factor or dispersion factor; a disposable parameter; and

ρ = projection ratio; ratio of the vertical distance between the top of the conduit and the natural ground surface adjacent to the conduit, to b_c; the conduit projection is $\rho\, b_c$.

DISCUSSION

Wilson V. Binger,[33] **Assoc. M. ASCE.**—Verification of the Marston theory of loads on underground conduits is given by Professor Spangler for heights of fill up to 20 ft (see Fig. 9). The writer believes it will be of value to present similar data, with which he is familiar, for heights up to 50 ft.

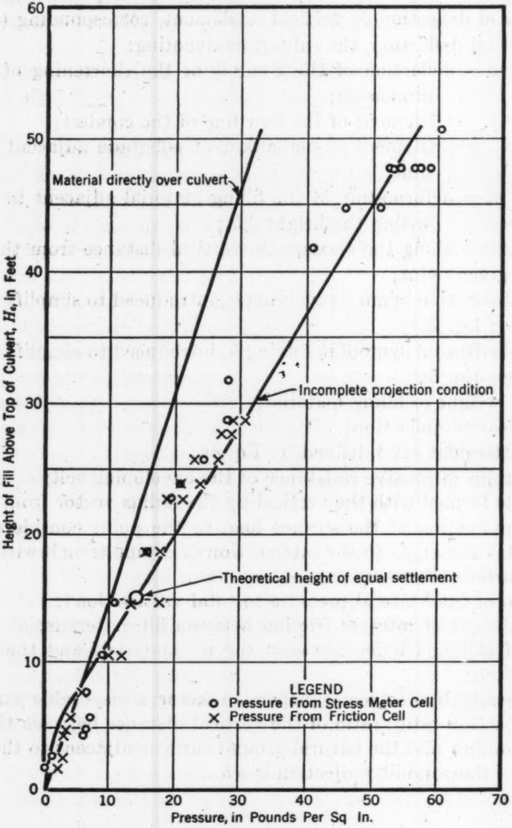

Fig. 19.—Pressures Versus Height of Fill Over Culvert for Full Load and for Incomplete Projection Condition

Relocation of a section of the Panama Railroad during the Panama Canal Third Locks Project involved construction of a reinforced concrete box culvert under a fill approximately 50 ft high. This culvert, built in early 1942, was 9 ft wide, 10 ft 10 in. high, and approximately 240 ft long. It was founded partly on weathered rock; and, where soft organic clay unsuitable as a foundation had been removed to depths of from 7 ft to 10 ft, on a traffic-compacted backfill of residual clay. Pressure cells of two different types were installed on this culvert during its construction in order to determine the relative efficiency of each. This work was carried out as a first step in determining the proper type of device for use in measuring the earth pressures against the structures of the Third Locks Project.

---

[33] Chf., Soils and Geology Branch, Missouri River Div., Corps of Engrs., Omaha, Nebr.

Two types of pressure-measuring devices were used. The first, three of which were installed, was the friction type developed by Professor W. C. Huntington, M. ASCE, whereas the second, two of which were installed, was the stress-meter type developed by Professor Roy Carlson, Assoc. M. ASCE. All cells were calibrated in the laboratory before installation in the culvert. One friction cell and one stress-meter cell were mounted in the wall of the culvert in order to measure side pressures; the results of these measurements are not within the scope of this discussion. The other two friction cells and one stress-meter cell were installed in the roof of the culvert under the center of the fill. After completion of the culvert, a 2-ft layer of red-brown clay common to the region was hand placed over the cells and compacted with wooden hand tampers. The rest of the fill, principally a fine-grained sandstone, was then placed and compacted in 2-ft layers by the normal traffic of three 12-cu yd scrapers and a 12-ton bulldozer.

Readings were taken on all cells once a day until the fill had reached its maximum height and the readings had become fairly constant. Above a fill height of 28.6 ft, the load on the friction cells exceeded the capacity of the spring balance used to determine the pressure. With the aid of a larger pulley to increase the torque applied to the cell, readings were continued but did not prove consistent. To determine the weight of the fill which was placed over the culvert, density samples were taken for each 2-ft layer as construction would permit. From these tests the average density of each layer was obtained and the pressure of the fill directly over the culvert determined.

Fig. 19 shows the pressure on the culvert plotted against the height of the fill, in a graph similar to Fig. 9. Computed pressures were determined for the "incomplete projection condition" by Eqs. 6*a*, 8, and 10, with the following constants and assumptions: $K \mu = 0.19$; $\delta = 0.5$; $\rho = 1.2$; $\gamma = 93$ lb per cu ft; and $b_c = 9$ ft.

Jacob Feld,[34] **M. ASCE.**—The casual reader of this paper might reach the conclusion that the problem of underground conduits was studied solely at the Iowa State College Experimental Station in Ames. The writer does not desire, in any way, to reduce the credit for the continuous attack on this problem, which was initiated in 1910 by Anson Marston, Hon. M. ASCE, which was aided from the early 1920's by W. J. Schlick, M. ASCE, and which has been continued since 1926 by the author. This paper is an authoritative summary of consistent practical results obtained from a program of research on one problem under a continuity of direction.

---

[34] Cons. Engr., New York, N. Y.

However, reference should be made to similar work performed during the same period. From 1923 to 1928, for instance, the experimental work conducted at the University of North Carolina in Chapel Hill consisted of full-size load measurements, together with the Goldbeck cell readings on culvert pipe of various materials (including pipe filled with concrete), which were under 50% projection and full projection conditions.[35] In 1923, William Cain sent copies of notes on the theoretical determination of vertical pressures (and, later, notes on stresses and deflections of pipe culverts) to several fellow workers in the field of soil mechanics. In a modified form, these notes were attached to the experimental report as Appendix I and Appendix II.[36] Mention should also be made of George L. Fowler's test on the load-carrying capacity of, and expected loads on, corrugated iron culvert pipe.

From a practical standpoint, construction methods have changed so radically from 1910 (or even 1923) to 1947 that many of the problems have become purely academic. To cite a few examples: Pipe trenches are seldom dug by hand, and back-hoe trenchers are used for depths as great as 25 ft in all types of soil. Trenches can be provided with substantially vertical sides and with fairly uniform widths, thus eliminating the benched hand-dug deep trench of greater widths at the surface, or the ragged clamshell excavation of indefinite width and shape. The ditch type, shown in Fig. 1(*a*), can be provided economically in widths from 20 in. to 54 in., with the added correction that the ditch can be backfilled better than "with relatively loose earth." In one airport project, in the clay fill area, the backfilling of the drainage trenches was so well done that they became relatively hard lines in the subgrade and showed up prominently during the final subbase rolling.

In regard to the projecting type of conduit (Fig. 1(*b*)), the use of heavy equipment to place and compact fills with the probability of damage and displacement of pipe laid on the natural ground makes it much more economical to place the fills first, and to trench through them for the drainage lines afterward. This type of installation is rapidly disappearing from the scene.

A modification of "first class" bedding shown in Fig. 13(*c*) is becoming a common practice because of the reduction of scarce hand labor. Excavation is made to the depths required for a concrete cradle, allowing some 4 in. below the pipe. The trench bottom is then lined with a layer of sand or other granular material, into which the pipe is bedded. The sand and the backfill required to cover the pipe by at least 1 ft (or by a depth equal to the pipe diameter) are tamped with special care. The load factor of such bedding should be close to 2.0, which strength value can be obtained without the experienced labor necessary to shape the ditch bottom, and without bringing in different labor trades to form and concrete a cradle base.

For combining the authoritative data covering all cases of design for underground conduits, the author deserves the thanks of the profession, which will look to this paper as the standard reference on drainage and piping installed below ground levels by open excavation methods.

[35] "Earth Pressure Experiments on Culvert Pipe," by G. M. Braune, William Cain, and H. F. Janda, *Public Roads*, November, 1929, pp. 153–165.

[36] *Ibid.*, pp. 165–175.

ZDENĚK BAŽANT, JR.,[37] **ESQ.**—In this interesting review of the test results obtained at the Iowa Engineering Experiment Station at Ames, the author states that rigid circular pipes of reinforced concrete are difficult to analyze by the principles of mechanics. The writer's opinion differs on this point, because he has used this type of analysis for the design of reinforced concrete pipes since 1944 with good results.

For ditch conduits the author uses a design load factor (under the heading, "The Supporting Strength of Underground Conduits") "* * * which is defined as the ratio of the strength of a pipe under any stated condition of loading to its three-edge bearing test strength." For concrete cradle (under the heading, "Ditch Conduit Beddings") he gives the load factor values varying from "2.2 to 3.4." The designer has a choice within these broad limits, but elsewhere he can find more precise data and can determine different load factors for various dimensions of cradles.[21]

If a form of cradle is designed for which values have not been published, the empirical load factor is not known; however, it can be calculated theoretically. The pipe is considered a circular arch fixed into the cradle. In the writer's opinion it is possible to use this method of calculation for all forms of cradles and to eliminate the empirical load factor completely. A comparison can be made of the accuracy of this assumption for the dimensions of the cradles tested.[21] As an example for comparison, pipes 24 in. in diameter have been chosen. In the Iowa tests the pipes were tested with a 120° upper sand bearing, which causes uniform load. Theoretical representation of this load on a circular arch is shown in Fig. 20.

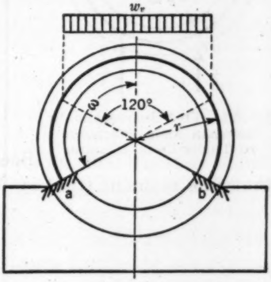

FIG. 20.—PIPE CONSIDERED AS CIRCULAR ARCH FIXED INTO CONCRETE CRADLE

The maximum moment occurs at points a and b, where the first cracks occur and

$$M_a = M_b = M_e - H\,(r\cos\omega - t_o) - C = n_1\,w_v\,r^2 \ldots\ldots\ldots (16)$$

in which

$$M_e = -\,w_v\,r^2\,\frac{\sqrt{3}}{2}\left(\sin\omega - \frac{\sqrt{3}}{4}\right) \ldots\ldots\ldots\ldots\ldots (17)$$

$$H = -\,w_v\,r^2 \; \frac{r\,\frac{\sqrt{3}}{2}\left(\sin^2\omega - \frac{\sqrt{3}}{2}\sin\omega + \frac{1}{4}\right) + t_o\left(\sqrt{3}\cos\omega + \frac{3}{4}\,\omega - \frac{5\,\pi}{12} - \frac{3\,\sqrt{3}}{8}\right)}{r^2\,\omega + r^2\sin\omega\cos\omega - 4\,t_o\,r\sin\omega + 2\,t_o^2\,\omega} \ldots (18)$$

$$t_o = \frac{r\sin\omega}{\omega} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

---

[37] Associate Prof. of Foundations, Univ. of Technical Sciences, Prague, Czechoslovakia.

and

$$C = -\frac{w_v r^2}{2\omega}\left[\sqrt{3}\cos\omega - \frac{\sqrt{3}}{2}\left(\omega - \frac{\pi}{3}\right) + \frac{\pi}{6} - \frac{\sqrt{3}}{8} + \frac{\sqrt{3}}{2}\right] \ldots (20)$$

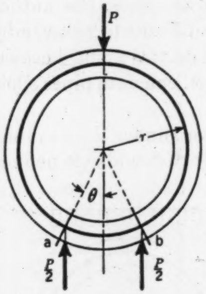

FIG. 21.—PIPE CONSIDERED AS CIRCULAR ARCH SUBJECTED TO THREE-EDGE BEARING

For three-edge bearing (Fig. 21),

$$M'_a = M'_b = \frac{P\,r}{2\,\pi}\left[\cos\theta - (\pi - \theta)\sin\theta + 1\right] = n_2\,P\,r \ldots\ldots (21)$$

From Eqs. 16 and 21, in which n_1 and n_2 are absolute numbers for definite ω and θ,

$$F_p = \frac{w_v\,r\,\sqrt{3}}{P} = \frac{\dfrac{M_a\,\sqrt{3}}{n_1\,r}}{\dfrac{M'_a}{n_2\,r}} \ldots\ldots\ldots (22a)$$

Because the pipe cracks occur in both cases under the same moment (that is, $M_a = M'_a$),

$$F_p = \frac{n_2\,\sqrt{3}}{n_1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22b)$$

Numerical results are given in Table 1. The distance ab for three-edge bearing is assumed to be 3 in., thus making $\theta = 5° 44'$. The load factor is expressed for ultimate load, from which the allowable load is obtained by applying a safety factor. The load factor computed for the first crack cannot be used for the comparison, because it is not proportional to the moments obtained by analysis. However, if Table 1 proves the usefulness of the writer's methods, simplifications are made by neglecting the normal thrust, the effect

TABLE 1.—COMPARISON OF TEST RESULTS WITH THEORETICAL CALCULATIONS FOR 24-IN. DIAMETER PIPES

Type of cradle[a]	Thickness of upper part of cradle	ω	n_1[b]	n_2[b]	LOAD FACTOR, F_p	
					Observed for ultimate load	Calculated by Eq. 22b
(1)	(2)	(3)	(4)	(5)	(6)	(7)
4....	$\frac{b_s}{8}$	138° 35'	0.159	0.269	2.74	2.93
5....	$\frac{b_s}{4}$	120° 0'	0.131	0.269	3.25	3.56
8....	$\frac{b_s}{2}$	90° 0'	0.101	0.269	4.20	4.62

[a] "Concrete Cradles for Large Pipe Conduits," by W. J. Schlick and James W. Johnson, *Bulletin No. 80*, Iowa Eng. Experiment Station, Ames, Iowa, 1926, p. 39. [b] Absolute numbers, neglecting sign.

of thickness of pipe, the influence of dead load of pipe, and the elastic fixing of pipe into the cradle.

Thus, the circular arch concept can be used for designing pipes on concrete cradles. Despite the elaborate appearance of the computation, the design is actually simple, because the n-coefficients can be calculated for each angle ω and for each type of load.

Security against the first crack is obtained with the writer's method by using a safety factor fixed experimentally for each kind of pipe so that tension stresses do not exceed the selected allowable value. Further investigation is needed to ascertain the exact manner in which the rigid cradle causes concentration of loads on the pipe. It is quite possible that it increases the load coefficient C. However, despite the present lack of data the writer considers this effect negligible.

ANSON MARSTON,[38] PAST-PRESIDENT AND HON. M. ASCE.—In this paper Professor Spangler has made a good, concise presentation of the writer's theory of external loads on conduits under fill materials. In the paragraph containing Eqs. 4, he quotes the writer as defining[4,6] "* * * the various settlements, y, as the * * * increments due to the addition at or above the height of equal settlement of any [the same for all] incremental uniform layer of fill materials." This definition is so worded because the calculation coefficient C_e in the load equation (Eq. 8) for projection conduits contains the value at height H_e of the coefficient C_e in Eq. 6b—thus providing for all fill loads (including their time lags) due to settlements (also including time lags) below H_e. To clarify its character further the plane at H_e in the writer's theory should be termed the "plane of equal additional settlements." It should be noted that all inequalities in the settlements of fill materials in the vertical prism over the culvert and those in the masses of "alongside" embankment materials, which develop during the construction work up to the height H_e, are leveled up in grading.

Following Eq. 8 in the paper, the author states two conditions that are used in deriving the writer's equation for evaluating H_e:

> "*a*. The internal friction in the embankment materials distributes the infinitely small increments or decrements of pressure from shear into the interior prism [that over the culvert] below the plane of equal [additional] settlement in such manner that their effect on settlement may be assumed to be substantially the same as for uniform vertical pressure; and
>
> "*b*. The internal friction in the embankment materials distributes the infinitely small decrements or increments of pressure from shear into the exterior prism so completely that their effect on settlement may be neglected" (but the "alongside" embankment fill materials are just masses of indefinite horizontal extent, not distinct vertical prisms of determinable—or assumable—width).

In the foregoing quotations the interpolations in brackets and parentheses are the writer's. Assumption *a* is the same as that previously found to be true (for ditch conduits) for all values of b_d investigated.[2,3] The late Milo S. Ketchum,[39] Hon. M. ASCE, verified it for distances of at least 40 ft between the walls of bins filled with granular materials. In each case, the horizontal distance over which uniform pressure due to shear is transmitted is that between two vertical planes, one on each side, along which slippage occurs because of settlement. In the cases of ditch conduits and culverts, the planes are those of the two sides of the vertical prism of fill materials overhead. For bins filled with granular materials the two planes of slippage are the side walls of the bins.

---

[38] Dean Emeritus of Eng., Iowa State College, Ames, Iowa.

[39] "Design of Walls, Bins and Grain Elevators," by Milo S. Ketchum, McGraw-Hill Book Co., Inc., New York, N. Y., 3d Ed., 1919, pp. 310–311.

In reality, assumption *b* is the same as assumption *a*, but on each "alongside" there is no definite, opposite, vertical plane of settlement slippage in a typical embankment to stop the uniform distribution of pressure caused by the shear, due to the addition of the embankment materials above H_e before it has spread so widely as to have only negligible effect on settlement.

Concerning assumption *b*, the writer stated, in 1922,[4] in announcing the discovery of the "plane of equal additional settlement":

> "The only possible real test of the reliability of the new theory of loads on culverts from embankment materials (as proposed above) is comparison of the theoretical loads with the loads actually weighed in carefully conducted experiments with culverts"

—and he proceeded to show extremely close agreements of the final weighed and theoretical loads on the culverts under the 20-ft top soil (1919–1920) embankment and the 16-ft sand and gravel (1922) embankment. After 1922 similar close agreement between weighed and theoretical loads has been found in nine more experiments at the Iowa Engineering Experiment Station (IEES) with different culverts under different embankments; and the correctness of the writer's theory has been so completely verified in addition by detailed field studies of more than five hundred culverts under highway and railway embankments, that it is entitled to be admitted unreservedly.

However, as stated by Professor Spangler in the text following Eq. 10, at least two possible modifications of the theory have been suggested. The most appealing of these is the one based on the assumption of a "plane of equal total settlements." This, as investigated by the author for the case of the IEES "permanent" concrete pipe culvert (constructed in 1927 and still under observation), gives different values for H_e for different values of H (beginning 5 ft too high as proved by the actual settlement measurements), and gives values for the culvert load 17% higher than that weighed at $H = 15$ ft and 11% higher than that computed for the writer's theory for $H = 73$ ft. This is not the method that Professor Spangler found (as stated, following Eq. 10) to give computed loads "* * * nearly the same as those obtained by Dean Marston's original analysis, being somewhat less for high values of $\frac{H_c}{b_c}$ and $\delta\,\rho$."

Any paper on the theory of culvert loads should include mention and discussion of the twelve culvert pipe load experiments made at the University of North Carolina at Chapel Hill, from 1924 to 1927, in two series.

First Series, 1924 to 1926.—Three tests were made with 30-in. cast-iron pipe sections (32 in. in outside diameter) projecting 50% above subgrade. In the first test, the embankment was of sand, 20 ft high; in the second test, the embankment was of clay, 14 ft high; and in the third it was of clay, 11 ft high, in which a ditch, 43 in. wide and 48 in. deep, was dug during construction directly over the pipe and then loosely refilled (copying a similar IEES experiment in 1920–1921 with a sand embankment). All embankments were kept covered by tarpaulins during construction "except during actual work on the fill or during pressure observations," and the clay embankments were rolled at each 1-ft layer above 3 ft, using a 4-ton roller. The first and second embankments were removed promptly on completion. The third was continued in place from February, 1925, to April, 1926. From August, 1925, the load decreased 33%, doubtless because of "* * * the drying and shrinking of the initially saturated clay, resulting from the summer's unusually low rainfall."[40] It then began a slow increase, which was still in progress when it was removed.

Second Series, 1926–1927.—In the second series of tests six 29-in. to 32-in. (inside diameter) pipe culverts (from 30.2 in. to 34 in. in outside diameters), and three 20-in. to 21-in. culverts (from 20 in. to 21.15 in. in outside diameters) were tested, successively (with 100% projection above subgrade), on the same load-weighing apparatus, under sand embankments 12 ft high above the culvert tops, which were kept covered by tarpaulins as for the first series. Each embankment was removed promptly on completion. The culvert pipes were, respectively, of thin, smooth iron, corrugated metal, steel tubes, cast-iron pipe, reinforced concrete pipe, and solid concrete plugs.

The final detailed report[35] on these tests was made by the late G. M. Braune and H. F. Janda, Members, ASCE, with appendices by the late William Cain,[36] M. ASCE, long eminent for retaining wall pressure and column-formula mathematics. The support and weighing arrangements for the North Carolina tests were quite different from those adopted in the IEES experiments cited in Professor Spangler's paper.

The pipes were all mounted direct, without any bedding beneath, on what was practically like a solid rock formation. During the second series bank construction, some fill materials worked under; but a central strip from 60° to 80° wide was left bare.[36] The weighing apparatus was housed in a reinforced concrete structure on solid rock, covered by a reinforced concrete slab extending 10 ft, 7 in. on each side of the vertical prism over the pipe. This made the values of y_g and y_f each equal to 0 in the settlement ratio formula—

$$\delta = \frac{(y_m + y_g) - (y_c + y_f)}{y_m} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

so that

$$\delta = 1 - \frac{y_c}{y_m} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Because they did not recognize that the curved, lower parts of their plotted load curves proved the existence of planes of equal additional settlements at some heights H_e above the tops of the pipes, or that there were any settlement ratios δ, the North Carolina investigations made no measurements or discussions of y_m, or any other embankment settlements except y_c.

---

[40] "Earth Pressure Experiments on Culvert Pipe," by G. M. Braune, William Cain, and H. F. Janda, *Public Roads*, November, 1929, p. 157.

The use of tarpaulins and the prompt removal of embankments eliminated the time load lags, which other experiments and field studies prove would have added from 15% to 30% to the recorded culvert loads in the North Carolina tests.

The writer has made a thorough restudy of the detailed results of the North Carolina culvert tests, and finds that, adding proper percentages for time load lags, using the known value 1.00 for δ in the cases of the solid concrete plugs, and semi-empiric values of δ for the other culverts, the North Carolina culvert test results conform closely to results calculated by the writer's theory.

Neither Dean Braune[35,41] nor Professor Cain finally derived a definite comprehensive culvert load theory from the North Carolina results, although both toyed considerably with Dean Braune's idea[42] that they confirmed

> "* * * the theory on culvert pipes, namely, that the pressures vary inversely as some power of the deflection of the pipe, and values of the ratio, *K*, have been obtained ranging between limits above and below unity."

A similar idea was stated in his final report. The "*K*" referred to was the ratio of the culvert load to the weight of the fill materials directly overhead. The idea that the culvert load might equal $K\ w\ b\ H$ was suggested by the writer in 1921 in his "First Progress Report," but was promptly abandoned by him in 1922, upon his discovery of the "plane of equal additional settlements."[4]

Professor Cain has stated[43]

> "All of the preceding results show that the deflection of the pipe is a leading factor in the theory of the vertical pressure actually exerted on the pipe"

and again[44]—"The value of *K* can only be obtained by experiment for a particular earth * * *."

GEORGE E. SHAFER,[45] ASSOC. M. ASCE.—This summary of valuable research on underground conduits should stimulate more practical use of the proved but too little accepted methods of determining the loads that drainage structures must withstand. For more than twenty years the writer has followed and helped disseminate the results of various research on culvert loads and design. Field experience during this period justified the feeling that much money has been wasted because engineers have not made use of the data available.

The writer had the pleasure of cooperating with Anson Marston, Past-President and Hon. M. ASCE, in the derivation and verification of the equations for "complete" and "incomplete" ditch condition discussed in the forepart of

Professor Spangler's paper. Referring to the section, "Flexible Pipes," the writer and his associates were perhaps the first to recognize that flexible pipes do not fail as soon as the metal is stressed beyond the elastic limit, but continue to function structurally until the deflection resulted in a change in shape to the extent of reversing the curvature in the top or bottom of the structure. If one agrees with the author that structural failure of corrugated metal structures is due to excessive deflection, the problem then is to determine a method of predicting deflection.

Referring to Fig. 22, a flexible pipe is in equilibrium when the inherent strength of the pipe, R_I, plus the side support, W_H (developed in the earth as passive pressure due to outward movement of the sides of the pipe), is equal to the vertical load, W_c, on the pipe and its accompanying reaction.

How much a pipe deflects depends on all three factors—the larger the values of R_I and W_H the smaller will be the vertical deflection, y_c, and the larger the value of W_c, the greater that deflection. Therefore,

$$y_c = f\left(\frac{W_c}{R_I + W_H}\right) \quad \text{(25)}$$

Eq. 15 is in this form and includes those three factors.

Prior research on the design of flexible structures resulted in an empirical equation for deflection. This research should be considered, so that the results of the two equations can be compared. In 1926, after it was fully recognized that flexible structures fail by change in shape (excessive deflection), the writer and his associates set out to determine: (1) The law of deflection, so that structural performance could be predicted, and (2) the maximum permissible deflection, so that some part of the maximum could be used as a safe design deflection.

As to the law of deflections, it was known that deflection would vary directly as some power of the fill height, H, and the diameter, D, and inversely as the thickness of metal, t. Thus,

$$y_c = k\,\frac{H^m D^n}{t^s} \quad \text{(26)}$$

Using the deflection data from the American Railway Engineering Association (A.R.E.A.) investigation,[46] wherein the deflections were accurately measured as the fill was slowly made (permitting partial settlement to take place), along with measurements taken on numerous large diameter, high fill, unstrutted structures under both highway and railroad service, the values of k, m, n, and s were determined.

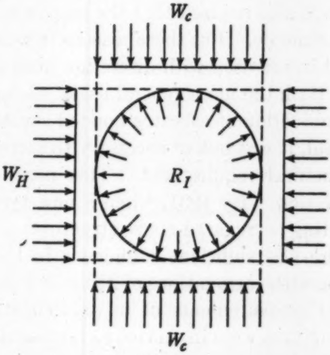

FIG. 22.—CONDUIT LOADING DIAGRAM

---

[46] "Culvert Load Determination," *Bulletin No. 284*, A.R.E.A., 1926.

The maximum deflection before failure occurred was readily determined by inspecting numerous, large diameter pipe installations with shallow cover of the "horse and buggy" days in California. With better roads and flatter grades, many of these structures, because of their good material and structural performance, were left in place and extended to permit the fill height to be increased. In some cases, the additional cover was sufficient to cause considerable additional deflection. The maximum recorded was 22% at a localized point. The average safe maximum deflection was determined as 20% of the vertical diameter. Using the conservative factor of safety of 4, the design deflection was established at 5%.

During the thirty years prior to 1926, when the empirical equation for riveted corrugated pipe was derived, the use of corrugated pipe was steadily increasing. By 1926 there were in use approximately 100,000,000 ft of average size corrugated pipe. With acceptance and use, gage tables based on experience had been compiled. Each large producer had his own gage table; however, all were practically the same. A new gage table based on the empirical equation using 5% deflection checked very closely with the old gage tables then in use, which were based on experience. Both were based on average installation conditions.

At that time, especially in certain parts of the United States, there were some questions regarding the durability of light gage, metal drainage structures. Gages that satisfied structural requirements often had to be increased because of durability requirements. For this reason, a gage table based solely on the equation was impractical. One of the objectives of the A.R.E.A. investigation[46] was a rational design for flexible pipe. The objective was never obtained; the empirical equation likewise fell short of the A.R.E.A. objective. It was also realized that the empirical equation was new and somewhat radical in principle. For these reasons it was not published. Like a new and untried tool it was used with discretion until its merit was established.

With the more general use of asphalt coated and paved invert pipe, plus the introduction of asbestos bonded sheets to insure adhesion of the asphalt to the metal, it was not so necessary to increase the gage of metal over and above the structural requirement. This permitted a more rigid use of the empirical equation. By 1931, when a new type of large diameter metal pipe made by bolting corrugated curve structural plates together in the field was introduced, there was sufficient confidence in the original empirical equation for riveted pipe with corrugations of $2\frac{2}{3}$ in. by $\frac{1}{2}$ in. so that a new equation was derived from field measurements of unstrutted structural plate pipe as soon as sufficient structures were in service to represent a good average. The equation was later revised as more installations were made and a new equation was derived for field strutted structures. These equations served to predict deflection. The bolted longitudinal seam was designed separately. Thousands of riveted and bolted structures have been designed on the basis of the empirical equations with almost faultless structural performance.

None of the equations have been published—not because they were considered trade secrets, but because the men who derived them knew their limitations.

The equations have just one application—to determine the required thickness of metal for a given diameter of pipe and height of cover or dead load. A tabular form giving the required gage for all structurally safe combinations of diameter and fill height is a gage table. Such tables, based on all three equations, have been available since the equations were derived. In some cases, light gages have been modified because of durability requirements; and, in others, to take care of various live load conditions. Since a gage table is far more convenient to use than an equation, the public or profession has not suffered because the exact equations were not known. The form of the equation and the fact that the gage tables were based on an empirical equation were published in 1937.[47]

When Professor Spangler proposed his investigation on the structural design of corrugated pipe various members of the industry took interest and cooperated. Those familiar with the empirical design hoped a rational design that would take into account installation conditions, type of soil, and other factors would result, so that, when possible, a more economical design could be used. When the investigation was completed and Eq. 15 was published, its use was investigated. The apparent weakness of the equation at that time necessitated the selection of the proper value of ϵ (modulus of passive resistance of the soil) to use for various soils. Later, the writer tried to use the equation to verify some live load tests and extend them into a gage table for airport loading. Again it was difficult to find the proper value of ϵ.

Perhaps the best way to discuss the application of Eq. 15 is to compare the permissible heights of cover for a range of diameters and gages with those obtained by the empirical equation. In Table 2, the heights of cover for Eq. 15 are based on $\Delta = 0.1\ r$, or 5% deflection, with $F_d = 1.5$, $F_k = 0.1$, $E = 30{,}000{,}000$, and $\epsilon = 20$. In general, the two equations agree fairly well for certain combinations of diameter and gage, but vary widely for other combinations. Eq. 15 does not give as much value to difference in gage as does the empirical equation and as is warranted by experience. It also permits higher fills for large diameters and light gages.

TABLE 2.—COMPARISON OF FILL HEIGHTS, IN FEET, OBTAINED BY EMPIRICAL EQUATION AND BY EQ. 15

Gage	24 IN. IN DIAMETER		48 IN. IN DIAMETER		72 IN. IN DIAMETER	
	Empirical	Eq. 15	Empirical	Eq. 15	Empirical	Eq. 15
16	26	24.2	7.2	15.9	3.5	21.7
12	62	36.6	18	17.4	8.8	22.2
8	140	53.7	39	19.6	18.5	22.2

Those engaged in the manufacture and distribution of flexible drainage structures see a definite need for a rational method of design. Not because design based on experience, such as the empirical equation, is wrong, but because it is possible that the full economy of flexible construction is not utilized in all cases. Furthermore, engineers prefer a rational approach to any problem, even though they use empirical methods in the solution of many problems. The rational approach also leads to a clearer understanding of the basic principles involved.

---

[47] "Handbook of Culvert and Drainage Practice," Armco Culvert Mfrs. Assn., Middletown, Ohio, 1937.

With this desire for a rational design in mind, the writer makes the following comments on each factor in Eq. 15 in the hope that by constructive criticism a solution will be evolved that will form the basis of all flexible conduit design.

Referring back to Eq. 25, the simplified form of Eq. 15, the writer has already implied agreement with the Marston theory for determining the vertical load on flexible structures. The part of Eq. 15 involving inherent strength R_I is based on the elastic theory of a closed ring. Referring to Fig. 23, this means that the load-deflection relation is a straight line and may coincide with the actual deflection curve from two-edge bearing tests for small deflections, or may deviate appreciably when the ring is stressed beyond the elastic limit.

Regardless of whether the load for two-edge bearing is determined from the equation,[30]

$$y_c = 0.149 \frac{P r^3}{E I} \quad \text{(27)}$$

or for the factor of Eq. 15 corresponding to R_I in Eq. 25, the result is the same, when F_d and F_k are assumed equal to 1.5 and 0.1, respectively. Therefore, the strength that is built into the pipe can be determined by Eq. 27. It is realized that Eq. 27 does not apply beyond the elastic limit of the metal, yet the comparison is made on the basis of 5% deflection, slightly beyond the limit, because that deflection has become standard practice in the design of corrugated metal pipe. In Table 3, values of P or W are given for 5% deflection and for a representative range of diameters and gages. The data on two-edge bearing loads does not include the Iowa tests, but does include unpublished data from several other investigations.

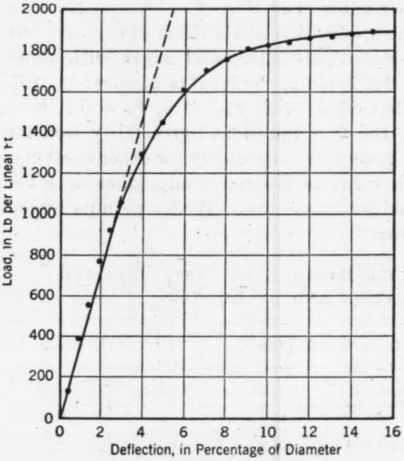

FIG. 23.—LOAD-DEFLECTION CURVE FOR 36-IN. DIAMETER CORRUGATED METAL PIPE (WALL THICKNESS, 0.112 IN.; ½-IN. CORRUGATIONS)

The loads determined by Eq. 27 for pipe 24 in. in diameter are approximately 2¼ times those from tests, and for pipe 72 in. in diameter they are approximately equal. If the effect of gage is considered regardless of diameter, Eq. 27 shows 8-gage pipe to be approximately 2¾ times stronger than 16-gage pipe, whereas the test data show this ratio to be approximately 4. These differences tend to affect the final design resulting from Eq. 15 by failing to show the full effect due to gage, regardless of diameter. This is a general comment regarding the use of Eq. 15 in actual practice. There are two other factors that should be considered with the foregoing data: (1) How much stronger is a flexible pipe in uniform vertical loading, as compared with concentrated loading, and (2) how much does uniform loading raise the elastic limit over that for concentrated loading?

TABLE 3.—COMPARISON OF INHERENT PIPE STRENGTHS[a] AS DETERMINED BY EQ. 27 AND BY ACTUAL TESTS

Gage	24 IN. IN DIAMETER		48 IN. IN DIAMETER		72 IN. IN DIAMETER	
	Iowa[b]	Test[c]	Iowa	Test	Iowa	Test
16	3,530	1,300	880	500	375	295
12	6,080	2,826	1,510	1,110	675	665
8	9,630	5,220	2,370	2,100	1,060	1,190

[a] Load in pounds per foot at 5% deflection. [b] Calculated by Eq. 27. [c] Determined by actual tests.

The usually accepted conversion factor for uniform loading from two-edge or three-edge bearing for rigid pipe is 1.5. According to the elastic theory, either by deflection of the ring or for moment in the ring, the factor should be approximately 2.0. It is the writer's opinion that a ratio of 2.0 is conservative.

Undoubtedly the elastic limit is higher (Fig. 23) for uniform loading as compared to concentrated loading, because of the more gradual and uniform change in shape or curvature under uniform load. Just how much the limit is raised is difficult to determine. If the change is small, then factors in Eq. 15 entering into inherent strength should be changed so that instead of being based on the elastic theory they would be based on actual concentrated load test data corrected for uniform vertical load. The average concentrated loads per foot of pipe to produce 5% deflection can be determined from the empirical equation,

$$P = \frac{4.825 \times 10^6 \, t^{1.40}}{D^{1.35}} \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

in which t is the thickness of the metal in inches (corrugations $2\frac{2}{3}$ in. by $\frac{1}{2}$ in.) and D is the pipe diameter in inches.

The side support part of Eq. 15 is based on certain assumptions, two of which will be discussed:

1. " * * * the horizontal pressure on the (side of a) pipe at any point bears a nearly constant relationship to the horizontal movement of the point."[30]

2. The distribution of passive pressure on the sides of the pipe is assumed symmetrical about the horizontal axis.

Considering first the assumption that horizontal pressure has a constant relationship to movement of the pipe sides, it is true that the Iowa data support this contention. Earlier research work[35] at the University of North Carolina

(Chapel Hill) seems to offer verification, except for very low fills. Referring to Fig. 24, the assumption is correct when the pressure and movement curves are straight lines. The pressure curves are straight lines, but the deflection is not a straight line for low fill heights. The deflection curve for Professor Spangler's first experiment has a similar characteristic.

If the pressure movement ratio is constant, the value of ϵ should be a constant for any soil characteristic and should not vary with fill height, or with the degree of rigidity of the pipe. There seems to be evidence that ϵ varies with fill height, or pipe rigidity—or both. Considering first the data supporting the claim that ϵ varies with fill height, in Fig. 24 the value of ϵ calculated using Eq. 15 varies from less than 30 for a 1-ft fill to more than 70 for a 12-ft fill. Similar values of ϵ for the 20-in. pipe in the same investigation are not as consistent as those plotted in Fig. 24 for the 30-in. pipe, but do vary from 28 for a 2-ft cover to 56 for an 8-ft cover.

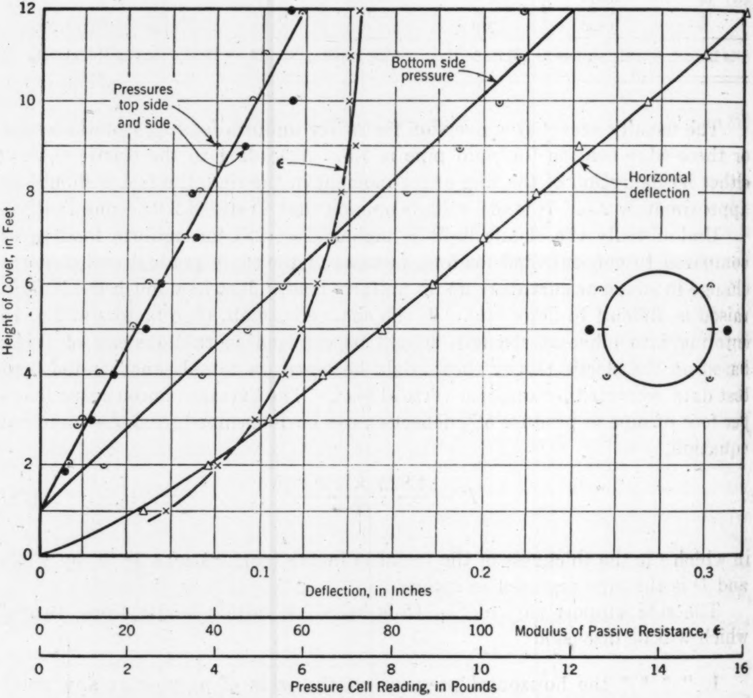

FIG. 24.—PRESSURE DEFLECTION DATA FROM UNIVERSITY OF NORTH CAROLINA STUDIES ON 30-IN. DIAMETER CORRUGATED METAL PIPE (WALL THICKNESS 0.108 IN.)

In 1928 accurate deflection measurements were taken on a rather large number of metal pipes installed in a new line of the Union Pacific Railroad Company. Original diameters were measured before backfilling, and final readings were taken nine years later. The number of unstrutted structures for which there was complete data (diameter, gage, average load, two-edge bearing strength at 5% deflection, and calculated ϵ according to Eq. 15) are shown in Table 4. Also included in Table 4 are similar data on two other investigations—those at the University of North Carolina[30] and the unpublished data on a live load test made by the writer. As further proof that ϵ may vary with the fill height, note how the average ϵ decreased with the average fill. The thirty-eight structures included in this investigation were installed under various conditions. For that reason, a comparison between individual structures is unwarranted, although a comparison between the averages for any pipe size seems permissible.

Referring to Table 4(*b*), the North Carolina tests were carefully made so that all pipes were installed and backfilled as nearly alike as possible. The three pipes listed are those that can be considered as flexible, the most flexible being a smooth pipe that had to be braced to hold the circular shape until the pipe was covered with sharp bank sand. The second and third pipes were progressively more rigid, as evidenced by the fact that the load factors (the percentage of load directly above the pipe actually carried by the pipe under 12-ft fill) were 61, 80, and 87, respectively. The values of ϵ, as calculated from Eq. 15 are 29, 45, and 85, respectively. These data tend to show that ϵ is a function of pipe rigidity. In Table 4(*c*) live load is the predominant load. All structures were carefully installed under the same installation conditions and loaded in the same manner. In this case ϵ varies with the pipe rigidity.

[a] Two-edge bearing strength at 5% deflection. [b] Smooth pipe, very flexible. [c] Unknown. [d] Steel tube.
[e] Average for three different live loads (4,635 lb, 8,700 lb, and 13,695 lb) per wheel.

It will be noted that the ratio of two-edge bearing strength at 5% deflection to ϵ is much more constant than the values of ϵ.

To summarize the data in Table 4, there is evidence to show that ϵ varies with pipe rigidity more than with fill height. Nevertheless, in the Union Pacific data (Table 4(a)) for 36-in., 10-gage pipe and the 48-in., 8-gage pipe, the rigidity is approximately the same, where average ϵ varies from 38 for an average fill of 17 ft to 18 for a fill of 5 ft. This, added to the variation in ϵ shown in Fig. 24 for the same pipe under varying fill heights, leads the writer to believe that ϵ may vary both with fill height and pipe rigidity.

It is unfortunate that all the pipes in the author's third experiment, the major part of his tests wherein conditions were identical, were of approximately the same rigidity. In selecting the size and gage of pipe to use, the aim was to keep them as flexible as possible within the limits of practicability. The inherent or two-edge bearing strengths of the four pipes in the third experiment, according to the writer's data, are shown in Table 5. Had the tested pipe been of widely different degrees of rigidity, the resulting data might have indicated that ϵ is a function of pipe rigidity.

48	14	685
60	1	815

[a] At 5% deflection.

Considering the second assumption, that the passive pressure on the sides of the pipe is symmetrical about the horizontal axis, the right half of Fig. 25 shows the development by Professor Spangler of a "witch-shaped" (witch of Agnesi) curve representing the locus of the horizontal movement of all points on the half circle, as the circle changes to an ellipse, their horizontal axes being coincident. In actual installations the inverts are coincident if there is no settlement. The left side of Fig. 25 shows the approximate shape of the locus based on coincident inverts and the same parabolic curve Professor Spangler used, which closely simulates the witch curve. The new center of the parabola is below the horizontal axis of the pipe by an amount equal to $y/2$. Actually, the difference in shape of the sides is not great, but the difference in shape combined with increased pressure below the horizontal could appreciably change the pressure diagram or composite loading.

Referring to the North Carolina data[35] for the 30-in. pipe, the pressure curves in Fig. 24, which were drawn to show the increase in pressure starting at a 1-ft fill, show the average pressure 45° above the horizontal "top side" to be approximately equal to the average side pressure. The average pressure 45° below the horizontal "bottom side" is more than twice the side pressure. This does not mean that the horizontal component of the measured pressure on the bottom side is greater than the horizontal component on the top side. It does, however, indicate that there can be a high pressure under the haunches of the pipe. Professor Spangler's composite loading, on which Eq. 15 is based, is shown on the right side of Fig. 26. The pressure at a point 45° below the horizontal, according to this loading, is very small. The data justified that assumption, but the writer believes that, had the pipe in the tests deflected more, or had the pipe been installed under 100% projection, the load diagram would be similar to that shown on the left side.

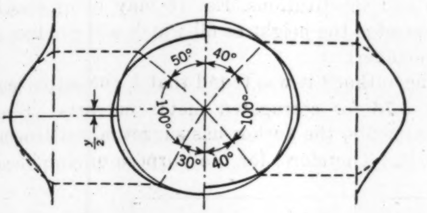

FIG. 25

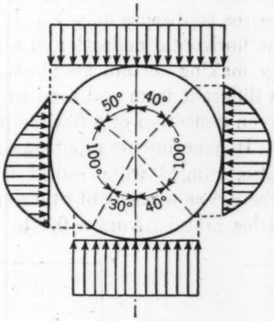

FIG. 26

As further proof of greater pressure under the haunches than that assumed by the author, the averages of all the pressure cell readings for the three flexible pipes in the 30-in. size tested at North Carolina[35] are shown in Fig. 27. These pressures are in pounds per square inch, and are the average increase in pressure due to any additional foot of fill from 0 ft to 12 ft. These data show that, with the exception of the top point, the greatest pressure is at the haunches, or 45° below the sides. Previously published data[48] show the haunches to be points of low pressure for low fills, with a trend toward more uniform pressures for higher fills. Such a revised pressure diagram would complicate the mathematical analysis but would, in the writer's opinion, more nearly fit field conditions for design deflections and the usual installation conditions, wherein the foundation is often quite yielding.

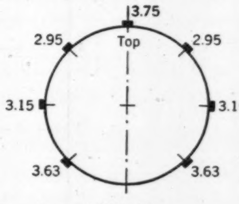

FIG. 27

To summarize, Professor Spangler's investigation and interpretation are steps in the right direction. It is unfortunate that the test pipes in the third experiment were all of virtually the same inherent strength. This, plus the fact that the range of diameters was small, apparently led to a solution that gives undue value to the side support factor for large diameters. Additional data are needed on working values of ϵ, especially under live load conditions. Whether there are sufficient test data available from all sources to revise Eq. 15, so that the results will be more consistent with actual practice, is unknown to the writer. It is emphasized again that the comments in this discussion are intended to be constructive and to encourage ideas and data that will eventually lead to a solution of a rather complex problem.

[48] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Iowa Eng. Experiment Station, Ames, Iowa, 1941, Figs. 24 and 25.

E. F. Kelley,[49] **Esq.**—This is an excellent summary of the results of the research work on underground conduits that has been carried on over a period of years by the Iowa Engineering Experiment Station at Ames, under the direction of Anson Marston, Past-President and Hon. M. ASCE. The writer desires to discuss only Eq. 15, which is presented as a method for computing the horizontal deflection of a flexible pipe, such as a corrugated metal culvert. By making certain assumptions and substitutions, Eq. 15 may be expressed in different form and used to determine the height of fill which will produce a given deflection of a flexible pipe culvert.

In experiments reported by the author[50] it was found that δ, the settlement ratio, ranged from -0.14 to -0.76 for corrugated metal culverts. Elsewhere,[51] as a result of other experiments, the author has suggested settlement ratios ranging from -0.4 to $+0.8$. Therefore, for the purpose of simplification and illustration it is considered sufficiently accurate to assume the settlement ratio equal to zero.

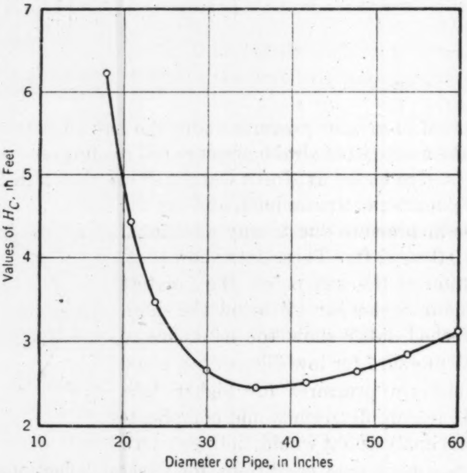

Fig. 28.—Relation Between Height of Fill, H_c, and Diameter of 16-Gage Corrugated Metal Pipe, Computed by Eq. 15 for a Deflection of 1% of the Pipe Diameter

It is apparent from Fig. 8 that when $\delta = 0$, $\delta\,\rho = 0$ and

$$C_c = \frac{H_c}{b_c} \qquad (29)$$

Also, with b_c expressed in feet and r in inches,

$$b_c = \frac{2\,r}{12}, \qquad (30)$$

[50] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Iowa Eng. Experiment Station, Ames, Iowa, 1941, p. 56.

[51] "Analysis of Loads and Supporting Strengths, and Principles of Design for Highway Culverts," by M. G. Spangler, *Proceedings*, Highway Research Board, National Research Council, Vol. 26, 1946, p. 198.

Substituting Eqs. 29 and 30 in Eq. 6*a*,

$$W_e = \frac{H_e \gamma r}{6} \qquad \text{(31)}$$

Thus, if W_e is expressed in pounds per linear foot of pipe, Eq. 15 may be reduced to the form,

$$H_e = \frac{72\,\Delta\,(E\,I + 0.061\,\epsilon\,r^4)}{F_d\,F_k\,\gamma\,r^4} \qquad \text{(32)}$$

Computed values of H_e for corrugated metal pipe having diameters from 18 in. to 60 in., inclusive, are shown in Fig. 28. For the purpose of the computation it was assumed that: $\Delta = 1\%$ of the pipe diameter $(= 0.02\,r)$; $E = 30{,}000{,}000$ lb per sq in.; $I = 0.001766$ in.^{4} per in., a value computed for 16-gage corrugated metal; $\epsilon = 20$ lb per sq in. per in.; $F_d = 1.5$; $F_k = 0.10$, corresponding to a bedding angle of about 35°; and $\gamma = 120$ lb per cu ft.

It is quite generally agreed that the deflection of corrugated metal pipes in service should be limited to a maximum of 5% of the pipe diameter. However, as the author has pointed out, Eq. 15 is applicable only within the elastic range of the pipe metal and it is not known that a 5% deflection of a pipe in service is within this range. It is known that, when corrugated metal pipe is subjected to the three-edge bearing test, a deflection of 5% is generally outside the elastic range, whereas a deflection of 1% is well within it. It is for this reason that, for purposes of illustration, the relatively small deflection of 1% of the pipe diameter has been selected.

For the smaller sizes of pipe Fig. 28 shows, as would be expected, that H_e decreases as the diameter of pipe increases. However, the minimum value of H_e is obtained for a diameter of 36 in.; thereafter the value of H_e increases with increases in the pipe diameter. Such results are unreasonable and cannot be accepted as correct.

There may be one or more reasons for the questionable results shown in Fig. 28. It may be that empirical Eq. 15, although applicable within the range of the author's experiments, may not have a general application. It may be also that the writer's assumption of a constant settlement ratio or a constant value of the modulus of passive resistance, or both, may be incorrect.

These questions, and the further question as to whether a deflection of a pipe in service of the order of 5% is within the elastic range of the pipe metal, lead to the conclusion that, on the basis of present knowledge, Eq. 15 cannot be accepted for use in the design of flexible pipe culverts.

BAILEY TREMPER,[52] ESQ.—In the State of Washington there are many pipe culverts installed under embankments of from 50 ft to 75 ft in height and in at least one case of 130 ft. The record of performance of these installations ostensibly should afford an excellent opportunity to check the theories of load and supporting strength as developed by Anson Marston, Past-President and Hon. M. ASCE, and reviewed by the author.

---

[52] Materials and Research Engr., Dept. of Highways, State of Washington, Olympia, Wash.

The difficulties in evaluating the theories in the light of such experience become apparent from a study of Fig. 8. The very wide range in loads shown for varying values of projection and settlement ratios requires that these conditions be known with considerable accuracy before proper evaluation can be made.

This discussion will be confined to observations of reinforced concrete pipe culverts in service with no intention of conveying the idea that other types have not been used satisfactorily. In many cases good records are available of the depth and width of trenches in which the culverts were installed. Such trenches, however, usually were dug in steeply sloping ground to one side of the watercourse. The depth varied greatly within short distances and, characteristically, was far from uniform on the two sides of the culvert. A good estimate of projection ratio can be assumed only within wide limits. No information is available on the settlement ratio at any site. Although the three-edge bearing strength of the pipe is known within reasonably close limits, the actual care used in bedding and backfilling, and hence the supporting strength of the pipe in place, can only be assumed.

With no good basis for estimating either the loads on the culverts or their supporting strength in place, definite conclusions as to the validity of the theory are not warranted. Based on careful study of the available data of construction and inspection of the condition of the culverts, it appears, however, that satisfactory service is being obtained under heights of fill greater than that indicated by the theory, and certainly greater than conservative design, based on the theory, would indicate.

The writer, therefore, believes that certain modifications of the theory with respect to loads under high fills and the performance of reinforced concrete pipe culverts are warranted. In so far as is known, the experimental work on which the theory of load is based did not involve fills greater than 20 ft in height. Therefore, data for the curves shown in Fig. 8 for higher fills seem to have been obtained by extrapolation. When the load on the culvert resulting from uniform increments of earth to the partly completed embankment is calculated by the Boussinesq equation, the result for high fills is less than is indicated by the curves in Fig. 8. For example, for embankments having a width at the top of 40 ft and side slopes of 1 on $1\frac{1}{2}$, the loads on the culvert, calculated by the Boussinesq method, are the following percentages of those derived from the curve $\delta\, p = 0$ in Fig. 8:

Fill height, in feet	%
30	95
50	90
70	87

The author has found that the Boussinesq solution is in good agreement with measured forces transmitted by concentrated live loads. Therefore, it should be valid for distributed dead loads.

In estimating the supporting strength of reinforced concrete pipe, the author treats it as a rigid structure, making no allowance for flexibility. Actually after the first crack is formed, the pipe begins to exhibit measurable flexibility. At some point, approximately that of a 0.01-in. crack, vertical and horizontal deformations increase rapidly with increasing load during the test. When installed as culverts, the passive pressure of the adjacent soil must afford considerable resistance to deformation and must therefore contribute appreciably to the supporting strength of the pipe. Flexibility in the pipe tends to reduce the settlement ratio as well, and thus reduces the load reaching the culvert from the superimposed embankment.

Some of the pipe in the culverts, to which reference has been made herein, was found to be cracked to widths of 0.01 in., or somewhat more, when examined a few years after construction. Subsequent inspections have revealed frequent cases of autogenous healing or apparent closing of the cracks. Rarely have cracks, when measured on a second inspection, been found to be of greater width than on the first. These findings lead to a belief that cracks in well-made reinforced concrete pipe culverts, when of the order of 0.01 in., are not harmful. A report published in 1947[53] indicates that serious corrosion of the reinforcement is extremely improbable.

It is suggested, therefore, that reinforced concrete pipe culverts be designed to the full estimated supporting strength of the pipe at a 0.01-in. crack, and that its flexibility beyond this point be considered as an adequate factor of safety. It is not intended to imply that ultimate strength requirements should be eliminated from specifications, as tests to ultimate strength are necessary to establish proper functioning of the reinforcement and capacity to withstand moderate deformation without undue structural damage.

Modern methods of compacting embankments appear to make it unnecessary to install culverts in trenches made for the sole purpose of reducing the projection ratio. Usually the density and strength of the embankment can be made greater than those of the soil in its original position. With proper attention to moisture control and compaction in the areas adjoining the culvert, more favorable conditions can be produced than in a dug trench. This is so because of less width, less settlement at the sides of the culvert, and better opportunity for good bedding. A condition approaching an imperfect ditch results from the usual restriction against heavy equipment passing over the culvert until the fill is a few feet above its top. The zone immediately above the culvert is therefore likely to be in relatively loose condition. The depth of the imperfect ditch, of course, can be increased when found desirable at little additional cost.

It is believed that designs of pipe culverts under assumed incomplete projection ratios are neither economical nor necessary. With reasonable requirements for compaction of embankments, and their adequate enforcement in the vicinity of the culvert, a condition should be obtainable such that the load on the pipe is less than, or does not exceed, that of the weight of the earth directly above it.

---

[53] "The Corrosion of Reinforcing Steel in Cracked Concrete," by Bailey Tremper, *Journal*, A.C.I., June, 1947, p. 1137.

M. G. Spangler,[54] M. ASCE.—The time and effort put forth in preparing this paper have been more than compensated for by the stimulating ideas which have been expressed by the various discussers. Of particular value are the data presented by Mr. Binger relative to the pressures measured on a concrete box culvert under a 50-ft fill on the Panama Railroad. The close correlation between the measured pressures and those indicated by the Marston theory when applied to the conditions of the installation serve, powerfully, to reinforce the confidence which engineers may place in the principles involved in the theoretical development.

Mr. Binger's data are significant for two reasons: First, they show the load produced by a fill two and one-half times higher than any previous fill for which loads have been measured; and, second, the fill was compacted by modern heavy equipment during construction.

Mr. Feld is entirely justified in referring to the researches on underground conduit loads which were conducted at the University of North Carolina in Chapel Hill. In preparing any paper the matter of scope becomes highly important and in this case it was decided to limit the paper to the work which had been done at Iowa State College in Ames. Dean Marston has made an exhaustive study of the reports covering the North Carolina experiments and has concluded that the measured loads in those tests conform closely to the results calculated by the Marston theory, as he has stated in his discussion.

It is difficult to subscribe to Mr. Feld's characterization of the problems discussed in the paper as purely academic. Although it is true, as everyone knows, that methods of earth handling and construction have undergone radical changes during the past quarter of a century, the principles of stress transfer embodied in the Marston theory are ageless and will be applicable many years hence when present-day construction methods become outmoded. The ditch conduit analysis may be applied with equal validity to a hand-dug or a machine-dug trench without reference to the slope or irregularity of the sides, provided the correct ditch-width factor is used in the analysis. If the backfill material is placed in the condition which Mr. Feld describes as "better" than relatively loose earth, considerable harm may result in that the loads on the pipe may be very greatly increased as compared to the loads under the more usual manner of backfilling. In the example cited where the backfills of drainage trenches became relatively hard lines in the subgrade, there is little doubt in the writer's mind but that the load at the base of the trench was relatively high, because the transferred shearing stresses would be additive to the weight of the backfill instead of subtractive as in the more usual case.

The method of constructing projecting conduits in trenches dug through compacted embankments has distinct advantages from the standpoint of loads produced on the structure, in addition to the advantages mentioned by Mr. Feld, since placing the pipes in ditches tends to cause the shear stress increments to act upward on the prism of material in the ditch, provided the backfill is loosely placed. The California Highway Department has developed methods of construction based on this principle which appear to be efficient in reducing loads on the pipes. These procedures, together with excellent bedding and backfilling practices, have permitted a substantial increase in safe heights of fill over drainage conduits under highways in that state. However, it seems doubtful whether the practice of building an embankment first and then trenching through it to construct a drainage line can ever be widely applicable, inasmuch as climatic conditions in many localities are such that a heavy rainstorm between the time of completion of the embankment and the construction of the trench through it might be very detrimental or even disastrous. The favorable load condition produced by this method of construction is recognized, however, and it is clearly within the scope of the Marston load theory. The deeper the trench through the embankment in relation to the trench width, and the more loosely the backfill is placed in the region immediately above the conduit, the farther toward the left side of Fig. 8 the situation falls and the less will be the load on the structure.

---

[54] Research Prof., Civ. Eng. Dept., Iowa Eng. Experiment Station, Iowa State College, Ames, Iowa.

Mr. Tremper's remarks indicate that similarly good results are being obtained in the State of Washington by installing pipe culverts in sidehill ditches to one side of the watercourse. Where practicable, this procedure would appear to be better than that suggested by Mr. Feld, because drainage water could be cared for in the natural watercourse during construction of the culvert. The discussions by both Messrs. Feld and Tremper lend emphasis to the more favorable load situation that can be achieved in culvert construction when specific attention is given to creating conditions in which pressures are transferred by shear from the interior prism of soil to the exterior masses.

From Prague, Czechoslovakia, comes a very interesting analysis of concrete pipe rings from which values of the load factor for cradled pipe have been determined. There is no difference of opinion between Professor Bažant and the writer relative to the analytical determination of bending moments in a reinforced concrete pipe. This procedure is precisely that employed by the writer prior to 1933 which led to the development of Eq. 14*b*. The difficulties in design arise when one attempts to convert the calculated moments into stresses in the steel and concrete of which the pipes are made.

Professor Bažant's calculated load factors shown in Table 1 are approximately 10% greater than the average experimental values obtained by W. J. Schlick, M. ASCE, and James W. Johnson.[55] These differences are not significant and readily may be accounted for by the fact that the sand-bearing load was assumed to be uniformly distributed in the analysis, whereas it is known that the pressure in the test is greater at the center of the bearing than at the sides and that it approaches a parabolic distribution.

However, several circumstances and assumptions connected with the analysis contained in the discussion lead to the conclusion that the correlation shown in Table 1 may be more coincidental than basic. For example, it is assumed that: "The maximum moment occurs at points a and b, where the first cracks occur * * *." In the Schlick and Johnson experiments, 94% of the cradled specimens cracked first at the top of the pipe. The first cracks in the remaining 6% occurred simultaneously either at the top and bottom or at the top and sides of the pipe. Also, in every case the cradle cracked in the region below the bottom crack in the pipe and at the same time that the bottom crack occurred. In no case did the first cracks occur at the junction of the pipe wall and the cradle as assumed by Professor Bažant.

---

[55] "Concrete Cradles for Large Pipe Conduits," by W. J. Schlick and James W. Johnson, *Bulletin No. 80*, Iowa Eng. Experiment Station, Ames, Iowa, 1926, p. 39.

The comparison between computed and experimental values of the load factor for ultimate loads is probably not valid, even though the values appear to be reasonably close numerically, because at ultimate load the pipe and the cradle have long since ceased to be a continuous arch body. At ultimate loadings, the experimental pipes were cracked in many places, the cradles were broken into two parts, and the bond between the cradles and the pipes was destroyed, so that the structures were considerably different after they were cracked from the structures which Professor Bažant analyzed. For these reasons it would seem that a comparison between calculated and observed load factors at "first crack" load would be much more appropriate. Such comparisons for the three cradle types included in Table 1 show that the calculated load factors exceed the observed values by 18%, 37%, and 35%, respectively.

Mr. Shafer's discussion is a most welcome addition to the literature on the supporting strength of flexible pipe conduits. He has had wide experience in this field, has made extensive observations of the performance of this type of structure, and has brought rare good judgment to the interpretation of his observations. The writer has a very high regard for the utility of Mr. Shafer's empirical Eq. 26. It has served both the industry and the users of metal culvert pipes very well since its inception in 1926.

In the writer's opinion, however, the flexible pipe problem is far too complex to rely solely on experience for a solution. Theory is needed to supplement judgment and to guide the interpretation of the shotgun pattern of the facts gleaned in the field. The empirical formula falls short in the achievement of scientific design of flexible pipe culverts and tends to stifle progress in that direction, since it does not take into account several important variables that influence the problem. One of these is the passive resistance of the soil side fills, which is widely recognized as a highly important factor (probably the most important single factor) on which pipe deflection depends. The empirical formula throws all the effect of side pressure into the factor k, and the best that can be expected under these circumstances is the determination of "average" deflection, which may be greatly exceeded in individual cases. Very few field data are available to the profession from which to judge the correlation between actual deflections developed in the field and deflections predicted by the empirical formula. Such data as the writer has seen show a very wide range of deflections, many individual specimens being in excess of 100% above the "average," and extreme cases being from 400% to 500% above.

Another variable factor which the empirical formula submerges in the "average" is the relationship between the height of fill and the load on a culvert. It is unfortunate, but nonetheless true, that the load and the height of fill are not related by a constant factor for all culverts. This fact is clearly shown by Fig. 8. In the present state of knowledge it is difficult to predict values of the settlement ratio, which has such an important effect on the relationship between load and height of fill. Nevertheless, it is present and effective in every culvert installation and scientific progress demands that it be recognized and studied. This same comment applies to the projection ratio, except that the latter factor is more easily determined for a specific pipe installation.

For these reasons and others, the writer does not consider that the fill height data given in Table 2 are validly comparable. It would be the purest coincidence if the fill heights shown in the parallel columns were in agreement. The only valid check on Eq. 15 is a comparison of the deflections computed by the formula with actual measured values when all the factors relative to a culvert installation which influence the deflections are known or can be estimated with a reasonable degree of precision.

When Eq. 15 was developed and published, it was intended to be used to compute the deflection of a flexible pipe culvert when the diameter of the pipe and its physical properties (the height of fill, the settlement ratio, the projection ratio, the width of bedding, the unit weight of the fill, and the character of the soil as it influences passive resistance pressures) are known. Immediately after publication, many engineers turned the formula around and attempted to use it to calculate a fill height that would produce some predetermined deflection of the pipe. This practice has led to some difficulties and erroneous concepts concerning the formula. Mr. Kelley rejects the formula as giving unreasonable results, because the fill height to produce a given deflection, expressed as a constant percentage of pipe diameter, is larger for large pipe than it is for some smaller pipe sizes. His point would be well taken if it could be definitely stated that, when two pipes of different diameters have deflected under a fill an amount equal to 5% of their diameters, they have both progressed the same distance toward failure and are, therefore, on a comparable basis as far as strength is concerned. The writer does not believe this is true.

This premise opens the whole question as to the theory of failure of flexible pipes and a suitable criterion for an allowable design limit. The metal pipe industry has for many years suggested a deflection limit of 5% of the diameter as being a suitable criterion and many engineers have accepted this value. The writer has looked on the 5% limit as a good value to "shoot at," but he has come to realize that neither it nor any other constant percentage-of-diameter deflection represents the same strength situation for all diameters of pipes. As evidence on this point, the writer has investigated the pipes for which Fig. 28 was drawn by computing the fill heights to produce a constant value of bending moment at the bottom of the pipes. The equation for the moment at the bottom of a flexible pipe under field loading conditions (for a bedding angle of 35°) is[56]

$$M = 0.176\, W_c\, r - 0.166\, h\, r^2 \quad \ldots\ldots\ldots\ldots\ldots (33a)$$

---

[56] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Iowa Eng. Experiment Station, Ames, Iowa, 1941, p. 58.

in which

$$h = \epsilon \frac{\Delta}{2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33b)$$

Substituting Eq. 15 in Eq. 33*a* and using the same values of various factors that were used by Mr. Kelley, it is possible to compute heights of fill over the various diameter pipes to produce the same bending moment in each of the pipes. The bending moment in the 36-in. pipe of Fig. 28 was arbitrarily chosen as the common value for all the pipes. The results are shown in Fig. 29. On the basis of this criterion the height of fill decreases with increasing pipe diameter, which seems to be more reasonable. Since both Eq. 15 and Eq. 33 are based on the elastic analysis, the author believes that Fig. 28 throws a cloud of uncertainty on the validity of applying a constant percentage-of-diameter deflection limit to all sizes of pipe, rather than on the validity of Eq. 15.

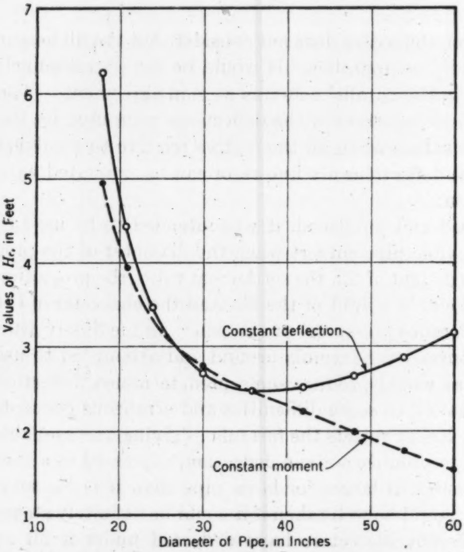

Fig. 29.—Height of Fill Versus Pipe Diameter

Mr. Shafer goes further and applies the 5% limit to pipes loaded in two-edge bearings and compares the loads to produce this deflection by elastic analysis and by actual test. Since the smaller sized pipes tested were obviously loaded beyond the elastic limit of the metal, the calculated loads to produce 5% deflection were considerably greater than the test loads. This discrepancy between calculated loads and test loads is cited by Mr. Shafer as an indication of a weakness in Eq. 15. The writer believes that the comparisons in Table 3 are wholly fortuitous and irrelevant and that Mr. Shafer's conclusions based on them are not valid.

In support of this contention, it is pointed out that, if the test specimens had been made of metal having a higher elastic limit, the difference between the loads calculated by Eq. 27 and the test loads would have been materially less. In Fig. 23, the metal in the 36-in. pipe for which load-deflection data are plotted apparently reached its elastic limit at a load of 1,056 lb per lin ft, or 88 lb per lin in. The bending moment at the top and bottom of a circular ring loaded in two-edge bearing is[57]

$$M = 0.318\, P\, r \ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

in which P is the load per unit length of pipe; and r is the radius of the pipe. By the flexure formula,

$$s = \frac{M\,c}{I} \ldots\ldots\ldots\ldots (35)$$

The elastic limit of the metal in this pipe is approximately 46,000 lb per sq in. by Eqs. 34 and 35.

Corrugated metal pipe culverts are made of many different kinds of iron and steel, ranging from commercially pure iron having a relatively low elastic limit to copper and copper-molybdenum iron or steel alloys having high elastic limits. In the research work on which Eq. 15 was based, the metal pipes furnished for the tests by four different manufacturers varied in elastic limits from 47,800 lb per sq in. to 65,500 lb per sq in. If the 36-in. pipe of Fig. 23 had been made of metal having an elastic limit of 66,000 lb per sq in. instead of 46,000 lb per sq in., the load-deflection diagram would have been approximately as shown by the dotted line in Fig. 30 and the difference between actual loads and those computed by Eq. 27 would have been much less.

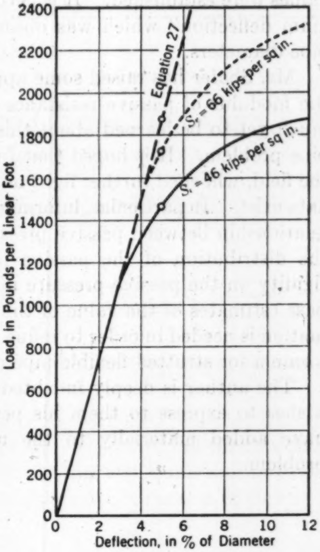

FIG. 30.—LOAD-DEFLECTION DIAGRAM FOR CORRUGATED METAL PIPE CULVERTS

Likewise, the data shown in Table 3 are intimately dependent on the elastic limits of the particular pipes tested. It is the writer's view that these data do not provide a proper basis for generalization without some detailed knowledge of the elastic limits of the metals from which the test specimens were made.

The data in Table 3 are irrelevant because the load and reaction in a two-edge bearing test are much more concentrated than in the field loading for which Eq. 15 was developed and it seems probable that the difference between computed loads and actual loads would be much less in the latter case, even when the pipe metal is stressed beyond its elastic limit at localized points—that is, the load-deflection curve under field loading would probably deviate from a straight-line elastic relationship much less rapidly than under concentrated loading. Mr. Shafer appears to agree with this view. Obviously, also, pipes made of metal having a high elastic limit would deviate less from the elastic line and would have less deflection for a given load than would pipes made from low elastic limit metal.

---

[57] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Iowa Eng. Experiment Station, Ames, Iowa, 1941, p. 14.

The data shown in Table 3 again raise the question of whether it is valid to apply a constant limiting deflection to all sizes of pipe. Mr. Shafer has given an interesting account of the origin of the commonly accepted 5% limit. He would do the profession a service if he would publish the data on which the values were established. It is pertinent to ask whether the "average safe maximum deflection" which was observed was the same percentage value for all pipe diameters.

Mr. Shafer has raised some appropriate questions concerning the nature of the modulus of passive resistance of soils, and the writer agrees that there is much yet to be learned about this property and its application to the flexible pipe problem. It is hoped that future research, both in the laboratory and in the field, will shed further light on this factor concerning which so little factual data exist. In particular, information is needed to determine more definitely the relationship between passive pressures and movement of the sides of the pipe, the distribution of the passive pressures, the effect of fill height and pipe rigidity on the passive pressure modulus, and soil test procedures on which to base estimates of the value of the modulus for design use. Such added information is needed in order to refine and improve Eq. 15 and to develop a parallel formula for strutted flexible pipe culverts.

The author is deeply indebted to those who have discussed the paper and wishes to express to them his personal thanks. He believes the discussions have added materially to the understanding of the underground conduit problem.

SUBSIDENCE OF THE TERMINAL ISLAND-LONG BEACH AREA, CALIFORNIA

BY FREDERIC R. HARRIS,[1] M. ASCE, AND EUGENE H. HARLOW,[2] ASSOC. M. ASCE

WITH DISCUSSION BY MESSRS. JAMES GILLULY AND U. S. GRANT, JACOB FELD, AND HYDE FORBES.

SYNOPSIS

By early 1945 the subsidence taking place in and around Terminal Island, Long Beach, Calif., had reached a maximum of more than 4 ft and the rate was approaching 1 ft per yr. Therefore, to protect existing structures and to evaluate the risks in future engineering enterprises in the area, it became imperative to determine the answers to three questions:

(1) What is the cause of the subsidence?
(2) Can its future progress be predicted?
(3) What effect will it have on civil engineering works?

This paper presents answers to these questions. It now appears certain that by far the predominant influence is the effect of pumping oil from the Wilmington oil field, which coincides in location and extent with the subsiding area. Extensive data were gathered to determine the factors producing oil field settlements, and laboratory tests were performed on samples of shales from different depths to determine the relative compressibilities. Calculated theoretical subsidence was compared with observed subsidence, a correction factor was computed, and theory was then extended into a prediction as to the future course of the settlement. From these studies it is concluded that the maximum rate of settlement has probably been reached and that henceforth the rate will gradually diminish until eventually, in perhaps ten or fifteen years, the maximum subsidence will reach about 9 ft.

Elevations of waterfront structures, gravity flow pipe lines, etc., may have to be adjusted accordingly. Since differentials will be gradual, only very long or rigid structures will be subjected to warping or cracking.

NOTE.—Published in October, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

NATURE OF OBSERVED SUBSIDENCE

Occurrences of differential movements in the Los Angeles-Long Beach harbor areas of California have long been recognized (1)(2)(3)(4).[3] However, comparison of records of tide gages maintained at several points in the Los Angeles and Long Beach Harbor areas for many years with observations at La Jolla and San Francisco show that the gage at berth 60, municipal pier No. 1, Los Angeles harbor, referred to as "tidal 8," has not changed in elevation since 1931 by more than about 0.1 ft.

FIG. 1.—CONTOURS OF SUBSIDENCE—1945

Subsidence at various bench marks in the affected area during different periods was determined, in general, by subtraction of corresponding elevations. Those for 1933 were taken as representing zero subsidence, because study of the Long Beach outer harbor tide gage record, as well as of frequent levelings by the Southern California Edison Company, reveals the 1933 leveling to be the most recent extensive survey prior to the beginning of the rate of subsidence prevailing in 1945 and 1946.

---

[3] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix).

Fig. 1 shows contours of the subsidence that occurred from 1933 to 1945. Profiles taken on several dates along a representative line through the area are given in Fig. 2. Fig. 3 shows the increase of subsidence at certain bench marks plotted against time.

GEOLOGY OF THE REGION

The geologic history of the region has been amply described in previous reports and papers (5)(6). Generally, all the sediments in the upper 7,000 ft are poorly consolidated "shales" and sands of Miocene, Pliocene, Pleistocene, and recent origin. The Miocene and lower Pliocene strata are warped into a gentle anticline with its axis in a northwest-southeast direction, forming an elongated dome whose highest parts are close to the east end of Terminal Island. These strata are all highly faulted, and form the structure of the Wilmington oil field, at present one of the largest producing fields in California. The faults have been traced upward to an unconformity at the base of the Upper Pliocene, or Pico, formation, about 2,000 ft below the surface, but not above this point Varying thicknesses of beds in the underlying Repetto formation indicate that the motion along these faults was still occurring until late Pliocene times, but did not continue into later periods. The upper 1,800 ft of sediments generally contain more or less fresh water in the voids, and have been the source of fresh water supply to residents of the basin for many years.

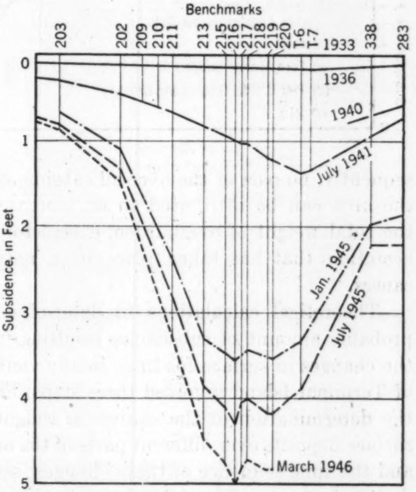

FIG. 2.—SUBSIDENCE ALONG SEASIDE BOULEVARD

FACTORS CONTRIBUTING TO THE SUBSIDENCE

At least five major sources of settlement operating in this area have contributed to the observed subsidence in varying degree. They are: (*a*) Changes in the land surface from filling and dredging; (*b*) pumping of water for industrial and domestic uses; (*c*) pumping of water during dewatering of the site of dry dock No. 1, United States naval dry docks; (*d*) pumping of oil from five major oil zones in the Wilmington oil field; and (*e*) tectonic forces. Any study of this problem resolves itself finally into an opinion based on factual observation and accepted principles of statics and mechanics, concerning the relative importance of these possible sources. Therefore, each of them is discussed.

Filling and Dredging Operations.—Development of the Los Angeles and Long Beach harbor areas has been in progress since about 1900. At that time, Terminal Island, then called Rattlesnake Island, was a low sand spit. It has been gradually enlarged by dredged fill to several times its initial size, and was eventually built up to about El. +13. However, as far as is known, no fill materials have been brought by man into this area from any distance. Consequently, no part of the over-all subsidence of the area can be attributed to an increase in the total weight of overburden, except for the accretion that has taken place from natural causes.

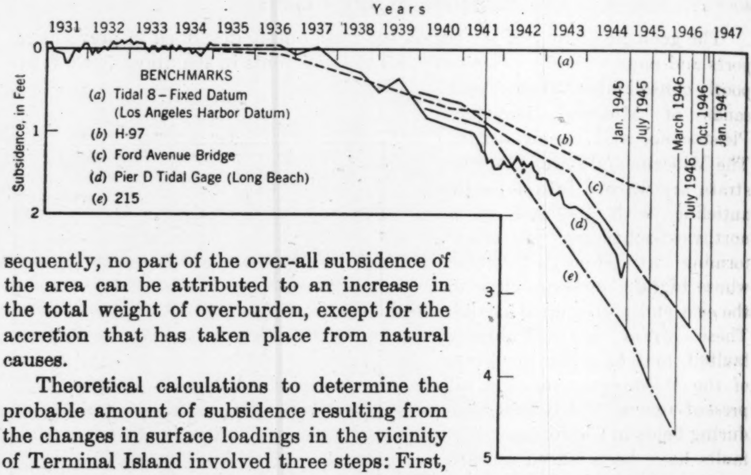

FIG. 3.—SUBSIDENCE OF TYPICAL BENCH MARKS IN PERIOD 1931–1947

Theoretical calculations to determine the probable amount of subsidence resulting from the changes in surface loadings in the vicinity of Terminal Island involved three steps: First, the determination of the change in weight of surface deposits over different parts of the area, and the time sequence of these changes; second, the total consolidation of underlying compressible strata that should ultimately occur; and, third, the influence of time effects during the consolidation, which reflect the proportion of the settlement that would cause observed movement of surface bench marks. From a study of many consolidation tests on clays and loams by several investigators (7)(8), it was concluded that, of the total subsidence measured, perhaps in the strip along the seaward side of Terminal Island, about 0.2 ft could be attributed to surface loading.

General Effect of Pumping Liquids.—If the ground-water table is lowered, all the sediments between the initial and final ground-water surfaces will experience a loss of buoyancy, and will rest more heavily on the underlying soil skeleton, which will eventually compress. The compression may not occur suddenly, since reduction in volume requires the escape of excess water in the voids. According to the theory of consolidation advanced by Karl Terzaghi, M. ASCE, the time required varies as the square of the thickness of the stratum undergoing compression. Since the more compressible strata are generally the fine-grained silts and clays, which may exist in layers between more pervious sand beds, time is needed for such a volume change before a static equilibrium is reestablished.

If two or more pervious beds are separated by continuous impervious clay strata, the water pressures in the voids of the lower bed may not conform to the ground-water table in the upper bed (9). Also, if the water pressure in the lower or confined aquifer is reduced, the pressure and level of the water in the surface aquifer will not be affected (see Fig. 4). However, the lower aquifer will undergo compression throughout its thickness.

FIG. 4.—PRESSURES IN SOILS
(*a*) Before Pumping
(*b*) During Pumping from Lower Aquifer

From the foregoing, it is seen that there are two distinct effects that may result from the pumping of a liquid from the ground:

1. Loss of buoyancy of the soil particles. This occurs if the ground-water surface is lowered, causing compression of all underlying strata.
2. Increased intergranular pressures in a pervious zone confined between impervious layers. This occurs if the liquid pressure in the confined zone is reduced, and results in compression of the confined zone and of adjacent parts of the "aquicludes" (impervious layers) at top and bottom.

The same general principles apply to the effect of pumping any liquid—whether water or oil.

Water Pumping for Industrial and Domestic Uses.—Fresh water in the Long Beach-Wilmington coastal plain is obtained from two water-bearing zones. The upper or Gaspar zone occurs in the surface deposits of recent age and consists of from 100 ft to 200 ft of alluvial deposits of sand and gravel interbedded with silt and clay. It includes both surface waters and confined waters. The lower or Silverado zone is a confined aquifer of Pleistocene deposits of sand and gravel with intervening layers of silt and clay. The zone varies from 150 ft to 500 ft in thickness. It varies in depth, being from 200 ft to 900 ft below the land surface in the Wilmington section.

The Newport-Inglewood fault forms a partial barrier to the flow of underground water. The area to the northeast of the fault was originally highly artesian, deriving pressure from water entering the pervious strata in the foothills of the mountains which surround the basin. The area to the southwest of the fault was probably only slightly artesian originally. Water-bearing zones in this area are replenished mainly by underflow across the Newport-Inglewood fault, through imperfections in the fault barrier. As a result, the effect on lowering the ground-water levels by pumping is much more noticeable in the coastal area south of the fault than in the areas to the north.

Development of ground water in the Los Angeles coastal plain began about 1870 (10). Records show that wells drawing from the Gaspar and Silverado zones had static water levels from 10 ft to 30 ft above sea level in 1903, gradually dropping to about sea level in the Gaspar zone and to as much as from 60 ft to 70 ft below sea level in the Silverado zone (11).

Changes in elevation of the ground surface caused by pumping water from the lower strata are almost certainly part of the reason for early survey difficulties. The influence is probably still contributing, but to a moderate extent, with the fraction of total subsidence resulting from this source amounting to inches, not feet. The center of the depression would be expected to lie some distance north of Terminal Island.

Dewatering of the Site of Dry Dock No. 1.—Pumping water from surface and confined pervious strata during the construction of dry dock No. 1 drew down the pressure levels in these beds from sea level to about El. −75, based on mean lower low water datum. The pumping covered a period from June, 1941, to April, 1942. Maximum drawdown in water levels did not occur until some weeks after pumping was begun. After pumping was stopped, readings on near-by wells indicated that the pressure levels rapidly rose to their initial elevations, close to mean sea level.

Water levels in wells in the upper aquifers were affected varying amounts as far north as 2 miles. Local subsidence was observed in the affected area, varying with the drawdown in pressure level, roughly in inverse proportion to the distance from the dock site. The Southern California Edison Company, whose Long Beach steam station is about 2,000 ft northeast of the dock, installed fifteen observation wells, some 35 ft deep and some 150 ft deep, to measure the reduction in water pressure level in the two principal pervious strata of the local part of the aquifer (7). Observations were also made of the motion of bench marks around the plant.

Within a radius of 2,000 ft of the dock site the ground settled as much as 0.45 ft around the casings of many oil wells. In most instances, the construction of the derrick foundations permitted the ground and concrete base slabs to settle around the casings without appreciable damage to either casings or concrete. There were a few occurrences of cracked base slabs, and damage was reported to at least one well casing. Differential movement between the ground surface and the casings was observed only during the period of pumping at the dock site. Prior to and since that time, the oil well casings have apparently behaved as if they were part of the ground surface.

To estimate how much of the total subsidence was caused by dewatering the dock site, the theoretical consolidation resulting from the effect of the observed drawdown of liquid pressure levels was computed.

From a study of the stratification and drawdown records, it appears that the substrata affected by the pumping consist of sands and gravels of the Gaspar aquifer, extending in depth from about El. −70 to about El. −270. The silty clay materials bounding, and within, the aquifer were assumed to have a coefficient of compressibility (C_c) of 0.144. Calculated contours of equal subsidence resulting from this pumping appear consistent with the measurements of motion around well casings. When pumping was stopped, in the spring of 1942, water levels rose to their previous values, and the consolidation ceased. In fact, a slight rebound, or increase in volume of the consolidated strata, occurred. Therefore, this settlement is considered to represent merely an incident in the general subsidence phenomenon in the area, and its effect was felt solely in the period from June, 1941, to April, 1942.

Pumping from the Wilmington Oil Field.—The mechanics of liquid flow during production from an oil well are generally the same as those for pumping water from a confined aquifer. The oil sands forming the equivalent of the aquifer are bounded top and bottom by impervious layers of "shale," or silt and clay compacted by the weight of the overburden. The oil in the sand voids is initially subjected to pressures which depend mainly on the depth of the strata below sea level. As oil is withdrawn from the well, there is a pressure reduction, which produces a gradient toward the well from all sides. This gradient depends on the rate of pumping, the permeability of the sand, and the extent and uniformity of the stratum as it affects the resistance to liquid replacement of the oil withdrawn. In oil wells the flow is complicated somewhat by the presence of large amounts of gas, either free or dissolved in the oil, and by the presence of at least two liquids, oil and water, with different physical properties (12).

As with pumping water from a confined aquifer, reduction in the liquid pressure in the oil sands produces a compensating increase in the intergranular or effective pressures in the soil structure within the stratum affected. Compression of the oil zones results. The amount of compression is influenced by the amount of decrease in liquid pressure and by compressibility of the materials within and bordering the affected zone, at top and bottom.

Compression of oil zones has frequently resulted in subsidence of the ground surface above ((5)(13)(14)(15) and unpublished reports). It is significant that, in the Los Angeles basin, noticeable subsidences have been recorded by first order leveling in the areas of a number of oil fields. Among these are the Wilmington, Signal Hill, Santa Fe Springs, Playa del Rey, Inglewood, and Huntington Beach fields. However, first order levels have not been run across many fields sufficiently often to detect possible subsidence. The relation between the amount of the unchecked compression of the oil zones and the corresponding surface subsidence depends on the structural strength of the sediments in between. It is quite common for extensive oil fields to experience no noticeable surface subsidence. On the other hand, subsidence of large areas from any cause is seldom noticed in inland areas. Along the seashore, the relatively constant sea level provides an automatic reminder whenever subsidence of appreciable amount occurs.

The Wilmington oil field was discovered in 1932, but little attention was paid to it until the last half of 1936, when a carefully cored and tested well revealed the presence of four major oil zones. The drilling boom started in the Los Angeles harbor area thereafter, spreading to the Long Beach harbor area in 1937 (6)(16)(17). Maximum production of 100,000 bbl of oil per day was reached in February, 1938, dropping gradually to about 82,000 bbl per day in 1940, and then rising again to around 100,000 bbl per day by 1944. The field's oil production rate in 1945–1946 is the highest in California by a wide margin. This time sequence agrees generally with the occurrence of most of the subsidence, as is apparent from a comparison between Fig. 3 and Fig. 6. The anticlinal structure of the oil field shows a remarkable correlation with the contours of equal settlement.

To ascertain the importance of oil pumpage from the Wilmington oil field in producing settlement, quantitative studies were made in 1945 based on actual measurements of the several factors governing consolidation of sediments in the oil zones. These factors consist primarily of the stratification of the sands and shales, the compressibilities of the sands and shales, and the reduction in liquid pressure of the oil and water in the voids after different periods of time.

Stratification was determined from oil well electric logs and coring records. Fairly detailed information is available and has been plotted on contour maps and profiles by the oil companies and by various other agencies interested in the field. The general structural characteristics are shown in Fig. 5. There are five major zones: Tar, Ranger, Upper Terminal, Lower Terminal, and Ford, in that order, varying in depth from about 2,200 ft at the top of the Tar zone to about 4,700 ft at the top of the Ford zone. The basement complex of igneous rock, a schist, is encountered at about 6,500 ft below mean sea level. Each zone varies in thickness to some extent; but except for faulting the differences in stratification between one point and another are remarkably small. The faulting, however, represents the most serious complication. A series of faults extending in a roughly north-south direction divide (see Fig. 5) the field into five major fault blocks, which are themselves broken by innumerable smaller faults,

so that most cross sections of the field do not attempt to trace all details of the complex pattern. The locations of faults are determined mostly by inductive reasoning, through study of the oil well electric logs (18).

Fluid pressures in oil wells constitute one of the most important subjects for study by oil producing companies. Measurements of flowing and shutoff pressures are made to determine the productivity of the well, which enables estimates to be made of future production, and also data to be obtained for use in operation to insure maximum total production from the field. The usual custom is to shut off the well for 24 hours or longer before taking the measurements, to allow time for the pressure to build up close to the maximum. A pressure recording instrument is lowered into the well, and readings are taken at intervals so that a pressure-depth curve can be plotted.

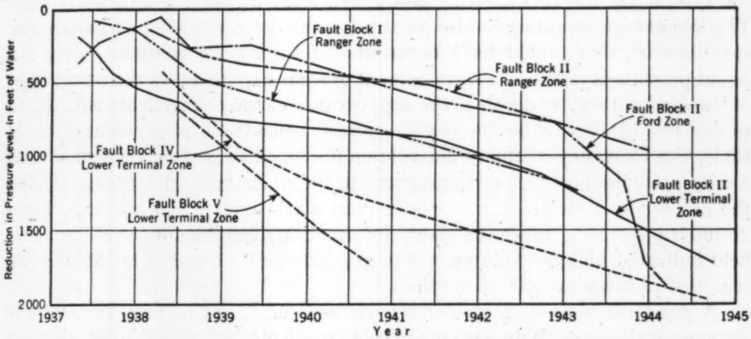

FIG. 6.—REDUCTION IN OIL ZONE PRESSURE LEVELS FOR TYPICAL WELLS

Initial pressures in the field, as determined from a large number of initial measurements on early wells, were approximately the same as if the underground liquids were composed of salt water with the surface at mean sea level. Continued pumping has generally caused a steady reduction in the pressures. If pressure at any depth is reduced to terms of pressure level, or the level at which a column of salt water would stand in static equilibrium in a tube whose lower open end is inserted in one of the confined sands of an oil zone, then it may be stated that the pumping has caused a gradual reduction in the pressure level below the initial mean sea level elevation. Typical curves showing pressure levels at various times for different wells are shown in Fig. 6. Pressure levels in the various zones are not the same, because of the impervious shales separating them. It has also been observed that the pressure levels on opposite sides of a fault are likely to differ, the displacement along the fault plane apparently having caused a breakdown of the normal sand structure and the formation of relatively impervious materials, which act as a barrier to the flow of liquids.

Pressure relations in the oil zones are complicated to some extent by the presence of gas. Initially, gas in the Wilmington field is believed to have existed in a near saturated solution, without any appreciable free gas cap. However, as pumping continued, pressure reduction has caused the formation of some free gas, which may have accumulated in gas caps at the crest of the structure and along faults in some zones. The near saturated condition of the original oil is indicated by the fact that wells originally "came in" as gushers, the gases rapidly expanding out of the solution in the casings, carrying the oil upward in the typical gas lift action. Gas production from the field is still fairly high. The free gas affects intergranular pressures generally by causing a smaller pressure increase than would have occurred had the gas been absent, since the liquid pressure is reduced. Development of a gas cap increases the unit weight of the sand within the depth of the cap, because of the change from submerged to dry weight; but, since the gas is confined beneath an impervious dome of shale, the buoyancy of the liquid volume displaced by gas of very small unit weight produces lower effective pressures in the strata below the shale. Unless the gas cap is quite thick, its presence has a relatively small effect on intergranular pressures. Since the scanty information available for the Wilmington field indicated no large volume of free gas, its effect on consolidation was disregarded in these subsidence studies.

A great many pressure measurements were made in the first five years of development of the Wilmington oil field, particularly by the large property owners. There are many smaller operators, particularly in the northwest part of the field, known as the "Townlot Area," who have made practically no pressure measurements in that section, although there has been considerable pumping since early in the field's history. Also, pressure measurements by the large operators were less frequent after the beginning of World War II. Since insufficient measurements were available for 1945, data were also included for measurements made in 1943 and 1944, which were given the same weight as the 1945 measurements, in preparing pressure contour maps for areas and zones where the later data were not available. Thus, discrepancies were introduced between calculated and observed subsidence for 1945, as will be noted hereafter.

Compressibility of sedimentary materials at the pressures existing in oil zones several thousand feet below the surface is a matter about which little information is available (19)(20)(21). To obtain data more applicable to this problem, it was decided to perform tests on actual samples of materials taken from oil wells in the Wilmington field. For several reasons, shale cores only were selected for testing. In the first place, shales, the product of silts and clays, composed of fine-grained particles, were expected to be much more compressible than sands. Previous tests had demonstrated fairly conclusively that sands, and particularly sandstones, show extremely small volume change when subjected to very high pressures. Secondly, relatively undisturbed shale cores, suitable for testing, could be obtained with much less difficulty than sands, because of their cohesive quality. Most of the sands from the Wilmington field are quite friable, and break up easily.

It was also felt that, rather than adopt triaxial tests, the procedure would more nearly duplicate the consolidation process in nature if the applied load were confined to the vertical direction, at the same time preventing lateral volume change, as is essentially the usual practice for standard consolidation tests on silts and clays. In most consolidation phenomena, where the load is applied to a relatively wide area in proportion to the thickness of the compressing stratum, the volume change is predominantly vertical. This condition can be approximated in the laboratory by subjecting a sample to increased vertical pressure, at the same time restraining it against lateral expansion.

Available samples consisted of cores drilled from various oil wells. Most of these cores were several years old, having been obtained during the period when the oil companies were exploring the field. In a few instances, fresh cores were obtained from wells where drilling was currently in progress. The cores varied in size from 1½ in. to 5 in. in diameter.

Equipment used in performing the tests was designed to accommodate two sets of samples simultaneously. The apparatus, which is pictured both in assembly and in detail in Fig. 7, employs a manually-operated screw-driven jack for applying the load, and a beam gage for measuring the load. Porous stones, placed on both ends of each 1-in.-thick sample, enabled application to, and drainage of water from, the samples. Two sets of three equally spaced 1/10,000-in. micrometer dials were used to measure the compression of the samples. In determining the reduction in thickness of each sample from the

average of the dial readings, it was necessary to measure the deflections occurring in the porous stones and to make appropriate adjustments.

Samples to be tested were first placed in a saturated atmosphere to reestablish in them, as nearly as practicable, a saturated condition. They were then accurately trimmed in a lathe—all weathered or damaged parts being removed in the process—to fit the internal diameters of the sample holders, and the ends were faced to provide samples of the desired thickness. After machining, the samples were kept in a saturated atmosphere until ready to be placed in the testing apparatus.

Immediately after application of a small initial load, screws holding the sample holders in position during the setting-up process were released, and water was applied to the top and bottom of the samples through the porous stones, which were kept constantly wet throughout the remainder of the test. Load was applied in a series of increments, with each increment being twice its predecessor, except that two or more additional increments were superimposed on the basic series of increments in the vicinity of the preconsolidation load. On removal of the samples from the testing apparatus, the moisture content, dry density, and the specific gravity of the soil grains were determined for each sample. A typical curve of pressure versus voids ratio data obtained from the shale consolidation tests is shown in Fig. 8, for a 2.416-in. diameter sample. Typical compression-time curves are shown in Fig. 9. Each point in Fig. 9 represents the average of a set of three dial readings, expressed in terms of the

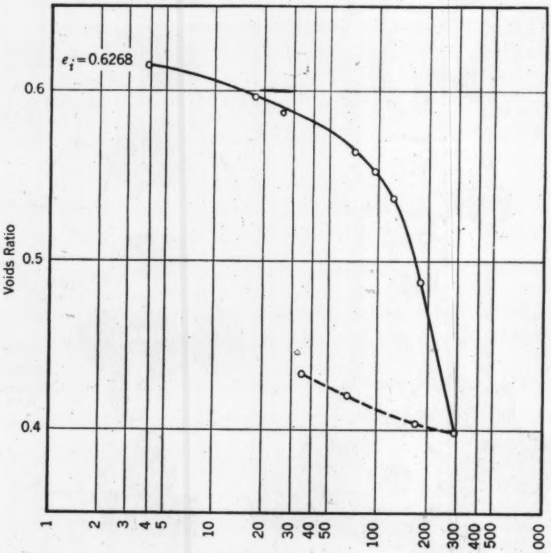

FIG. 8.—TYPICAL CONSOLIDATION TEST OF SHALE

percentage of the total deflection observed at the end of the first 1,440 min during which a particular load was applied.

For the highest pressure to which two of the samples were subjected, it was observed that some of the material was squeezed by plastic flow into the space between the porous stones and the sample ring. In these instances, in arriving at the straight-line approximation, a correction was made to the voids ratio for the last point on the curve in proportion to the amount of material displaced. This plastic flow probably would have been avoided if the diameter of the porous stones could have been made closer to that of the cylindrical openings in the testing rings. No other evidences of plastic flow were observed.

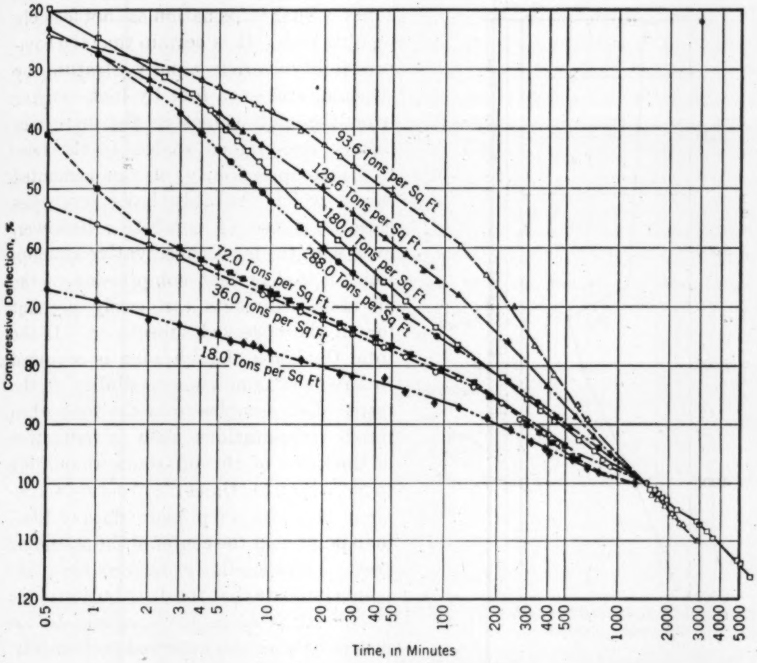

FIG. 9.—CONSOLIDATION TESTS OF SHALES

For comparative purposes, the compressibility of each sample can be defined in terms of a coefficient (C_c) determined by the slope of the assumed initial compression curve, or the change in voids ratio for a tenfold increase in pressure. The initial compression curves were assumed to be tangent to the steepest sections of the test curves, and to represent an approximation to the probable compression curves of the shales in their original condition in the ground. If these compression coefficients are plotted against depth, a definite variation is seen to exist (Fig. 10). The inference is that the shales encountered near the contact between the Lower Pliocene and the Upper Miocene deposits, represented by the

Tar, Ranger, and Upper Terminal zones, are more compressible than are materials at greater or lesser depths, under the same conditions of loading.

To compute theoretical consolidation accurately, it would be necessary to know in minute detail the variation in compressibility of all strata encountered by a vertical section through the oil zones. Such information cannot feasibly be obtained. It is certain that the compressibility varies rapidly stratum by stratum, and even foot by foot, ranging from the high values in the more uniformly fine-grained shales, to the relative incompressibility of the cemented sands, which probably have properties close to those of concrete. However, even with the most conservative assumptions, it is clear that compression of the oil zone sediments can easily account for all the observed subsidence. If the total thickness of each zone is assumed to have the same compressibility as the tested shale samples from the zone, then rough computations show a reduction in thickness of the oil zones amounting to more than ten times the observed settlement, based on the pressure data of 1945, for a point near the center of the subsiding area. Data similarly derived for other points indicate that the distribution of the consolidation corresponds closely to the distribution of the observed settlement.

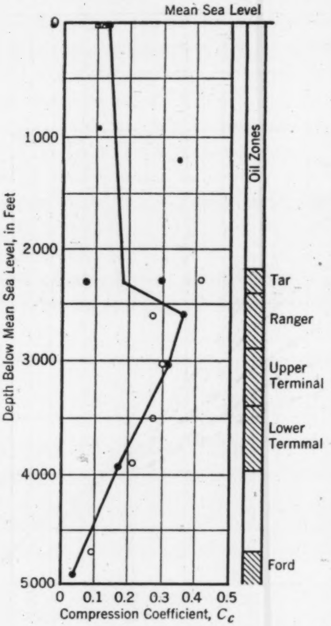

FIG. 10.—COMPRESSIBILITY OF WILMINGTON OIL SHALES IN RELATION TO DEPTH

An estimate of the future course of the subsidence was made, based on the following procedure: Ultimate drawdown of pressure levels in each oil zone was estimated, and a correction factor to be applied to the total thickness of the oil zones was computed. This factor was determined by deducting from the observed subsidence of a point near the center of the depression the computed settlement from water and dock site pumping, as of 1945. The difference was assumed to represent the effect of oil pumping to that time. A constant percentage of the thickness of each zone was chosen so as to make the calculated consolidation at that particular point equal to this difference. Using this factor, the same for all zones over the entire area of the field, together with the average compressibility coefficients, different for each zone, and the total thickness of the zones, which varied over the area of the field, consolidation was computed at some two hundred points. These computations were made using the pressure data of 1945 and also using estimated pressures that may occur in the future. Theoretical subsidence from oil pumping, in 1945, is shown by the contours of Fig. 11.

The many factors that influence the theoretical subsidence computed in this manner perhaps warrant some discussion. In the first place, the consolidation computed for the oil zones was assumed to produce an equal surface subsidence, except for smoothing out local irregularities. This assumption neglects the effect of possible lateral stress changes, which probably may result from the structural strength of the deep beds. The domed structure of these beds itself may result in a certain amount of arching action, which tends to transfer laterally the vertical loads applied near the center of the field, relieving the centrally located shales of some of the increased pressure they would otherwise experience. This action may reduce not only the local irregularities, caused by local variation in drawdown of the liquid level, but also the total surface subsidence at the center of the depression, spreading it over a wider area. However, the same errors from this source exist in the calculated 1945 consolidation as in the calculated ultimate consolidation. Since the predictions for the future are derived from the difference, the net error should be relatively small. This factor may partly explain the lack of agreement in detail between the contours for calculated oil zone consolidation (Fig. 11) and the contours of observed subsidence (Fig. 1), neglecting the relatively small and uniform consolidation from water pumping.

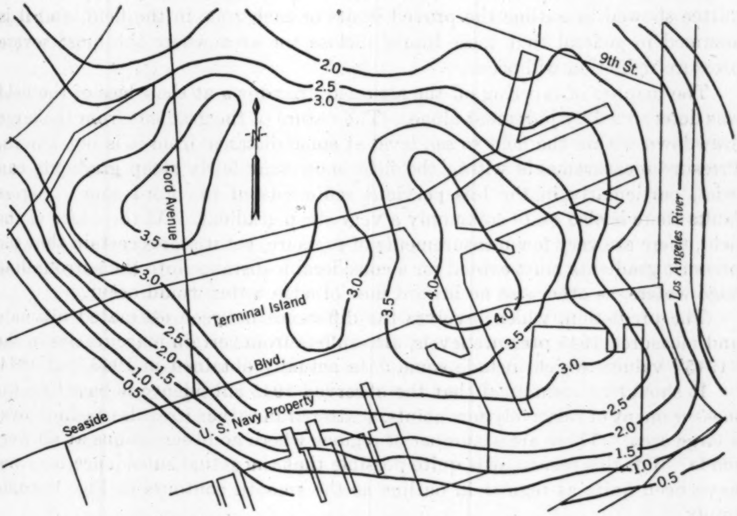

FIG. 11.—CALCULATED CONSOLIDATION OF OIL ZONES—1945

The estimates of future drawdown in each of the oil zones probably constitute the greatest single source of error in the estimate of future subsidence. They were obtained in a purely arbitrary manner, but were based to some extent on past experience and on certain limiting factors.

Leading petroleum engineers and geologists familiar with the Wilmington field agree that eventually, as a result of pumping, oil zone pressures will be greatly reduced. In some oil fields, as oil is withdrawn, edge waters encroaching from the sides of the structure replace it freely enough to prevent extreme pressure reductions in the oil. In such cases, the oil reservoirs may be completely depleted with only moderate reduction of the oil pressure level—the rate of oil removal governing to a large degree the amount of pressure reduction. In the Wilmington field, however, it appears that reasonable pumping rates cannot be maintained without gradual reduction in the liquid pressures, since experience shows that edge-water replacement is not sufficiently rapid. This may be caused by low permeabilities in the oil bearing strata, by fault barriers, or by confinement of these strata within relatively impervious layers.

With these factors in mind, it was concluded that ultimate liquid pressures may very likely be reduced to about 200 lb per sq in.—equivalent to about 400 ft of water head at the top of each zone. The distribution of this drawdown over the area of the field is an uncertain matter, but it appeared that the report prepared in 1941 by the Wilmington Field Engineering Committee contained sufficient data for reasonable approximations. Maps prepared by this committee showed in outline the proved limits of each zone in the field, and it is assumed in general that these limits enclose the area where the most severe pressure reduction will occur.

The manner of tapering off the assumed drawdown at the edges of the field was determined by judgment alone. The nature of the gradient from the large drawdown within the field to sea level at some distance from it is not known. Pressure measurements within the field show that fairly steep gradients can exist, particularly in the less pervious sediments of the Ford zone. Across faults there is also quite commonly a very steep gradient. At the edges of the field, there are very few measurements of pressure, yet it seems certain that the pressure gradients must extend for a considerable distance into the surrounding edge waters, as otherwise no inward flow of edge water would occur.

The prediction, which involves the difference between estimated ultimate and measured 1945 pressure levels, also suffers from certain inaccuracies in the "1945" values, which include some data actually obtained in 1943 and 1944.

It should be mentioned that the observed 1945 subsidence is based on the measurement of relatively few points, scattered in rather irregular fashion over a large area. There are a number of regions where no observations at all were made. For this reason, it is quite possible that the actual subsidence may not have been quite as regular in outline as the smooth contours of Fig. 1 would imply.

Compressibility of the oil zone sediments should not change appreciably with time, in the relatively brief geologic interval of this subsidence. Therefore, if the true average compressibility were known for all zones at a given point, and the increase in drawdown after 1945 were the same for all zones, future consolidation could be predicted quite accurately. However, pressure reductions to be expected in the future vary in the different zones. For example, in fault block III, near the center of the depression, a much larger proportion of the ultimate pressure reduction has already taken place in the Upper Terminal and Lower Terminal zones than has occurred in the Tar, Ranger, and Ford zones. Thus, the proportion of the total consolidation caused in each of the zones, for a given increment of pressure reduction, becomes important. This proportion depends on the total thickness of compressing materials in each zone and on the average compressibilities of those materials.

Thicknesses of each of the zones were determined principally from the contour maps prepared by the Wilmington Field Engineering Committee. These maps showed the variation in elevation of the top of each zone. The thicknesses of the Tar, Ranger, and Upper Terminal zones were taken as the differences between the elevation of the top of the zone and the elevation of the top of the next zone below. The Lower Terminal zone has not generally been productive as deep as the top of the Ford zone, and has not been pumped for this full thickness. The Lower Terminal zone was therefore taken to have an average thickness of 500 ft, based on cross sections prepared by the committee and others and on various electric logs. Similarly, the thickness of the Ford zone was taken as 750 ft. The proportion of each zone composed of shale layers varies over a considerable range, but averages about 50%.

Calculated consolidation, both for 1945 and for the future, was obtained for each zone by multiplying the full thickness of the zone by a correction factor of 8% to adjust the calculated change in thickness, for a point at the center of the depression, with the observed subsidence as of 1945. The surprisingly low ratio between observed and calculated unadjusted settlement may be explained by the facts that: (*a*) Total thickness of oil zones was used in the calculation; and (*b*) each zone was assumed to have the compressibility of the average of the tested shale samples. Thus, the presence of sands of low compressibility is disregarded as are the relatively incompressible sediments composed of shales mixed with sands, which affect the average greatly. The presence of many water-bearing strata that may not be greatly affected by pumping is also neglected, since well casings are not perforated in water zones. Also, as previously mentioned, the tested samples were chosen for their suitability for machining, were very fine-grained, and therefore were more compressible than the majority of shales examined at the oil companies' storage racks.

This method leaves much to be desired, when compared with the degree of accuracy usually sought in consolidation studies. However, it is believed to be sufficiently accurate for the purpose required, because most errors inherent in the theoretical approach are canceled by the adjustment to an already sizable consolidation, representing a major part of the possible total, which has been actually measured.

In all the calculations of oil zone consolidation, it was assumed that the time lag between the imposition of load, through reduction of the pressure level, and the corresponding decrease in voids ratio of the compressible shales has been relatively small. Inspection of the time-compression curves obtained in the laboratory tests (Fig. 9) shows that a majority of the curves do not have the same shape as typical time curves explained by the Terzaghi theory of consolidation (22).

In general, the shape of the time curves resembles the results of certain soil tests in which, because of the character and thickness of the sample, the so-called "secondary" time effects have practically concealed the "primary" effects, or those resulting from squeezing out water. In such cases, instead of the typical reversed S-shape on the semilogarithmic plot, the time curve may be straight, or even slightly concave upward.

The time required for primary consolidation is assumed to vary as the square of the thickness of the compressing layer. The time required for secondary consolidation is more or less an unknown factor, but it is generally held to be independent of the thickness of the layer. In other words, secondary consolidation may occur in nature, in a layer many feet thick, at the same rate as it occurs in the thin laboratory sample.

Those test curves that do display some similarity to the theoretical time curve indicate that for pertinent load increments 90% consolidation takes place in less than 400 min. On this basis, if the average thickness of individual shale laminations, between sand streaks, is assumed to be 2 ft, then 90% consolidation in the oil field would require about 290 days.

For the compression of oil shales considered in this study, many unknown factors influence the time rate. Even the average thickness of the compressible layers is complicated to evaluate, since there are many layers of varying thickness in each of the oil zones. Consequently, no attempt was made to calculate how many of the time effects result from primary compression, inasmuch as the laboratory curves show this influence to be minor compared to that of the secondary or plastic characteristics. The time required for these latter effects is a matter of days, instead of months or years, and it was neglected in computing theoretical consolidation at any particular time. Since the loads themselves are applied gradually, over a period of years, the error introduced by this procedure is probably not very large.

Influence of Tectonic Forces.—It is well known that, in the coastal area of California, motions of the earth's crust are constantly in progress. No attempt will be made to describe the many faults in the subsiding area and around it, or to describe the seismic history of the region (5)(13). It is obvious that in an area interlaced with active faults, where minor quakes are registered almost continuously at the near-by Pasadena Seismological Laboratory, movements along fault zones are more or less likely to occur as the result of slow relative motion of adjacent land masses.

As far as is known, there is no reliable method of estimating or timing the probable occurrence of movements resulting from tectonic forces. However, as far as evidence derived from observations at oil wells is concerned, it appears likely that movement along the many faults in the oil field area ceased in Pliocene times. During these movements, the oil field was generally lifted upward, with downward "cave-ins" of some of the central blocks in the field. A general upward movement of this section of the coast is evident also from the terraced contours of the San Pedro hills around Point Fermin. Geologically, this gradual uplift may still be in progress.

The area that might be affected by tectonic forces is likewise indeterminate. The Newport-Inglewood fault, which is the major known active fault zone passing through the Los Angeles coastal basin, lies some 4 or 5 miles northeast of the center of the subsiding area. Although it might appear that the subsiding area, which coincides with the Wilmington oil field, is a very highly faulted one, compared with other areas, it should be remembered that knowledge of the subsurface details in this area is highly developed from observations made at many hundreds of oil wells. There is no assurance that many other similarly faulted areas of the Pliocene and Miocene sediments do not lie undetected merely for lack of exploration.

In weighing the probability of tectonic forces causing a major part of the subsidence, several factors must be considered along with the known possibility of such movements in this region. One such factor is the lack of any marked increase in seismic activity in recent years in the Long Beach area. Since the rate of subsidence there has increased to a degree unprecedented in California history, if tectonic forces and movements of underlying rock masses were largely responsible, the area might properly be expected to develop a nest of shocks, as the earth stresses produced during such severe strains readjusted themselves. However, although innumerable shocks have occurred in Southern California, no such nest of shocks has been observed at Long Beach.

Another such factor is the absence of damage to oil well casings in the Wilmington field. If there had been any appreciable motion along the faults traversed by the wells, pinching and shearing off of the casings or puncturing of cement plugs should have taken place; and it seems highly improbable that all the relative motion along these inclined faults could have occurred at depths below the oil wells, without producing considerable displacements in the upper sediments. In this connection, experiences at Dominguez Hills in 1941 indicate that motions along faults of as little as a fraction of an inch were sufficient to collapse oil well casings passing through the faults (23). In many cases, motions of more than a foot were observed, shearing off casings completely—yet this condition occurred at an oil field where surface subsidence, if it took place at all, was so small as to go unnoticed. It is considered, therefore, that, although slow tectonic movements have occurred in the area in question, and probably are occurring at present, these movements are very gradual, possibly on the order of 0.04 ft per yr or less, vertically. They may be either upward or downward; and available facts are insufficient to determine which, or to establish the rate, concealed as it is beneath the very much more rapid subsidence phenomenon centered over the oil field.

CONCLUSION

Estimated ultimate subsidence, after 1933, from oil and water pumping is shown by Fig. 12, in which some of the irregularities in contours derived on a mathematical basis have been smoothed out, on the assumption that arching and other effects will in nature reduce abrupt changes and transitions in the over-all pattern. This contour map, by no means considered infallible, can serve as a guide for future construction in this area. The most vital conclusion brought out by the contours is that in all probability there will be no large-scale inundation of the easterly end of Terminal Island. Wherever present freeboards above extreme high tide level exceed 5 ft, the chances are that there will be no overtopping of the ground surface.

Nevertheless the possibility of differential movement should be considered in the design of any large structures to be built in the subsiding area. In general, since the depression in the ground surface covers a very wide area, with flat side slopes, the amount of differential motion to be anticipated in the length of most buildings will be very small. If the buildings are sufficiently flexible to withstand such motion without excessive stresses, no particular damage will result.

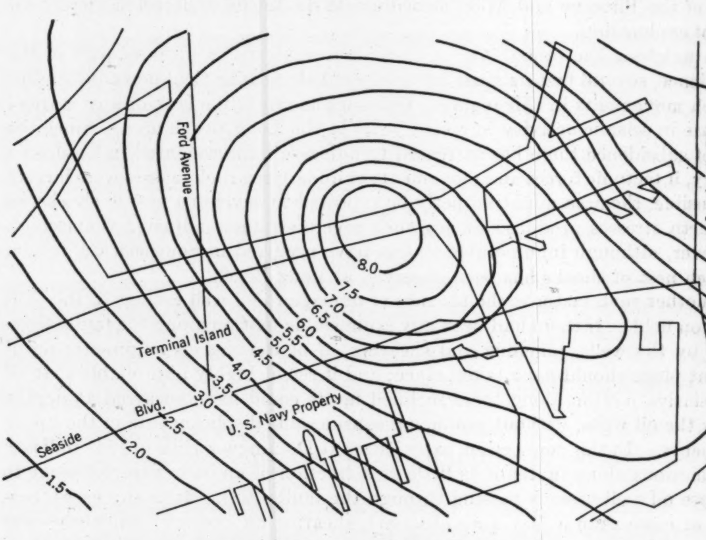

Fig. 12.—Probable Ultimate Subsidence

Continued subsidence will necessitate a restudy of the elevations and grades of certain facilities. The design of gravity sewers should be re-examined in the light of probable future differential changes in grade. Lack of proper drainage may result in some places as the subsidence continues. The same problem applies to surface grades. Such sources of future difficulties can thus be anticipated to some extent, and provisions can be made to insure continued satisfactory operation.

In conclusion, this study indicates that this vicinity should continue to serve as the site for industrial development. Present structures will continue to function satisfactorily if suitable preventive measures are adopted to avoid known possibilities of trouble; future structures can be designed to allow for probable future subsidence, which will continue for many years at a slowly reducing rate.

Acknowledgment

This paper is based on a report prepared for the Bureau of Yards and Docks, United States Navy Department, by Frederic R. Harris, Incorporated, Consulting Engineers of New York, N. Y., dated December 18, 1945, with a supple-

ment dated February 25, 1946. Invaluable assistance was rendered by R. R. Desmond, and C. M. Duke, Juniors, ASCE, who, together with the junior author, assembled the basic data examined during the investigation. Gratitude is due many individuals and agencies for their assistance in making available the necessary data—Capt. H. E. Wilson, Public Works Officer at the Terminal Island Naval Base, and members of his staff; Lt.-Comdr. A. S. Porter and Frank F. Mead and Trent R. Dames, Members, ASCE; Messrs. R. Winterburn and Butterfield of the Union Pacific Railroad Company; and many others. To all these sincere appreciation is offered.

DISCUSSION

James Gilluly,[4] Esq., and U. S. Grant,[5] Esq.—It appears that this paper contains some fundamental assumptions that are incorrect and that are believed to have led to an unacceptable conclusion. The authors (under the heading, "Factors Contributing to the Subsidence: Pumping from the Wilmington Oil Field") state:

> "As with pumping water from a confined aquifer, reduction in the liquid pressure in the oil sands produces a compensating increase in the intergranular or effective pressures in the soil structure within the stratum affected. Compression of the oil zones results. The amount of compression is influenced by the amount of decrease in liquid pressure and by compressibility of the materials within and bordering the affected zone, at top and bottom."

The writers agree with this statement. However, they wish to point out that it is entirely unproved and highly improbable that the decrease in liquid pressure has been significant except within the oil sands. It is, therefore, gratuitous to assume that it has affected appreciably the interbedded shales.

The authors essentially attribute all the subsidence to compaction of the shales interbedded in the oil sands, and bounding them above and below. They were apparently influenced by an assumption that the sands were relatively incompressible and "probably have properties close to those of concrete." Good concrete, with a low voids ratio and permeability, can hardly be similar to porous, more or less incoherent, highly permeable oil sand, such as occurs in the Wilmington oil field, Long Beach, Calif. If these two materials were similar, there would be little oil and no appreciable flow of oil in the highly productive oil wells. Inasmuch as the authors state that the amount of compression is influenced by the "compressibility of the materials within and bordering the affected zones," it is surprising that they failed to test the compaction of the sandstones, because it is only within the sands that certainty is assured of the decline in fluid pressure on which the mechanism appealed to by them depends. They omitted any tests of the sands because they believed the shales to be much more compressible, which, of course, they are, and secondly, because it was easier to obtain undisturbed shale cores than sand cores. Both these reasons are believed irrelevant.

Tests of the sandstone cores by the writers showed them to be significantly compressible, both elastically and by plastic flow—the plastic flow accomplished presumably by movement of cement from points of high pressure to stress shadows between the grains. At any rate, whatever the mechanism of the flow, these tests indicate that the sandstones are sufficiently compressible to account for the entire subsidence without appealing to the very dubious addition of shale compression. Computations for the compression of the sandstones alone yielded a theoretical subsidence about twice the actual—a discrepancy readily explicable, as the pressure drop was necessarily measured at the well points and therefore must be far greater than the average decline through the inter-well areas of the oil sand. The authors' conclusion that the subsidence was due entirely to shale compaction is somewhat surprising in view of the fact that the writers' data and conclusions were available to them in an unpublished report to the Long Beach Harbor Department in 1945.

---

[4] Prof. of Geology, Univ. of California at Los Angeles, Los Angeles, Calif.

[5] Prof. of Geology, Univ. of California at Los Angeles, Los Angeles, Calif.

The correction factor of 50%, derived from the use of the writers' sandstone compaction data, is to be compared with the correction factor of 8% that the authors must use in order to reconcile the theoretical with the actual subsidence in accordance with their theory. In other words, the theoretical subsidence by the authors' theory is about twelve times the actual. They apply a pressure decline measured in the relatively permeable oil sands to a great thickness of shales that are known from geological evidence to have a very low permeability, and within which it is very doubtful that any appreciable reduction in fluid pressure has occurred.

It is obvious that the fluid pressure within the shales can decline only by loss of fluid from them. Drilling and electric logs of the wells show that, at Wilmington, as in most other sandstone reservoirs, the oil is confined to the sandstone beds and that the shale beds associated with them are saturated with water. That the shale beds have very low permeability, at least in the direction transverse to the bedding planes, is proved by the fact that this impermeability is responsible for the trapping of the oil through geological time. Furthermore, several water sands have been sealed off from the oil sands by these same, nearly impermeable, "aquicludes." With trivial exceptions, the casings in the Wilmingtion oil field have been perforated only in the oil sands. Accordingly, the pressure decline owing to oil production has primarily occurred within the sand beds, not within the shales. Certainly loss of pressure within the sands has set up a pressure gradient within the shales which must be losing water (and hence compacting by the mechanism advocated by Messrs. Harris and Harlow). It is highly probable, however, that this is a very slow process and that it has not contributed significantly to the subsidence.

The requirement of fluid continuity demands that only as the shales lose water may the pressure within them decline. Their extremely low permeability, transverse to stratification, indicated by the geological evidence, makes it seem improbable that the water loss could have been significant within the brief period of oil extraction—ten years. The argument need not rest, however, on these grounds; yet, this assumption would be much more likely than that made by Messrs. Harris and Harlow.

The water loss from the shales, upon which their compaction must depend, can be estimated in a way most favorable to the authors' hypothesis, by assuming that all the water produced with the oil came from the shales associated with the oil sands. This assumption is known to be incorrect, because much of the small water cut at Wilmington is produced from sand zones. If it originated in the shales, and not in the edge water or interbedded water sands, such as are revealed by electric logs, it constitutes the most favorable assumptions for their hypothesis. The data on water production are highly significant, for they show that there is no relation whatever between the amount of water produced from a given block of the oil field and the subsidence of the surface over that block.

Water production from blocks III, IV, and V of the Wilmington oil field, from its discovery to January 1, 1945, is shown in Table 1, in which the data in Col. 4 were supplied by C. L. Vickers, engineer, Long Beach Harbor Department. Data in Cols. 2 and 3 are from unpublished records in the office of the Long Beach Oil Development Company. It seems significant that the subsidence shows no relation to water production, for shale compaction is absolutely dependent on loss of fluid from the shale and this fluid must be water, not oil. These data, together with the geological evidence of very low permeability of the shales, seem to compel the conclusion that the contribution of shale compaction to the subsidence has been insignificant. This is, of course, directly opposed to the authors' hypothesis.

TABLE 1.—WATER PRODUCTION AND SUBSIDENCE IN THE WILMINGTON OIL FIELD, CALIFORNIA

Block No. (1)	WATER PRODUCTION		Volume of subsidence (cu ft) (4)	Ratio of water volume to subsidence volume (5)
	Barrels (2)	Cubic feet (3)		
III	202,642	1,134,800	114,670,000	0.0098
IV	6,305,140	35,308,000	101,923,000	0.346
V	2,675,445	14,982,500	103,322,000	0.145

It is obvious that with the decline in fluid pressure and the thicknesses of oil sands, both of which are maximal in the central parts of the oil field, their product, multiplied by any arbitrary constant called "compressibility," is necessarily a maximum in the center of the oil field. Thus, the fact that the authors found a theoretical subsidence roughly proportional to the actual is not surprising, even though they applied the mechanical parameters of a substance that probably did not undergo the postulated decline in fluid pressure, and failed to consider the mechanical properties of the sands within which the fluid pressure is known to have declined.

JACOB FELD,[6] M. ASCE.—There are so few authentic data concerning the extent and cause of surface subsidence resulting from liquid removal from the subsoil that this paper should be read with interest and studied with care. From a qualitative point of view, the authors undoubtedly show the cause of the major portion of the recorded subsidence; from a quantitative approach, the methods used do leave "much to be desired," and cannot become a model for the solution of similar problems.

A comparison of the contours when drawn to the same scale shows: In Fig. 1, the actual subsidence measured from 1933 to 1945; in Fig. 11, the calculated subsidence as of 1945; and, in Fig. 12, the probable ultimate subsidence.

This comparison indicates the following general observations:

---

[6] Cons. Engr., New York, N. Y.

1. The ultimate subsidence will be about 175% of the amounts measured in 1945; and
2. There is no apparent correlation between the data in Figs. 1 and 11, and the pattern of the predicated ultimate subsidence bears no relation to that of the computed values.

These conclusions are not consistent with the information given in other parts of the paper. The shape of the settlement time curves of the four bench marks shown in Fig. 3 does not indicate a decreasing rate of settlement during recent years. Quite the contrary conclusion can be reached from the graphs in Fig. 2, as well as Fig. 3, since the first foot of settlement required about 5 years, the second foot and third foot each occurred in $1\frac{3}{4}$ years (average), and both the fourth foot and fifth foot occurred in about 1 year—all referred to 1933 as datum.

The chief cause of such a lack of coordination seems to be the implicit reliance on the method used for computing expected subsidence. Drilling cores, several years old, when tested in the laboratory were assumed to be typical of geological zones, and were taken to have average thicknesses of 500 ft and 750 ft, respectively. The computations were corrected by multiplying the shale, sandstone, and other expected compressible layers by 8% (that is, a reduction in computed values by 92%) to make one spot agree with the measured settlement at that point. It might be more logical to assume that only one layer—the weakest—caused all the subsidence.

The discussion of actual and expected consolidation settlements from soil compression and from unwatering operations indicates values quite consistent with those measured in similar soil areas along the eastern seaboard. Filled areas covering salt marshes and silt where the soil water is affected by tides, although protected by tight bulkheads, showed settlements of about an inch for each 5 years. The area along the Harlem River in New York, N. Y., has been under observation for about 75 years, and the total subsidence in that period is more than 15 in. For nearly a year dewatering in this area to a depth of 35 ft (45 ft below ground level) caused a maximum, almost immediate, additional settlement of about 5 in. nearest the excavation, with no measurable settlement some 150 ft away. In another area of similar soil conditions about 1,000 ft from tidewater, a ground-water lowering of 45 ft (55 ft below street surface) settled the surface about 3 in. In both cases very little rebound of the surface was noted when the water table was permitted to rise to normal level.

The paper, as printed, is a summary of a much longer report which may contain more convincing proof that the quantative method used is reliable, and, if so, it is hoped that the authors will publish such proof in the closing discussion.

Hyde Forbes,[7] M. ASCE.—Subsidence is a phenomenon common to many localities in California, caused by the increase in ground-water pumping, since about 1918. In this presentation of the measurement of the phenomenon, the authors advance the conclusion that it is caused principally by the consolidation of shale members of the productive oil formations underlying the area. This latter view is open to question. The total subsidence shown in Fig. 12 is less than that known to have occurred during the same period at the southern end of San Francisco Bay (California), where there was no oil production.

---

[7] Cons. Engr. and Geologist, Palo Alto, Calif.

The paper enumerates the factors contributing to the subsidence of the area in question (with which there is no disagreement) and then places a measure on each in turn:

(*a*) About 0.2 ft is attributable to surface loading;

(*b*) The effect of pumping water from the coastal plain southwest of the Newport-Inglewood fault is summarized (under the heading, "Factors Contributing to the Subsidence: Water Pumping for Industrial and Domestic Uses") as "the fraction of the total subsidence resulting from this source amounting to inches, not feet";

(*c*) The subsidence caused by the dewatering of the dock site to El. −75, based on the theoretical consolidation resulting, was assumed to be limited to the time of such dewatering and to cease with the measurement in the spring of 1942 (using curve (*e*) in Fig. 3, this would be less than 1 ft); and

(*d*) The subsidence resulting from the consolidation of the oil measures to considerable depths because of the extractions of gases and fluid. Item (*d*) is cited as the major factor.

The writer will discuss these factors from the point of view of his knowledge of conditions, believing that the subsidence in the Terminal Island area, in particular, is due to three causes which, although incapable of exact measurement (but in order of magnitude), are: (1) The dewatering and the compacting of the sand making up the island and its continuation toward the shore below tide level; (2) the dewatering and the compacting of the alluvium of the Southern California coastal plain with the increased draft upon ground water for water supply purposes; and (3) possibly some compaction of the sands of the oil measures with the withdrawal of their fluid content under the weight of the overburden. It is doubtful that the shale members of the bedded sediments have suffered any further consolidation since 1937. It is true that the interbedded sands would provide drainage of facilities equivalent to the porous stones (of the tests performed). However, the increased loading required for consolidation of the shale does not exist, because the additional surface loading to be transmitted to depth is much less than the fluid load that has been removed from the overlying beds and sediments.

The writer's first acquaintance with Terminal Island was in the school year, 1907–1908, when the Saturday field trips of the Los Angeles (Calif.) High School science class took him to the island and to the adjacent Long Beach-San Pedro coast line. The lecture about the island was of great interest and of lasting memory. It was used, by the well-informed Prof. J. Z. Gilbert, to illustrate the formation and composition of a sand spit, which was a section of an extensive sand bar extending above water level. The bar had been built up, torn down, reformed, and shifted in position from time to time by the action of ocean shore currents and waves upon the coarser sediments brought to the shore line and dropped by both the Los Angeles and San Gabriel rivers. The spit and bar, with the overlying estuary mud, consisted of more than 50% water by volume, and so was unstable under the attack of tidal current and wave action.

The writer sees no reason to change the concept passed on to him at that time. The construction of the breakwater and the dredging of the harbor minimized the wave and current action and, with the filling in of the marshland between the island and the present location of the Pacific coast highway, the sand above and below the estuary and shore mud and clay settled to firmer bearing as the loosely held water was forced out of the pore space. At that time ground-water levels were well above high tide. Fresh water springs flowed into slough channels in the marsh at low tide. Some of these channels were dammed to provide for fresh water duck ponds, and there were numerous bodies of fresh water in slough channels cut off from tidewater.

With these facts in mind, it is difficult to agree with the authors that the filling and loading of that extensive marshland and island, more than 1 mile in average width, was not responsible for continued settlement and the more than 0.2 ft adopted for the period. The base of the cut and cover fill placed over garbage deposited along the shore of San Francisco Bay is continuing to settle with the compaction of the bay mud. Also, considering the extent and physical make-up of the sand, it is unlikely that all settlement, due to dewatering those sands to El. −75 for dry dock construction, ceased with the cessation of pumping at the end of the construction period. Even though water levels in wells were shown to recover, that necessarily is not proof that the pore space between sand grains is not, although slowly, contracting further as the lesser amounts of water held in them rise to the former level registered in the wells.

The void space that comprises the storage capacity of a ground-water reservoir contracts with the withdrawal of water or with the lessening of hydrostatic pressure. When the water column again reaches its former level at the higher part of the reservoir or basin, equal hydrostatic pressures are transmitted throughout; but the void space or storage capacity is never recovered, constituent grains never being unseated. This has been clearly demonstrated in the Santa Clara Valley of California through the observation of well water levels and discharge and artesian flow from wells during the period from 1933 to 1948 (24). The same thing can be assumed to be true in relation to oil sands. When the oil migrated to the sand beds it occupied voids filled with water in which the sediments were deposited. The oil and gases (being lighter) rose in the water, forcing the water down the dip of the strata, and were compressed by the pressure so developed in the formation. As the volume of gas, oil, and water was removed from the sands, the void space would contract. Just when the subsidence due to dewatering the top sand to El. −75 ended (if it has), and just when the subsidence due to voiding the oil sands of their fluid became effective, is a matter for question, and, in the opinion of the writer, indeterminate.

During 1920–1921 the writer made a study of the Southern California coastal plain, from Redondo Beach (Calif.) to beyond Long Beach, for the Shell Oil Company to locate and determine the character of geologic structures buried by the alluvium of the plain through the application of ground-water hydrology. The study consisted of a canvass of all water wells of the area; a compilation of available information as to log, depth, water yield, and past water levels; and the determination and correlation of the then existing elevation of well water levels through lines of levels run by accompanying survey parties. Several facts had a bearing on the subsidence that was then occurring with the lowering of ground-water levels and the restriction of the artesian flow area with the increase of pumpage. The bench marks of the areas between Signal Hill, Dominquez, and Palo Verdes Hills and along the coast south and east of Signal Hill were consistently so much lower than their published datum that it was obvious that all minus determinations could not be attributed to accumulative error. Owners of dug wells along some sloughs volunteered the information that the water from those wells had been potable but, since the breakwater was built and the harbor was dredged, the tides changed and came so far up the sloughs that they seeped into their wells and made the water so brackish that they had to be abandoned. Obviously this condition was due to subsidence of the slough channels, and to decline of ground-water levels. Well water levels dating from 1902 were obtained for comparison from United States Geological Survey (U.S.G.S.) publications (10)(25)(26) and from the U.S.G.S. office in Los Angeles, as well as from the owners themselves. These showed the cause; the level lines, the effect. The lowering of the bench marks was also corroborated by the office of the United States Coast and Geodetic Survey.

This paper, as well as one covering the same area and subject (27) is of value in "pointing up," by direct analogy with the exhaustion of the valuable mineral resource, petroleum, the fact that the even more valuable resource to the semiarid west—ground water—is being exhausted by the gradual elimination of ground storage capacity through the contraction of the underground void space under the weight of the overburden with the lowering of ground-water levels through overdraft. It has long been a matter of concern to the writer, and has become particularly acute during the severe winter drought of 1947–1948 in California and Nevada. The writer has recommended shutting down the pumping plants of the well field of the City of Palo Alto (Calif.) and purchasing the total domestic supply from San Francisco's Hetch Hetchy surface water supply in order to conserve what ground-water storage capacity remains. He has also opposed the drilling of new wells for clients in the Santa Clara and San Joaquin valleys of California, because there is now more well capacity in the basins concerned than there is ground-water capacity to satisfy it. Overdraft will reduce water levels, allow contraction of pore space, and thus reduce ground-water storage capacity.

In view of the facts, the writer is of the opinion that the accelerated subsidence of the Terminal Island area since 1941 is attributable, in the main, to the dewatering, through continued pumpage necessary for constructing the dry dock, of the sand and other surface deposits down to El. −75. The tests on the shale samples are interesting, yet they are in no way conclusive, nor do they change the writer's previously expressed opinion (28)(29) that the application of the theories of soil mechanics and the results of tests upon small samples are of value only as a check on judgment based on determinable facts and should not be used to evaluate cause and effect in numerical terms.

Paper No. 2339

RIVER INFILTRATION AS A SOURCE OF GROUND WATER SUPPLY

By Raphael G. Kazmann,[1] Assoc. M. ASCE

With Discussion by Messrs. C. V. Youngquist, and Raphael G. Kazmann.

Synopsis

The characteristics of a ground water supply based on the infiltration of water from a near-by stream are discussed. The effect of changes in river stage upon yield, as well as the effect of changes in river temperature on well field yields, drawdowns, and water temperatures, is revealed through the data presented. The absence of pathogenic bacteria from the ground water despite the contamination of the source of water is shown.

The paper describes a method of testing a well field of horizontal collectors to determine the firm yield of the field under the worst probable conditions of river stage and temperature.

The construction of a horizontal collector is described and the production record and operating characteristics of a field of seven such units are given in

detail. The paper is based on more than four years of careful observation of the water supply of the Indiana Ordnance Works near Charlestown, Ind., and was written while the writer worked for the United States Geological Survey.

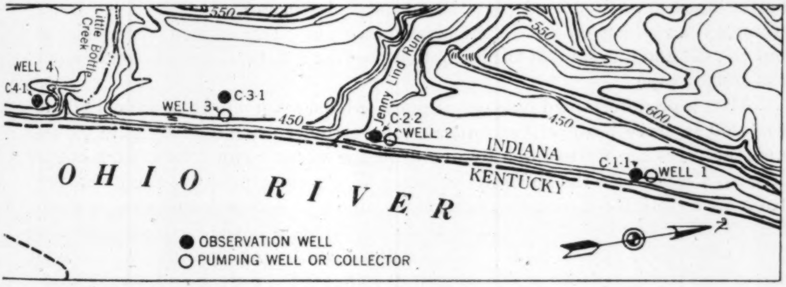
INTRODUCTION

An adequate supply of water is becoming more important as new industries develop which depend on large quantities of water for cooling purposes and in manufacturing processes. The producers of foods, synthetics of all kinds, and precision machinery are among the newer industrial water consumers. The problem of obtaining large quantities of satisfactory water at a minimum cost is a difficult one, even under the best of circumstances. If it is available, ground water is particularly desirable because of its cheapness and its relatively uniform quality.

This paper summarizes the data and conclusions obtained from a study of the ground water supply of the Indiana Ordnance Works. Since the well field is composed of seven horizontal collectors, a brief section is devoted to their construction. However, the greater part of the paper contains an analysis of data obtained during more than four years of continuous well field operation and includes the details of a test conducted to determine the capacity of the water production system.

LOCATION AND DESCRIPTION OF WELL FIELD

The well field of the Indiana Ordnance Works is situated on the Indiana shore of the Ohio River about 12 miles north of Louisville, Ky., between the river and the upland on a narrow flood-plain terrace composed primarily of gravel, although covered by a layer of silt and top soil. The geology is not significantly different from any one of a hundred terraces along the Ohio River. The log of observation well C-6-1, which is 30 ft from collector 6 (see Fig. 1) is typical:



INDIANA ORDNANCE WORKS

Depth (ft)	Description
0 to 18.5	Top soil
18.5 to 50	Gravel boulders and sand, mixed
50 to 65	Pea gravel
65 to 72	Sand and fine gravel
72 to 93	Fine gravel (screen set at 93 ft)

The bedrock floor, which is about 100 ft below the land surface at the river's edge, continues at that elevation inland from 200 ft to 500 ft. On the basis of test drilling inland there seems to be a sharp rise in the rock floor which flattens off about 30 ft or 40 ft below the land surface and meets limestone bluffs as much as 1,500 ft inland. On this basis alone the gravel area would seem to be a relatively large one. Actually, the width of the aquifer from which the collectors draw water ranges from about 200 ft to 500 ft, extending inland from the river's edge. Fig. 1 is a map of the Indiana Ordnance Works field which shows the collector locations. Production wells are plotted to scale but observation wells are spotted diagrammatically. The gravels extend into the river an undetermined distance, but gravel companies dredge gravel in the reach opposite the well field from about 500 ft to 1,500 ft offshore.

Construction of a Collector

A collector is a caisson in the lower end of which are one or more tiers of portholes. The portholes are spaced uniformly in each tier. After the caisson (usually 13 ft in inside diameter) reaches the requisite depth, a thick concrete plug is poured on the bottom to keep out water and extraneous material. After the plug has hardened, lengths of slotted well casing 8 in. in diameter are jacked hydraulically into the surrounding water bearing formation. The boring head of each slotted pipe lateral has holes in it enabling the returning water to carry fines with it to the central caisson. This flow of water washes out the silt and fine sand of the formation, leaving a natural gravel pack around the slotted pipe.

After a predetermined number of pipes, with a total length of from 1,000 ft to 1,200 ft, have been pushed out, all the portholes are closed by gate valves and the pipes are flushed one by one until the water coming from each one is free from sand. At the Indiana Ordnance Works the amount of sand removed from each collector during the pushing of pipe was between 50 cu yd and 100 cu yd. Fig. 2 shows a plan and section of collector 4 of the Indiana Ordnance Works which is a typical unit. The position of the laterals, relative to the Ohio River and to the bottom of the caisson, is indicated. Figs. 3 and 4 are photographs taken during the construction of similar collectors.

Collector Field Operation

The collector field consists of seven horizontal collectors spaced at intervals of from 1,300 ft to 2,000 ft within 100 ft of the river's edge at normal pool stage. In each unit two pumps were installed each capable of delivering 3,500 gal per min. Thus, the field had a pumping capacity of approximately 49,000 gal per min or about 70 mgd. The field was first pumped in April, 1941, and was in continuous operation until October, 1945.

From April, 1941, to April, 1945, inclusive, a period of forty-nine months of continuous operation, a total of 58.3 billion gal was pumped at an average rate of 39.7 mgd. The highest monthly pumping rate occurred in September, 1944, when an average of 51.2 mgd was pumped. The lowest monthly pumping rate during routine plant operation occurred in November, 1941, when 28.1 mgd were pumped. The days of greatest water production were September 15, 1942, when 55,975,000 gal were pumped and June 26, 1944, when 55,742,000 gal were pumped. No data are available for peak hourly water supply, but undoubtedly the field has been pumped at a rate of more than 60 mgd for short periods. The average daily water production for each month of plant operation is shown in Fig. 5.

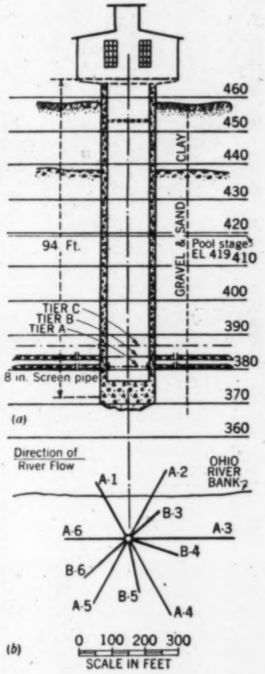


FIG. 2.—COLLECTOR NO. 4, FIG. 1

HYDROLOGY

It has been found that the principal source of water pumped by the collectors was water from the Ohio River which infiltrated to the aquifer. The source of the water can be demonstrated in a number of ways: By comparison of river and well hydrographs; by a study of river and collector field water temperatures; and by a study of the variations in water temperature which occurred in the several laterals of a single collector.

The relationship between water level, river stage, pumping rate, and the viscosity of water is indicated by a study of river and observation well hydrographs and pumpage.

For example, the Ohio River was approximately at pool stage, El. 420, throughout the months of January, 1944, and June, 1944. In January the average daily pumpage from the field was about 34 mgd; in June it was nearly 49 mgd. At collector 6 the average daily pumpage in January was slightly more than 5 million gal; in June it was slightly more than 9 million gal; yet, despite a constant pool stage and an increase in pumpage in the entire field, the average water level elevation in observation well C-6-2 (200 ft inland from collector 6) rose from 399.5 ft in January to 402 ft in June.

The only major variable factor not heretofore mentioned is temperature. In January the average collector water temperature was 59° F and in June it was 55° F. However, the river water temperature averaged 35° F in January and 78° in June. For rough computations, the average of the river and collector temperatures in January was 47° F; in June, 67° F. The kinematic viscosity of water changes from 1.38 to 1.01 centipoises in that range—a decline of more than 35%. This decline in water viscosity evidently accounts for an apparently contradictory condition: Same river level; more water pumped;

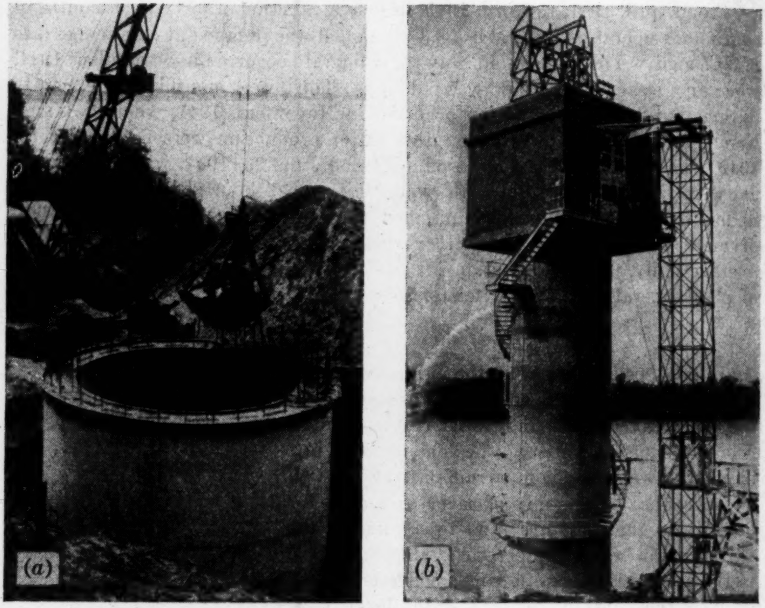

FIG. 3.—CONSTRUCTION VIEWS

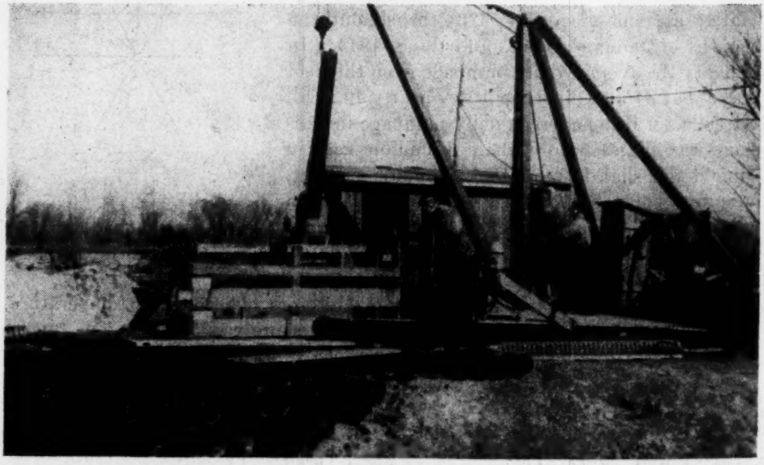

FIG. 4.—LOWERING SLOTTED PIPE INTO CAISSON FOR INSTALLATION AS RADIAL COLLECTORS

smaller drawdown in aquifer and pumped well. The subject is discussed more fully later in this paper.

The effect of a rise in the river stage was an immediate rise of water level in the pumped well and the observation well despite a constant pumping rate, as is illustrated by the rise in water level in well C–6–2 in April, 1945, paralleling a river rise despite a constant pumping rate at collector 6. The aquifer in the neighborhood of collector 6 was under water table conditions as long as the water level was below El. 420. Consequently, changes in water level represented a gain, or loss, in water storage.

Changes in the pumping rate at collector 6 also had an immediate effect on water levels in well C–6–2, regardless of the trend of water levels due to changes in the river stage. Detectable changes in water level in the vicinity of the collector were caused by minor variations in pumping rates.

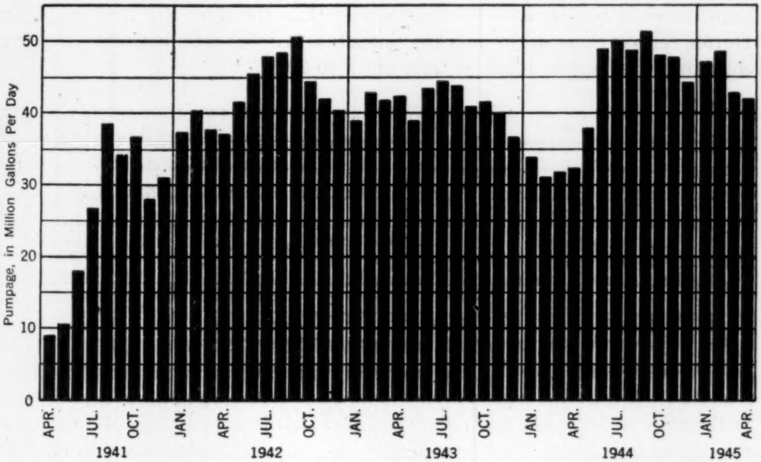

Fig. 5.—Average Daily Water Production from Well Field

River water temperatures and their effect on ground water temperatures form a very complex subject. Fig. 6 shows thermographs of the river water and of the water discharged by several of the collectors into one of the two main reservoirs of the plant. A study of the available data indicated that a seasonal trend in river temperatures was followed by a similar trend in collector water temperatures from eight to twelve weeks later. However, the period of lag has differed from collector to collector, being as little as six weeks in one and as much as fourteen weeks in another. The lag at any particular unit appeared to depend on the operation schedule and on the interference of near-by units and the geology of the aquifer, as well as on the abruptness of river temperature changes.

A study of the problem of temperature fluctuations in the aquifer shows that there were several factors involved: (1) The mixing of ground water with infiltrated river water when the field was first pumped; (2) the admixture of river waters of different temperatures while en route to the collector; (3) the heat storage of the aquifer and underlying rocks; and (4) the conduction of heat upward to the surface and laterally within the aquifer due to temperature gradients.

The water coming from the river entered the aquifer not only directly opposite the collector, but also upstream and downstream from it. Thus, different hydraulic gradients were established between the collector and the river depending upon the point of infiltration of the water. The nearer to the collector that infiltration occurred, the steeper the gradient and the greater the water velocity, all other things being equal. As a result, water that left the river a long time ago reached the collector by one path at the same time as water that left the river more recently reached the well along another path. Thus, an integrating process went on in the aquifer to produce water warmer than the river temperature lows and cooler than the river temperature highs. During certain times of the year the temperature differential between river and collector water was as much as from 18° F to 20° F.

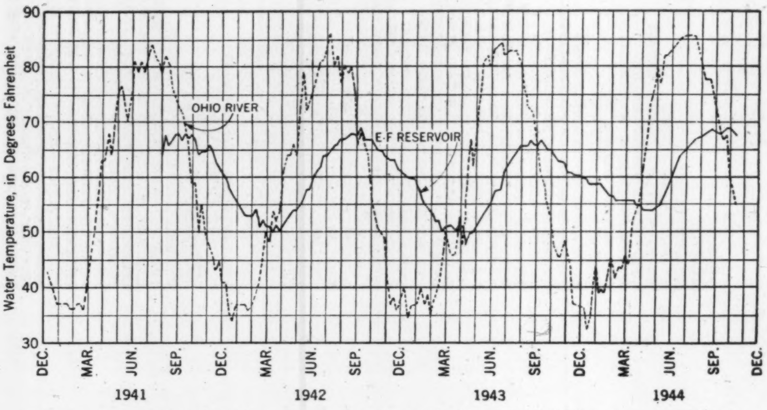

Fig. 6.—Thermographs of Ohio River Water and Pumped Water Entering a Reservoir

The foregoing description is, however, an oversimplification of the actual physical process involved. Superimposed on this idealized mechanism is the effect of temperature on the viscosity of the water and consequently on the manner of flow in the aquifer. The viscosity difference increases the percentage of warmer water entering the well as compared to the idealized case. In the summertime, when the river is warm, water coming from the reach opposite a well will have the advantage of decreased viscosity plus the steeper hydraulic gradient as compared to older (and colder) water already infiltrated from other reaches of the river. On the other hand, in the winter, when river temperatures are low, the viscosity factor will tend to increase the relative velocity of water infiltrated from the river at an earlier date and from greater distances as compared to the newer and colder water approaching the well along the direct path. This condition and others, such as heat flow within water and heat storage by the aquifer and its underlying bedrock, tend to make the exact mathematical analysis extremely involved for even the simplest example of flow to a well.

TEMPERATURE CHARACTERISTICS OF INFILTRATED WATER

The units at the Indiana Ordnance Works are composed of eight or ten laterals (actually horizontal wells) converging to a central caisson. In 1943, thermocouples were installed on eight of the laterals in collector 4 and arrangements were made to obtain periodic temperature readings. Fig. 7 gives typical thermographs.

When these thermographs and the layout of the laterals in Fig. 2 are studied, the relationship between the position of the lateral and the temperature variation becomes apparent. As might be expected, the laterals which project toward the river are more affected by river temperature changes than are those which project to the land side. A temperature differential of 16½° F existed on September 22, 1944, between laterals A-2 and A-5.

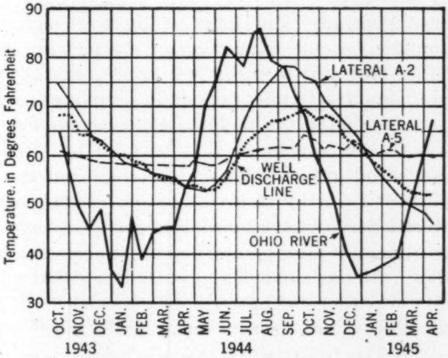

FIG. 7.—THERMOGRAPHS OF THE OHIO RIVER, DISCHARGE LINE FROM WELL 4, AND LATERALS A-2 AND A-5

One deduction to be made from this data is that, even under the same conditions of hydraulic gradient, the proportion of water entering the collectors from each lateral is constantly changing throughout the year in response to temperature changes in the aquifer. The reason for this is found in Darcy's equation for flow in porous media:

$$Q = \frac{P\,i\,A}{\mu} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which Q is the quantity of flow; P is the permeability of the materials composing the aquifer; i is the hydraulic gradient; A is the cross-sectional area perpendicular to the direction of flow; and μ is the viscosity of the fluid. Ignoring other factors, in the range of temperatures shown in Fig. 7 from 46° F to 78° F, the coefficient of viscosity ranges from 1.39 to 0.88 centipoises. In other words, the coefficient of viscosity of 78° F is only 63% of the coefficient at 46° F.

SANITARY QUALITY OF COLLECTOR WATER

The bacteriological quality of the raw water from each collector has been periodically tested. Although the 37° C plate count has almost always shown the presence of bacteria in the water obtained from the collectors, further tests with lactose broth incubated for 24 hours and 48 hours have rarely shown the presence of gas forming bacteria. For example, between August 1, 1944, and April 1, 1945, a typical eight-month period which included a long period of high water during which the river overflowed parts of the collector field area, a total of two hundred and twenty samples was tested. Of these, a total of eight samples (10-milliliter portions) formed gas in lactose broth and only two confirmed.

The collectors that produced the gas forming water samples were retested as soon as possible. No gas forming organisms were found. Had the aquifer been generally contaminated by the source of recharge, the retesting undoubtedly would have revealed gas forming organisms. After a study of the entire four-year record it was concluded that the contaminated samples were probably due to minor errors in sampling technique.

Considering the polluted character of the Ohio River next to the field, it was further concluded that harmful bacteria were removed or killed in the sands and gravels between the river and the collectors. How this is accomplished is worthy of investigation, because tests by the United States Public Health Service have shown that some gas forming bacteria survive the complete treatment of filter plants[2] making it necessary to resort to break-point chlorination. Among some of the possibilities that have been suggested are: Adsorption of pathogenic bacteria by the particles of silt, clay, sand, and gravel (note the use of diatomaceous earth in the latest techniques of filtration); death of pathogenic bacteria due to change in environment or lack of food; filtration by the fines at the bottom of the river; and elimination of pathogenic bacteria by action of such organisms as plankton or ground bacteria. However, until a systematic study is undertaken which leads to a workable hypothesis the facts are that coliform organisms rarely, if ever, were found in the water pumped by the collector field of the Indiana Ordnance Works.

WILL SILT CLOG THE INTAKE AREA?

In comparing the infiltration of river water to an aquifer and the passage of water through a slow or rapid sand filter, there appears to be only one major point of similarity—the fact that water must pass through a porous medium. In a filter all the available water must pass through, and deposit all its fines on, the surface of the filter. In the infiltration area of an aquifer the principal movement of water is along the river bottom in planes roughly perpendicular to the direction of infiltration. The fines, therefore, do not remain on the surface of the area as they would if raw river water were led to sand beds without prior sedimentation. The fines are continually removed by the river and replaced temporarily by material coming downstream—that is, the bed is constantly scoured and built up. Moreover, occasional periods of increased discharge put the fines back into suspension, leaving only the heavier sands and gravels on the river bottom. Evidently river infiltration to an adjacent aquifer should not be expected immediately upstream from a dam as the deposition of silt and fines will occur and preclude infiltration.

---

[2] "Studies of the Efficiency of Water Purification Processes," by H. W. Streeter, *Public Health Bulletin No. 172*, U. S. Public Health Service, Washington, D. C., May, 1927.

The reason sand beds in a filter plant must be scraped or backwashed is that a gelatinous layer of fine silt and organic matter forms on the filter bed surface. The efficiency of the filtration process probably depends on the existence of this layer. The filter plant operator wages a constant struggle to maintain a certain amount of the material on the sand bed, yet to prevent it from sealing the filter completely. Periodically this layer is removed by scraping or backwashing. As far as can be determined, no such continuous layer has ever formed on the surface of the infiltration area supplying the Indiana Ordnance Works well field.

There is no evidence that permanent silting occurred during the period of collector field operation. All the data indicate that the production capacity of the field remained unchanged during the entire period of operation.

Calibration of the Collector Field and Prediction of Firm Yield

The field had been operating successfully for about a year when, for various reasons, it was decided to make pumping tests to determine the magnitude of interference between the units and the probable minimum yield of the system when operating at full capacity.

Since the plant was in full production at the time, the testing had to be performed without interfering with plant operations and no water could be pumped to waste.

It was planned to operate the field, or most of the field, the same way save for one difference in pumping rate in one collector. Most of the time this was not feasible so all variations in plant water demand had to be met at the end of the field farthest from the point of principal interest. Thus, while tests were being run on unit 1, variations in plant load if any were to be taken by units 7 and 6, respectively.

Presumably, after allowing for river stage fluctuations and water temperatures, all differences in drawdowns in collectors 1, 2, 3, and possibly 4, would be due to the change in the pumping rate of collector 1.

A systematic scheme of pumping the field was prepared and the testing was started with the fullest cooperation of the War Department and the E. I. du Pont de Nemours Company, the plant operators. The tests lasted for nearly four months, during which time a number of pumping schedules were nullified because of operating demands. Eventually, however, seven reasonably satisfactory pumping schedules were carried through and temperature and water level data were obtained as needed.

From previous experience it had been found that about four days of pumping at a constant rate were sufficient to establish a steady flow of ground water in the aquifer, so each schedule was followed for four days. Water levels within each caisson could be determined by automatic air-line water level recorders. However, since there was an observation well within 30 ft of each caisson, water levels were also determined there by steel tape measurements. It was found that the drawdowns in these observation wells were substantially the same as those in the respective production wells. As it was easier to secure accurate measurements in the observation wells, and as these wells fluctuated less due to slight variations in pumpage, the water level elevations of the observation wells were used in the computations.

During the test period, collector water temperatures were changing from 60° F at the start of the period to 70° F at the end. In order that the data might be comparable, the drawdowns were corrected to a standard temperature of 68.5° F at the collector where the temperature was measured. The corrections were made on the basis that, in steady state flow through porous media, the drawdown is inversely proportional to the viscosity—that is, a well pumping 10 mgd at a temperature of 60° F with a drawdown of 10 ft would have had a drawdown of only 8.9 ft at the standard temperature, 68.5° F. To illustrate the method of operation and the type of data obtained, an operation schedule is summarized in Table 1. All the usable data obtained during the pumping tests are given in Table 2.

[a] In observation wells. [b] Omitted from average because of antecedent conditions. [c] Mean river elevation: 419.45.

By a process of comparison the drawdown of each collector and its interference with all others, for a pumping rate of 10 mgd, was finally obtained. This was checked by recomputing the elevations at each collector taken from each pumping schedule using observed temperatures and river levels. These elevations were compared with the observed elevations; and, when a significant discrepancy appeared, the cause for the discrepancy was sought. Sometimes too much weight had been given to the poorer data. Minor corrections were then made on a trial basis. Finally, Table 3 was obtained, which summarizes the drawdowns caused at each production unit by any single collector pumping 10 mgd at a temperature of 68.5° F. Table 3 can be regarded as a mathematical model of the collector field in a state of steady flow.

[a] Variant. [b] Corrected to 68.5° F.

These tests furnish the factual basis for comparing the performance of the collector field with that at any future date. They will enable any theories as to apparently reduced collector field yields to be answered by a similar test. Any silting or reduced infiltration capacity of the aquifer would result in a reduction in water level elevations throughout the field as compared to the 1942 standard, under the same conditions of pumping, after corrections for temperature have been made.

7.....	....	....	....	....	1.4	2.4	10.8

The test results, moreover, can be usefully applied in predicting minimum collector field yields and in making sure that the installed pump capacity in each unit matches its capacity.

The first steps in predicting minimum collector yields were: (1) To test the ability of the mathematical model to predict drawdowns on the basis of observed pumping rates, water temperatures, and river levels; and (2) to compare such predictions with the observed drawdowns. If these data were reasonably accurate, the model might then be used in predicting minimum yields; but, as minimum yields are to be expected during low pool stages in the winter and early spring, the mathematical model also had to be tested under these conditions.

Since the temperature distribution in the aquifer is so complex, it would be on the safe side to use the lowest measured water temperatures during any period. In the summertime the lowest temperatures in the aquifer are near the water collector; and, as long as river water temperatures are above collector water temperatures, this condition must exist. The original calibration tests were conducted under such conditions; hence, temperature corrections were based on the temperature of water discharged by the collectors.

However, in the winter when river temperatures are low, theoretically the temperature to use would probably be that existing somewhere between the river and the collectors. There appears to be no logical reason why the arithmetic average of the river and collector temperatures should be used when the temperature distribution in the aquifer is so complex. In any event, over a period of from thirty to sixty days of constant operation in the winter, the governing temperature would seem to approach the average river temperature during that period as a limit. A study of river temperature records since 1910 furnished by the Louisville Water Company shows a normal range in temperature for the winter period from 32° F to 43° F, with occasional freakish days above 43° F.

A complete record of pumpage at the Indiana Ordnance Works since April, 1941, has been available to the writer. It might, therefore, appear to be a simple matter to find a number of three-day or four-day periods of pumping at a constant rate which would serve to test the mathematical model. However, because of the man-power shortage and the confidence of the plant operators in the permanence of the supply, the systematic measurements in the observation wells which had been made at weekly intervals in 1941 and 1942 were decreased in frequency until, in 1945, only one measurement was made a month. The constantly changing water demand of the Ordnance Plant further tended to decrease the probability of the water level measurements occurring at the end of a period of constant pumping. However, a careful study of all the data revealed six periods between August, 1942, and December, 1944, during which the requisite conditions were approximately satisfied. Of these, three occurred in the summer and three in the winter.

Table 4 summarizes the water levels computed by the mathematical model, the observed water levels, and the difference between them.

All errors preceded by a minus (−) sign are on the unsafe side—that is, the observed water elevation was lower than the computed water elevation. Some of the errors result from major pumping variations, as on August 20, 1943, when the pumping rate at collector 1 changed considerably during the selected period. However, other large errors are not so readily explained and may result from temporary curtailment or increase in pumpage due to discharge-line pressure changes just prior to making the water level measurements.

A study of the data shows that the mathematical model of the ground water supply system works reasonably well when discharge temperatures are used in the summer and average river temperatures are used in the winter.

After the mathematical model was tested, the percentages of maximum errors on the unsafe side for each collector in numerical order were found to be 14.3, 5.8, 2.4, 3.1, 10.6, 16.2, and 14.0, respectively.

It is of interest to note that all the maximum observed errors on the unsafe side occurred during the period dated August 20, 1943, when the temperature factor favored large yields.

[a] Estimated.

The final step in determining the firm yield of the collector field was to use the construction data as a basis for computing yields. The maximum drawdown in each unit is governed by the elevation of the uppermost tier of installed laterals and the contractor's instructions stated that a minimum of 3 ft of water was to be maintained above the uppermost tier. These specifications were used as the basis for computations.

The firm yield of the field was found by trial, using the mathematical model corrected to a temperature of 35° F. This temperature is believed to be the average that can be expected to occur for fairly long periods during a normal winter. Pool elevation is taken as 419.0 ft in computing allowable drawdown. A significantly lower pool elevation can be expected only when wickets of the Louisville Dam are lowered to break up ice jams, a truly infrequent occurrence. The first step is to compute Table 5, assuming a pumpage of 10 mgd from each well. Using Cols. 9 and 10, Table 5, as a basis, a first approximation of firm water is obtained by multiplying the ratio between the available drawdown and the computed drawdown by 10 mgd. Data thus obtained are placed in the mathematical model and a new set of drawdowns is computed and similarly compared with the available drawdowns. This procedure is repeated and new values of pumpage are obtained for each collector until the computed drawdown and available drawdown coincide. After repeating this process three times, the firm yields of Table 6 were obtained based on the assumption that the whole field is pumped at the same time. Pump installation to at least the indicated capacity is required in each collector to obtain the maximum well field yield under adverse circumstances.

TABLE 5.—TRIAL SPECIFIC DRAWDOWNS, IN FEET, CAUSED BY PUMPING EACH COLLECTOR AT 10 MGD WHEN THE TEMPERATURE IS 35° F AND THE POOL STAGE IS 419.0

Additional data on river temperature probabilities and a considerable amount of statistical analysis will be required to establish design temperatures for collectors or wells obtaining water from river infiltration. Incidentally, this branch of hydrology may also be valuable to engineers interested in protecting levees from dangerous underseepage; a levee that may be safe from dangerous underseepage during a February or March flood might be unsafe from an equal river stage occurring in May, June, or July. The phenomena, it should be noted, are fundamentally identical.

CONCLUSIONS

Study of the water supply of the Indiana Ordnance Works has demonstrated that nearly all the water pumped has originated in the Ohio River and has infiltrated to the aquifer. Water collectors or wells deriving water from such a source will furnish water whose temperature variation follows the variation in temperature of the river water, but with a lag and reduction in amplitude fixed by the hydrology of the aquifer and the operation of the field.

At the Indiana Ordnance Works, the temperature of the water pumped from the collector field as a whole varied from 49° F to 70° F, although individual units furnished water whose temperature was as much as 2° F above or below this range. The range in temperature is determined by the temperature variations of the source of water, the distance to the recharge area, the landward extent and transmissibility of the aquifer, the rates and durations of discharge, the heat storage of the aquifer and movement of heat within it, and the water contribution from the land side of the aquifer.

Furthermore, the temperature of water discharged by each lateral of a unit is primarily determined by its relationship to the source of recharge. At the Indiana Ordnance Works, a temperature differential between 15° F and 20° F was found to exist during certain times of the year in water entering a single caisson from individual laterals.

Temperature of the water has a profound affect on the minimum quantity of water, or firm water, available from units whose maximum drawdown is fixed. The design temperature for computing the firm water approaches the lowest average river temperature prevailing over a one-month or a two-month period.

The firm yield of an existing collector field deriving its water from river infiltration can be determined by methods which have been described in this paper. Such tests are valuable in so far as they furnish the operator with a quantitative method to detect any deterioration in the collectors or the infiltration capacity of the aquifer. They are also useful in balancing installed pump capacity with collector productivity. The firm yield of a field must be known in order that additions to water supply capacity can be logically planned.

The bacteriological quality of the water discharged by the collectors at the Indiana Ordnance Works was extremely good. Gas forming organisms were rarely found in the water and it is believed that the gas formers as well as the few coliform organisms which were found by bacteriological tests were the results of careless sampling technique, despite the heavy pollution of the Ohio River. Tastes and odors were apparently absent from the water discharged by the collectors, although no systematic attempt was made to detect them. Natural purification of polluted water by aquifers undoubtedly merits more study than it has received in the past.

ACKNOWLEDGMENTS

Nearly all the data collected during the four-year period covered by this report were collected by the personnel of the Indiana Ordnance Works. That the thousands of measurements of water levels, pumpages, temperatures, and bacterial quality could be correlated at all is tribute enough to the industry and ability of these men and women.

The assistance of the War Department and the E. I. du Pont de Nemours Company is acknowledged with thanks. Special mention should be made of the capable and cooperative commanding officers of the Indiana Ordnance Works during the period: Brig.-Gen. R. E. Hardy and Col. Kelly H. Lewis, his

successor. Captains A. L. Ahlers, E. E. Keiser, and A. J. Klemka and their civilian aides, including John E. Ulrich and the late L. G. Couter, also rendered valuable assistance.

The plant managers of the Indiana Ordnance Works—J. F. Daly, R. F. Boltz, and M. L. Valentine—cooperated fully to facilitate obtaining the required information. Power superintendents F. M. Acker and C. C. Hagerty, as well as members of the power and water staff, including C. F. Parcels, G. R. Calhoun, S. G. Ferris, and C. M. Fair, were most obliging and helpful. Members of the Wilmington (Del.) office of the E. I. du Pont de Nemours Company, especially E. B. Showell and W. J. Sloan, were most cooperative in facilitating the study.

E. W. Silitch, M. ASCE, and A. D'Audiffret of the Ranney Method Water Supplies, Inc., rendered substantial assistance by furnishing engineering information and construction data as well as some of the photographs used in this article.

The writer desires to thank the various members of the Division of Ground Water of the United States Geological Survey for criticism and supervision as well as encouragement in conducting the study described in this paper. In particular, thanks are due to O. E. Meinzer, formerly geologist-in-charge of the Division of Ground Water, under whose general supervision the work was done; the late D. G. Thompson, geologist; and L. K. Wenzel and C. E. Jacob, Assoc. M. ASCE, hydraulic engineers, whose criticism has been invaluable.

Acknowledgment is also made to the Director, Geological Survey, United States Department of the Interior, for permission to publish the material contained in this paper.

DISCUSSION

C. V. Youngquist,[3] **M. ASCE.**—A timely and thorough analysis is made for the profession of a water-supply installation, utilizing as its source ground water, which is replenished principally by river infiltration. The writer would like to add some general statements on river infiltration with particular reference to experience in Ohio.

The use of ground water has more than doubled in the decade from 1937 to 1947 because of its increased demand by industry, municipalities, and agriculture. Ground water is desired because of its low temperature, constant chemical quality, clarity, and freedom from pollution. The increased demand has required a more thorough inventory of the ground water resources, particularly those that determine quantities available for further development. Under conditions of ground water occurrence in Ohio the source and rate of ground water recharge is all important if a permanent supply is to be developed.

Investigations of Ohio's ground water resources by the Ohio Water Resources Board in cooperation with the United States Geological Survey have established the fact that the greatest ground water pumpage in Ohio occurs in present stream valleys underlain by permeable glacial gravels. In these areas the principal source of ground water recharge is generally river infiltration, which occurs continuously through the stream bed and, in some instances, through permeable areas in the flood plains when the river is at flood stage.

River infiltration can be ascertained by the following methods: (1) Actual measurement of stream loss through infiltration by current meter in the vicinity of a producing well field, which is possible only when the ground water pumpage is large enough to be an appreciable factor of the stream flow (which, of course was not the case in the example described by the author); (2) correlation of river fluctuations with those of the water table in the pumped area; (3) observation of changes in the temperature of ground water due to infiltration; (4) observation of changes in the chemical quality of water due to infiltration; and (5) a pumping test conducted with properly arranged observation wells indicating a distortion in the shape of the cone of influence where river infiltration occurs. A plotting of drawdown against distance from the pumped well indicates steepening hydraulic gradients in a direction toward the stream from the pumping well as infiltration occurs.

All these methods have been used in Ohio ground water investigations. Although the investigations are not intensive or extensive enough, some quantitative data are available. For example, some direct measurements of river infiltration by current meter at Canton, Ohio, on the middle branch of Nimishillen Creek in the vicinity of the City of Canton's northeast well field, indicate infiltration rates of 3,600,000 gal a day per acre of stream bottom in certain reaches of channel at moderate stream flows. Additional data indicate presumptive evidence of rates of 5,000,000 gal a day per acre or 6,000,000 gal a day per acre at flood stages when water levels in the aquifer have been lowered sufficiently to receive the recharge.

---

[3] Chf. Engr., Ohio Water Resources Board, Dept. of Public Works, Columbus, Ohio.

These data are of increasing interest to engineers because they aid in the quantitative analysis of a projected ground water supply with more assurance than is generally believed. The stream-flow record, duration curve, flood-frequency analysis, and mass diagram are used in a manner similar to their use in the design of a surface reservoir. The dimensions and contour of the underground reservoir are ascertained as for a surface reservoir. Additional factors, particularly the physical properties of an aquifer (such as transmissibility and specific yield), must be considered in designing for the utilization of a ground water reservoir which is recharged by infiltration, but in general they are determinable to a fair degree of accuracy.

The underground reservoir permits withdrawals for periods of time at rates greater than the infiltration rate, just as a surface reservoir permits withdrawals greater than the run of the river. This is possible in an infiltration supply with ground water storage because infiltration rates increase with increased river stage. Often a ground water reservoir underlying a stream receives its major recharge during flood stages, in much the same way as a surface reservoir.

One advantage of a ground water reservoir replenished by river infiltration is that useful and valuable land is not removed from productivity by inundation. This is especially important in Ohio where most of the land is valuable and is needed for a growing population.

It is hoped that engineers will awaken to the tremendous possibilities for the utilization of ground water, especially infiltrated supplies. Then, engineers will not allow ground water to remain, as Malcolm Pirnie, M. ASCE, has recently stated, "a neglected natural resource."

Raphael G. Kazmann,[4] Assoc. M. ASCE.—At the time the water supply of the Indiana Ordnance Works was conceived, information was available concerning only one similarly planned major infiltrated water supply in the United States—the Des Moines, Iowa, filtration gallery. Consequently, Mr. Youngquist's discussion is, in a sense, a measure of the advance in ground water engineering during the seven years since 1941, and in particular during the five years since 1943. In the course of developing from a qualitative, descriptive science, ground water hydrology has reached the stage of as much a quantitative science as surface water hydrology, and probably is more susceptible of yielding reliable quantitative answers than is applied mechanics.

In the field of water supply, ground water hydrology recognizes, and has reliable quantitative answers for, the following categories of problems when encountered in aquifers composed of unconsolidated materials:

1. An underground water supply based on infiltration—
   - (*a*) From rainfall on the immediate area where the wells are located;
   - (*b*) From rainfall on a distant area where the aquifer outcrops; and
   - (*c*) From rainfall and from a river or lake touching a distant outcrop area.

---

[4] Chf. Hydrologic Engr., Ranney Method Water Supplies, Inc., Columbus, Ohio.

2. An underground water supply based on infiltration from a near-by source such as—

- (*a*) A permanent river or lake that can readily supply all desired quantities of water if the aquifer will transmit them (for example, the Mississippi, Missouri, and Ohio rivers and their larger tributaries or, say, Lake Michigan);
- (*b*) An intermittent stream crossing deep buried valleys, such as Nimishillen Creek in the Canton (Ohio) area;
- (*c*) A "flashy" stream to furnish a variable-quantity infiltration supply which will supplement existing surface water sources during dry weather and furnish large supplies during floods, when the turbidity of surface water forms a major treatment problem for water works operators;
- (*d*) A permanent or intermittent stream with sufficient subsurface storage to furnish water with a small, predetermined temperature fluctuation, as compared to the large temperature variation of the surface water which is supplying the aquifer; and
- (*e*) A permanent or intermittent stream with sufficient subsurface storage to furnish water whose mineral quality will fluctuate only slightly as compared to the variations in quality encountered in the surface source, in order to minimize water treatment problems.

These problems are not listed in order of importance or magnitude. The Indiana Ordnance Works is classified in category 2(*a*) as is the supply of the City of Manitowoc, Wis. The use of such a stream as that listed under category 2(*b*) as a source necessitates knowledge of flow-duration curves, the dimensions and contour of the underground reservoir, and the storage coefficient of the reservoir to determine the yield, as Mr. Youngquist has shown. In addition, the physical characteristics of the water already in storage should be determined, as well as the approximate quantity of areal rainfall reaching the underground reservoir, although this is usually a relatively small quantity. The recently completed stream infiltration supplies of the cities of Anderson, Ind., and Canton are classified in this category. In category 2(*d*) both the quantity and the approximate temperature variations of the water can be predicted.

Of course, there are other specialized water supply problems for which reliable quantitative answers can be obtained, but the bulk of all underground water supply problems are included in categories 1 and 2.

The reverse side of the water supply problem has not been touched, of course, in either the original paper or the discussion—that is, the problem of subsurface drainage and the removal of unwanted water from specific areas. The same quantitative ground water procedures are applicable to dewatering problems as to problems of underground water supply.

One paragraph of Mr. Youngquist's discussion is of special interest to hydrologic engineers because it summarizes, perhaps too briefly, the use of underground storage in an infiltration system. This paragraph compares the magnitude of withdrawals from an aquifer with withdrawals from a surface reservoir.

The function of the natural, underground reservoir is the same as that of a surface reservoir—to supply peak loads and to satisfy a predetermined minimum water demand during periods of low flow in the stream. The rate of infiltration to the aquifer (the equivalent of flow rate into a surface reservoir) is dependent on (1) the quantity of water flowing in the stream at any time; (2) the velocity of the stream; and (3) the stage of the stream relative to the general water level in the aquifer.

With the increase of each of these major factors, the rate of infiltration increases. If the subsurface storage is more or less depleted, as it will be at the end of a dry summer, the rate of infiltration during floods will be a maximum and will undoubtedly exceed the indicated 5 mgd or 6 mgd per acre of stream bed proposed by Mr. Youngquist. The bulk of recharge to an underground reservoir occurs during floods for precisely the same reason that surface water reservoirs are filled by floods: Most of the water is there at that time.

Summary.—Underground reservoirs do not remove productive land from cultivation and, equally important, their storage capacity never decreases because they do not silt up. The planners of new water supplies should not overlook the available underground water in an area. Such supplies can be relied on to furnish perennial, and predetermined, quantities of water.

NEW FORMULAS FOR STRESSES IN CONCRETE PAVEMENTS OF AIRFIELDS

By H. M. Westergaard,[1] M. ASCE

With Discussion by Messrs. Robert Horonjeff, Evan P. Bone, and H. M. Westergaard.

Synopsis

The stresses investigated here are caused by loads. The load is a pressure transmitted through the oblong "footprint" of a tire of a landing gear. Three positions of this load are considered: The first is at a considerable distance from any edge or joint, in the interior of the area of a panel of the pavement; the second position is next to an edge or next to a joint that has no capacity for load transfer, but is at an appreciable distance from any corner of the panel; the third position is next to a joint that permits some transfer of load to the adjacent panel, but is at an appreciable distance from any corner of the panel. Formulas are given for stresses and deflections caused by such loads. The significant stresses are tensile stresses at the bottom of the slab. A fourth position of the load, at a corner of a panel, by which significant tensile stresses are produced at the top of the slab, is also important, but is not considered herein.

The boundary of the footprint of the tire is usually a curve that lies between an ellipse and a circumscribed rectangle, but for present purposes this curve can be replaced in most cases by an equivalent slightly more oblong ellipse, and the load can be considered to be distributed uniformly over the area of this ellipse. Specific formulas are derived under the assumption of such a load, but general formulas are also stated which apply for any shape of the footprint (including the case of dual tires).

The basic formulas for stresses under loads in the interior of the area of a panel have been published previously, but the remaining formulas are the result of new derivations.

The order of presentation is: Statement of assumptions; statement of the formulas; numerical examples; derivations; comments on evidence from tests; and conclusions.

Note.—Published in May, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

NOTATION

The following notation is used:

P = load transmitted through a tire to a panel of the pavement; if a part of the total load transmitted through the tire is on the other side of a joint or outside the edge, only the part transmitted to the panel under consideration is included in P;

a, b = semiaxes of an ellipse representing the footprint of a tire; if the load is next to an edge or joint, a is the semiaxis parallel to the edge or joint; either a or b may be the greater semiaxis, depending on whether the joint is longitudinal or transverse;

x, y = horizontal rectangular coordinates; if the load is next to an edge or joint, the axis of x is along the line of the edge or joint; if the footprint of the tire is represented by an ellipse, the axis of x is in the direction of the semiaxis a;

r, θ = corresponding polar coordinates;

z = deflection;

z_e = deflection at an edge or at a joint that has no capacity for load transfer;

z_j, z'_j = deflections at the line of a joint on the two sides of the joint when the joint has some capacity for load transfer;

σ_x, σ_y = tensile stresses at the bottom of the slab in the directions of x and y in the interior of the area of the panel;

σ_e = tensile stress at the bottom of the slab along an edge or along a joint that has no capacity for load transfer;

σ_j, σ'_j = tensile stresses along a joint at the bottom of the slabs on the two sides of the joint when the joint has some capacity for load transfer;

h = thickness of the slab, assumed constant;

E = modulus of elasticity of the concrete in the slab, assumed constant;

μ = Poisson's ratio of the concrete;

k = modulus of subgrade reaction, assumed to be a constant, measurable in pounds per cubic inch, and defining the reaction under the slab per unit of area as $k\,z$;

l = radius of relative stiffness, defined as:

$$l^4 = \frac{E\,h^3}{12\,(1 - \mu^2)\,k} \qquad (1)$$

Natural logarithms are used unless otherwise stated.

ASSUMPTIONS

The assumptions usually made in the study of slabs on a subgrade are: (1) Within the range of action the slab is elastic with single constant values of the modulus of elasticity E and Poisson's ratio μ; (2) the thickness, h, of the slab is constant; and (3) the reaction of the base on the slab is a vertical pressure, equal, per unit of area, to a constant k times the deflection z, the base being uniform in character and everywhere in contact with the slab. The constant k is called the modulus of subgrade reaction and is measurable in pounds per cubic inch. It is kept in mind that the third assumption is an empirical makeshift, which however has been found in the past to give usable results.

It is assumed furthermore—and this can be assumed without hesitation—that the average of the width and length of the footprint of the tire is greater than the thickness of the slab in all significant cases. Under this assumption, the ordinary theory of bending of plates or slabs can be used without the special corrections that would be needed if the loaded area were very small, as it sometimes must be considered to be in the corresponding problems of concrete highways.

Each panel of pavement is assumed to be fairly large and as yet uncracked. The load is assumed in no case to be close to more than one edge or joint; other edges or joints are assumed to be far enough away to have only a negligible influence on the stresses directly under the load.

STATEMENT OF THE FORMULAS

A. Stresses and Deflections in the Interior of the Area of a Panel.—

Case 1.—The load is applied in the interior of the area of the panel at a considerable distance from any edge or joint. The total load P is distributed uniformly over the area of the ellipse—

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

The principal tensile stresses σ_x and σ_y, in the directions of x and y, at the bottom of the slab under the center of the load may be computed either by the formula—

$$\left.\begin{matrix}\sigma_x \\ \sigma_y\end{matrix}\right\} = \frac{3\,P}{8\,\pi\,h^2}\left[(1+\mu)\log\frac{E\,h^3}{k\left(\dfrac{a+b}{2}\right)^4} \mp 2\,(1-\mu)\,\frac{a-b}{a+b}\right] \ldots\ldots (3)$$

or by the equivalent formula—

$$\left.\begin{matrix}\sigma_x \\ \sigma_y\end{matrix}\right\} = \frac{P}{h^2}\left(0.275\,(1+\mu)\log_{10}\frac{E\,h^3}{k\left(\dfrac{a+b}{2}\right)^4} \mp 0.239\,(1-\mu)\,\frac{a-b}{a+b}\right) \ldots (4)$$

The deflection at any point x,y within or near the loaded area may be computed either by the formula—

$$z = \frac{P}{8\,k\,l^2}\left(1 - \frac{a^2+b^2+4\,x^2+4\,y^2}{16\,\pi\,l^2}\log\frac{E\,h^3}{k\left(\dfrac{a+b}{2}\right)^4} - \frac{a^2+4\,a\,b+b^2}{16\,\pi\,l^2} + \frac{(a-b)\,(x^2-y^2)}{2\,\pi\,l^2\,(a+b)}\right) \ldots (5)$$

(in which l is defined by Eq. 1) or by the equivalent formula—

$$
\begin{aligned}
z = {} & \frac{P}{4}\sqrt{\frac{3\,(1-\mu^2)}{E\,h^3\,k}} \\
& - \frac{0.275\,(1-\mu^2)\,P}{E\,h^3}\left[\frac{a^2+b^2}{4} + x^2 + y^2\right]\log_{10}\frac{E\,h^3}{k\left(\dfrac{a+b}{2}\right)^4} \\
& - \frac{0.239\,(1-\mu^2)\,P}{E\,h^3}\left[\frac{a^2+4\,a\,b+b^2}{8} + \frac{a-b}{a+b}\,(-x^2+y^2)\right] \quad \ldots . (6)
\end{aligned}
$$

Case 2.—The load again is applied in the interior of the area of the panel at a considerable distance from any edge or joint, but the load now has a more general type of distribution. The total load P is distributed uniformly over any area A having both axes of x and y as axes of symmetry. Such an area may be the footprint of either a single or a dual tire.

The principal stresses σ_x and σ_y at the bottom of the slab under the center of the load may be computed by the following formula:

$$
\left.\begin{matrix}\sigma_x \\ \sigma_y\end{matrix}\right\} = \frac{3\,P}{2\,\pi\,h^2}\left[(1+\mu)\,(K+0.1159) \pm \frac{1-\mu}{2}\,S\right] \ldots\ldots\ldots (7)
$$

in which K and S are "area coefficients" defined by the equations:[2]

$$
K = -\frac{1}{A}\int dA \log\frac{r}{l} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)
$$

and

$$
S = -\frac{1}{A}\int dA \cos 2\,\theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)
$$

The integrations in Eqs. 8 and 9 are extended over the entire loaded area, and l is defined by Eq. 1.

The deflection at any point x,y within or near the loaded area may be computed by the formula:

$$
\begin{aligned}
z = \frac{P}{8\,k\,l^2} - \frac{P}{8\,\pi\,k\,l^4}\Bigg[& \frac{1}{A}\int r^2\,dA \log\frac{l}{r} + \frac{1.1159}{A}\int r^2\,dA \\
& + (K+0.1159)\,(x^2+y^2) + \tfrac{1}{2}\,S\,(x^2-y^2)\Bigg] \ldots (10)
\end{aligned}
$$

B. Stresses and Deflections at an Edge or at a Joint That Has No Capacity for Load Transfer.—

Case 3.—The load is next to an edge or next to a joint that has no capacity for load transfer. The axis of x is along the edge or joint. The total load P is distributed uniformly over the area of an ellipse which is tangent to the edge or joint and has the equation:

$$
\frac{x^2}{a^2} + \frac{(y-b)^2}{b^2} = 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)
$$

---

[2] "Stress Concentrations in Plates Loaded Over Small Areas," by H. M. Westergaard, *Transactions*, ASCE, Vol. 108, 1943, pp. 831–856, especially p. 835, Eqs. 21 and 22.

The tensile stress at the bottom along the edge or joint directly under the point of tangency of the ellipse, that is, at $x = y = 0$, may be computed either by the formula—

$$\sigma_e = \frac{3\,(1 + \mu)\,P}{\pi\,(3 + \mu)\,h^2} \left\{ \log \frac{E\,h^3}{100\,k \left(\frac{a + b}{2} \right)^4} + 1.84 - \frac{4}{3}\,\mu + (1 + \mu)\,\frac{a - b}{a + b} + 2\,(1 - \mu)\,\frac{a\,b}{(a + b)^2} + 1.18\,(1 + 2\,\mu)\,\frac{b}{l} \right\} \quad \ldots.(12)$$

or by the equivalent formula—

$$\sigma_e = \frac{2.2\,(1 + \mu)\,P}{(3 + \mu)\,h^2} \log_{10} \frac{E\,h^3}{100\,k \left(\frac{a + b}{2} \right)^4} + \frac{3\,(1 + \mu)\,P}{\pi\,(3 + \mu)\,h^2} \left[1.84 - \frac{4}{3}\,\mu + (1 + \mu)\,\frac{a - b}{a + b} + 2\,(1 - \mu)\,\frac{a\,b}{(a + b)^2} + 1.18\,(1 + 2\,\mu)\,\frac{b}{l} \right] \quad ..(13)$$

in which l, as elsewhere, is the radius of relative stiffness defined by Eq. 1.

The deflection at any point on the axis of symmetry perpendicular to the edge or joint at a moderate distance y from the edge or joint (or at the edge or joint itself) may be computed by the approximate formula:

$$z = \frac{P\,\sqrt{2 + 1.2\,\mu}}{\sqrt{E\,h^3\,k}} \left[1 - (0.76 + 0.4\,\mu)\,\frac{b}{l} \right] \left[1 - (0.76 + 0.4\,\mu)\,\frac{y}{l} \right] \quad ..(14)$$

The character of Eq. 14 as an approximate formula is indicated by the omission of quadratic terms in y, or in a and b. These quadratic terms are relatively unimportant when both b and y have moderate values.

Case 4.—As in Case 3, the load is again next to an edge or next to a joint that has no capacity for load transfer, but the total load P is now distributed uniformly over the area of one half of an ellipse. The ellipse has the principal radii a and b, and the diameter $2\,a$ is along the edge or joint. This condition may occur when one half of the footprint of the tire is outside the panel under consideration; P is then one half of the total pressure transmitted through the tire.

The tensile stress at the bottom of the slab along the edge or joint under the center of the ellipse may be computed by the following formula:

$$\sigma_e = \frac{2.2\,(1 + \mu)\,P}{(3 + \mu)\,h^2} \log_{10} \frac{E\,h^3}{100\,k \left(\frac{a + b}{2} \right)^4} + \frac{3\,(1 + \mu)\,P}{\pi\,(3 + \mu)\,h^2} \left[3.84 - \frac{4}{3}\,\mu - (1 - \mu)\,\frac{a - b}{a + b} + 0.5\,(1 + 2\,\mu)\,\frac{b}{l} \right] \quad ..(15)$$

The deflection at the center of the ellipse or at any other point on the axis of symmetry at a moderate distance y from the edge or joint may be computed by the approximate formula:

$$z = \frac{P\sqrt{2 + 1.2\,\mu}}{\sqrt{E\,h^3\,k}}\left[1 - (0.323 + 0.17\,\mu)\frac{b}{l}\right]\left[1 - (0.76 + 0.4\,\mu)\frac{y}{l}\right]\ldots(16)$$

Case 5.—As in Cases 3 and 4, the load is next to an edge or next to a joint that has no capacity for load transfer, but, as in Case 2, the load has a more general type of distribution. The total load P is distributed uniformly over any area A having the axis of y as an axis of symmetry. The axis of x is along the edge or joint.

The tensile stress at the bottom of the slab along the edge or joint at the point $x = y = 0$ may be computed by the formula:

$$\sigma_e = \frac{3\,(1 + \mu)\,P}{\pi\,(3 + \mu)\,h^2}\left[4\,K - 0.28 - \frac{4}{3}\mu - \mu^2 + (1 - \mu)\,S + 1.18\,(1 + 2\,\mu)\frac{\bar{y}}{l}\right]\ldots(17)$$

in which $\bar{y}$ is the distance from the edge or joint to the center of gravity of the load, l is the radius of relative stiffness defined by Eq. 1, and K and S are the area coefficients defined by Eqs. 8 and 9. In computing K and S by these formulas it should be noted that in this case, unlike Case 2, the axis of x, being along the edge or joint, is not an axis of symmetry.

The deflection at any point on the axis of symmetry perpendicular to the edge or joint at a moderate distance y from the edge or joint (or at the edge or joint itself) may be computed by the approximate formula:

$$z = \frac{P\sqrt{2 + 1.2\,\mu}}{\sqrt{E\,h^3\,k}}\left[1 - (0.76 + 0.4\,\mu)\frac{\bar{y}}{l}\right]\left[1 - (0.76 + 0.4\,\mu)\frac{y}{l}\right]\ldots(18)$$

C. Stresses and Deflections at a Joint That Has Some Capacity for Load Transfer.—

Case 6.—The load is at a joint and may be partly on one side and partly on the other side of the joint. The transfer devices are either continuous along the joint or are closely spaced. The joint is capable of transferring load with an efficiency j which may have any value in the range $0 < j \leqq 1$. The extreme value $j = 1$ represents 100% efficiency, which means that the deflections of the two adjacent slabs are certain to be equal at the line of the joint. The other extreme $j = 0$ would mean no transfer of load as in the preceding Cases 3 to 5. The meaning given here to any intermediate value of j is expressed by a formula which is recognized to be approximate only, but which nevertheless will serve the present purpose of estimating the relief of stress by load transfer; the formula is:

$$z_j - z'_j = (1 - j)\,(z_e - z'_e)\ldots\ldots\ldots\ldots(19)$$

in which z_j and z'_j are the deflections of the adjacent slabs at any point at the joint, while z_e and z'_e are the corresponding deflections that would occur at the same place if the joint had no capacity for load transfer. Eq. 19 must be considered as approximate only, because j is assumed to be constant over some distance.

Under these assumptions the tensile stresses σ_j and σ'_j at the bottom of the two slabs along the joint may be computed by the formulas:

$$\sigma_j = (1 - \tfrac{1}{2} j)\, \sigma_e + \tfrac{1}{2} j\, \sigma'_e \qquad (20)$$

and

$$\sigma'_j = \tfrac{1}{2} j\, \sigma_e + (1 - \tfrac{1}{2} j)\, \sigma'_e \qquad (21)$$

in which σ_e and σ'_e are the corresponding stresses that would be produced if the joint had no capacity for load transfer. That is, depending on the distribution of the load, σ_e and σ'_e may be defined by such formulas as Eqs. 13 15, or 17.

Similarly, the deflections of the two slabs at the joint may be computed by the formulas:

$$z_j = (1 - \tfrac{1}{2} j)\, z_e + \tfrac{1}{2} j\, z'_e \qquad (22)$$

and

$$z'_j = \tfrac{1}{2} j\, z_e + (1 - \tfrac{1}{2} j)\, z'_e \qquad (23)$$

It is observed that Eqs. 22 and 23 obey Eq. 19.

NUMERICAL EXAMPLES

The following values are selected as common to all the numerical examples:

(*a*) The total load transmitted through one tire is 50,000 lb. The footprint of the tire is taken as an ellipse with an average diameter $a + b = 30$ in. Either a or b is 20 in.

(*b*) The thickness of the pavement is $h = 10$ in.

(*c*) The modulus of elasticity and Poisson's ratio of the concrete are $E = 4{,}000{,}000$ lb-in.$^{-2}$ and $\mu = 0.15$. The modulus of subgrade reaction is $k = 200$ lb-in.$^{-3}$

With these values one finds the following constants which recur in the computations; the first being the radius of relative stiffness defined by Eq. 1: $l = 36.14$ in.; $l^2 = 1{,}305.8$ in.^{2}; and

$$\log_{10} \frac{E\, h^3}{100\, k \left(\dfrac{a + b}{2}\right)^4} = 0.5967 \qquad (24)$$

Example 1.—The load is in the interior of the area of the panel. The semiaxes of the loaded ellipse are $a = 20$ in. and $b = 10$ in.

The stresses σ_x and σ_y under the center of the load in the directions of the longer and shorter axis, respectively, are computed by Eq. 4 as

$$\left.\begin{matrix}\sigma_x \\ \sigma_y\end{matrix}\right\} = (410.6 \mp 33.9)\ \text{lb-in.}^{-2} = \left\{\begin{matrix}376.7\ \text{lb-in.}^{-2} \\ 444.5\ \text{lb-in.}^{-2}\end{matrix}\right. \qquad (25)$$

The three terms in Eq. 6 and the resultant deflection under the center of the load at $x = y = 0$ are stated as follows:

$$z = (0.02393 - 0.00109 - 0.00047)\text{ in.} = 0.02237\text{ in.} \tag{26}$$

The same results are obtained from Eq. 5.

At the end of the major axes, at $x = a$, $y = 0$, the value in Eq. 26 is changed, according to Eq. 6, by multiplying the second term by $\frac{21}{5}$ and the third by $\frac{7}{39}$. This gives the deflection at that point as $z = 0.01927$ in.

Example 2.—The load is next to a longitudinal joint that has no capacity for load transfer. The loaded elliptic area is tangent to the joint. The semiaxes are $a = 20$ in. and $b = 10$ in.

The stress at the joint is computed by Eq. 13. The two terms and the resulting value are as follows:

$$\sigma_e = (239.6 + 501.2)\text{ lb-in.}^{-2} = 740.8\text{ lb-in.}^{-2} \tag{27}$$

Eq. 14 gives the following values of the deflections z_e at the joint and z under the center of the load:

$$z_e = 0.0638\text{ in.} \qquad \text{and} \qquad z = 0.0493\text{ in.} \tag{28}$$

Example 3.—The load is next to a transverse joint that has no capacity for load transfer. The loaded elliptic area is tangent to the joint. The semiaxes are $a = 10$ in. and $b = 20$ in. The values in Eqs. 27 and 28 are changed by the exchange of the values of a and b to

$$\sigma_e = 663.8\text{ lb-in.}^{-2}, \quad z_e = 0.045\text{ in.}, \quad \text{and} \quad z = 0.025\text{ in.} \tag{29}$$

but the last of these values should be considered only as a crude approximation because the distance of 20 in. from the joint to the center of the load is rather large for this computation.

Example 4.—The load stradles a longitudinal joint, with half on each side; $a = 20$ in. and $b = 10$ in. The load on one side of the joint is 25,000 lb. The efficiency of the joint does not enter into the computation. Eqs. 15 and 16 give the stress and the deflection at the joint as

$$\sigma_e = 428.0\text{ lb-in.}^{-2} \qquad \text{and} \qquad z_e = 0.0373\text{ in.} \tag{30}$$

It is noted that the stress is a little less than σ_y in Example 1, in which the load is in the interior of the area, but the deflection is conspicuously greater.

Example 5.—The load is next to a longitudinal joint which has an efficiency $j = 0.8$ (or 80%) for load transfer. The loaded elliptic area is tangent to the joint. The semiaxes are $a = 20$ in. and $b = 10$ in. With σ_e taken from Eq. 27, Eqs. 20 and 21 give the following stresses on the two sides of the joint:

$$\sigma_j = 740.8\text{ lb-in.}^{-2}\,(1 - \tfrac{1}{2}\,0.8) = 444.5\text{ lb-in.}^{-2} \quad \text{and} \quad \sigma'_j = 296.3\text{ lb-in.}^{-2} \tag{31}$$

Similarly Eqs. 22, 23, and 28 give the deflections on the two sides of the joint:

$$z_j = 0.0383\text{ in.} \qquad \text{and} \qquad z'_j = 0.0255\text{ in.} \tag{32}$$

It is observed that σ_j in Eqs. 31 has the same value as σ_y in Eq. 25. This indicates that, under the circumstances, a joint efficiency of 80% or more would be desirable.

Example 6.—The load is next to a transverse joint which has an efficiency $j = 0.66$ for load transfer. The loaded elliptic area is tangent to the joint. The semiaxes are $a = 10$ in. and $b = 20$ in. Eqs. 20, 22, and 29 give:

$$\sigma_j = 444.7 \text{ lb-in.}^{-2} \quad \text{and} \quad z_j = 0.030 \text{ in.} \dots\dots\dots\dots (33)$$

DERIVATIONS

A. Stresses and Deflections in the Interior of the Area of a Panel.—

Eqs. 7, 8, and 9, which define the stresses when the loaded area has any shape, are taken from a former[3] paper by the writer, in which the use of area coefficients such as K and S in Eqs. 8 and 9, and place coefficients such as the constant 0.1159 in Eq. 7 were introduced.[3] Eq. 3 defines the stresses in the interior of the area when the loaded area is the ellipse in Eq. 2. It is obtained from Eq. 7 by substituting l from Eq. 1, omitting within the brackets a small positive term containing μ^2 and a nearly balancing negative term. By substituting the following values[4] for K and S:

$$K = \log \frac{2\,l}{a + b} + \tfrac{1}{2} \quad \text{and} \quad S = -\frac{a - b}{a + b} \dots\dots\dots (34)$$

Eq. 4 is a transcription of Eq. 3. With $a = b$ (that is, when the ellipse is a circle), Eq. 4 agrees with formulas published earlier.[5,6]

In a paper published in 1940,[7] the writer showed that even with a fairly large circular footprint of the tire the correction that would have to be added to the stress in the original formulas because of the large radius would be small. For example, with $a = b = 15$ in., but with other values as in the present numerical Example 1, the added stress would be only 4.6 lb-in.$^{-2}$. Such a small correction may well be ignored, and the correction of this type has been ignored in Eqs. 3, 4, and 7.

The 1940 paper[8] also contains a formula for the deflection at the center of a loaded circular area. That formula agrees with, and thus confirms, Eqs. 5 and 6 when these equations are applied with $a = b$ and $x = y = 0$; but Eqs. 5 and 6 apply when the loaded area is an ellipse. Eq. 5 is derived from Eq. 10 which applies when the loaded area is of a general type, but symmetrical about both axes of x and y. In performing this derivation the first integral in Eq. 10 can be obtained in a finite form; the second integral is merely the polar moment of inertia of the area; and K and S are given in Eqs. 34.

It remains to show the validity of Eq. 10. The terms containing x^2 and y^2 are verified by noting that they define the same curvatures as do the stresses in Eq. 7. On account of the symmetry of the load there can be no linear terms in x and y. The remaining terms in Eq. 10 are correct if the deflection due to a concentrated load P at the distance r from the point of application of P can be stated by the formula:

[8] *Ibid.*, p. 199, Eq. 11.

$$z = \frac{P}{8\,k\,l^2} - \frac{P\,r^2}{8\,\pi\,k\,l^4}\left(\log\frac{l}{r} + 1.1159\right) \qquad (35)$$

Eq. 35 is obtained from the exact solution,[9,10] by omitting terms containing r^4 and higher powers of r. This concludes the verification of Eqs. 5, 6, and 10.

B. Stresses and Deflections at an Edge or at a Joint That Has No Capacity for Load Transfer.—

The basis of Eqs. 17 and 18, which apply when the load is next to an edge and is distributed over a not too large area of any shape, is two formulas which are taken from a paper published in 1923.[11] The first defines the deflection z produced at the point x,y by a load P at $x = y = 0$ when the axis of x is along an edge and the slab covers the entire region $y > 0$. The second formula, which is used as an auxiliary equation, defines in a related form the deflection z_i, produced at the point x,y with $y \geqq 0$ by a load P at $x = y = 0$ when the slab covers the entire xy-plane. The formulas are:

$$z = \frac{2\,P}{\pi\,k\,l^2}\int_0^\infty \frac{\gamma\cos\frac{\alpha\,x}{l}\left[\cos\frac{\beta\,y}{l} + (1-\mu)\,\alpha^2\sin\frac{\beta\,y}{l}\right]e^{-\gamma y/l}\,d\alpha}{1 + 4\,(1-\mu)\,\alpha^2\,\gamma^2 - (1-\mu)^2\,\alpha^4} \qquad (36)$$

and

$$z_i = \frac{P}{2\,\pi\,k\,l^2}\int_0^\infty \frac{\cos\frac{\alpha\,x}{l}\left[\beta\cos\frac{\beta\,y}{l} + \gamma\sin\frac{\beta\,y}{l}\right]e^{-\gamma y/l}\,d\alpha}{\beta^2 + \gamma^2} \qquad (37)$$

in which α, β, and γ are three positive values obeying the relations:

$$\alpha^2 + \beta^2 = \gamma^2 \qquad \text{and} \qquad 2\,\beta\,\gamma = 1 \qquad (38)$$

Eqs. 36 and 37 can be verified by showing that they both satisfy the governing differential equation—

$$l^4\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)^2 z + z = 0 \qquad (39)$$

both give values converging toward zero as the distance goes to infinity; and both account for the load and satisfy the appropriate conditions at $y = 0$.

According to the Maxwell theorem of reciprocal deflections, z in Eq. 36 may also be interpreted as the deflection produced at the origin of the coordinates by a load P at point x,y. It follows that the diagram of deflections produced at the edge, at $y = 0$, by a load P at point $0,y$ may be obtained as the diagram of deflections produced at the distance y from the edge by a load P at the origin. It follows from this that the curvature $-\frac{\partial^2 z}{\partial x^2}$ produced at the origin by a load

---

[9] "Stress Concentrations in Plates Loaded Over Small Areas," by H. M. Westergaard, *Transactions*, ASCE, Vol. 108, 1943, p. 839, Eq. 48.

[10] "Stresses in Concrete Runways of Airports," by H. M. Westergaard, *Proceedings*, 19th Annual Meeting, Highway Research Board, December, 1939 (published in 1940), p. 197, Eqs. 30 and 34.

[11] "Om Beregning af Plader paa elastisk Underlag med særligt Henblik paa Spørgsmaalet om Spændinger i Betonveje," by H. M. Westergaard, *Ingeniøren*, Vol. 32, 1923, pp. 513–524, especially Eqs. 47, 30, and 34, and also Eqs. 48 and 33.

P at point x,y may be obtained as the curvature $-\frac{\partial^2 z}{\partial x^2}$ produced at point x,y by a load P at the origin of the coordinates.

The curvature in the direction of x at the origin of the coordinates defines the tensile stress along the bottom of the edge at that point as:

$$\sigma_e = -\frac{E\,h}{2}\frac{\partial^2 z}{\partial x^2} \quad \text{(40)}$$

According to the dual interpretation of the curvatures, if the load P is at point x,y, the function z in Eq. 40 is also the function z defined by Eq. 36. By use of Eq. 1 this gives the stress at the edge due to P at point x,y as:

$$\sigma_e = \frac{12\,(1-\mu^2)\,P}{\pi\,h^2}\int_0^\infty \frac{\alpha^2\,\gamma\cos\frac{\alpha\,x}{l}\left[\cos\frac{\beta\,y}{l} + (1-\mu)\,\alpha^2\sin\frac{\beta\,y}{l}\right]e^{-\gamma y/l}\,d\alpha}{1 + 4\,(1-\mu)\,\alpha^2\,\gamma^2 - (1-\mu)^2\,\alpha^4} \quad \text{(41)}$$

The function σ_e in Eq. 41 has a singularity at $x = y = 0$, with an infinite value at that point. The difficulty involved in this is overcome by dividing σ_e into two component parts, writing

$$\sigma_e = \bar{\sigma} + \sigma_c \quad \text{(42)}$$

and choosing the part $\bar{\sigma}$ so that it will have the same type of singularity as σ_e but will be of a simpler form. This leaves σ_c as a smooth function with a finite value at the origin of the coordinates.

The choice of the function $\bar{\sigma}$ is aided by noting the type of the singularity that the elastic surface of any plate must have at the point of application of a concentrated force applied at a free edge. A. Nádai[12] has defined that type. In this way one arrives at the following possible form of $\bar{\sigma}$:

$$\bar{\sigma} = -\frac{12\,(1+\mu)\,k\,l^4}{(3+\mu)\,h^2}\left[(3-\mu)\frac{\partial^2 z_i}{\partial x^2} + (1+\mu)\frac{\partial^2 z_i}{\partial y^2}\right] \quad \text{(43)}$$

in which z_i is the deflection produced at point x,y by a load P at the origin of the coordinates in a slab that covers the entire x,y-plane. The function z_i can be defined by Eq. 37; but in the vicinity of the origin of the coordinates the two second derivatives in Eq. 43 may also be expressed in the manner of Eq. 7 by the formula:[13]

$$\left.\begin{array}{r} -\dfrac{\partial^2 z}{\partial x^2} \\[2ex] -\dfrac{\partial^2 z}{\partial y^2} \end{array}\right\} = \frac{P}{4\,\pi\,k\,l^4}\left(\log\frac{l}{r} + 0.1159 \mp \tfrac{1}{2}\cos 2\,\theta\right) \quad \text{(44)}$$

This gives

$$\bar{\sigma} = \frac{12\,(1+\mu)\,P}{\pi\,(3+\mu)\,h^2}\left(\log\frac{l}{r} + 0.1159 - \frac{1-\mu}{4}\cos 2\,\theta\right) \quad \text{(45)}$$

The remaining part of σ_e is obtained as

$$\sigma_c = \sigma_e - \bar{\sigma} \quad \text{(46)}$$

---

[12] "Die elastischen Platten," by A. Nádai, Julius Springer, Berlin, 1925, p. 204.

[13] "Stress Concentrations in Plates Loaded Over Small Areas," by H. M. Westergaard, *Transactions*, ASCE, Vol. 108, 1943, p. 835 et seq., Eqs. 17, 21, 22, and 51.

with σ_e as in Eq. 41 and with $\bar{\sigma}$ again defined by Eq. 43, but this time with z_i substituted from Eq. 37, which thereby serves its purpose as an auxiliary formula. This gives:

$$\sigma_c = -\frac{24\,(1+\mu)\,P}{\pi\,(3+\mu)\,h^2}\int_0^\infty \frac{\cos\dfrac{\alpha\,x}{l}\,[1+(1-\mu)^2\,\alpha^2\,\beta^2]\,\beta\cos\dfrac{\beta\,y}{l}\,e^{-\gamma y/l}\,d\alpha}{1+4\,(1-\mu)\,\alpha^2\,\gamma^2-(1-\mu)^2\,\alpha^4}$$

$$-\frac{12\,(1-\mu^2)\,P}{\pi\,(3+\mu)\,h^2}\int_0^\infty \frac{\cos\dfrac{\alpha\,x}{l}\,[1+4\,(1-\mu)\,\alpha^2\,\beta^2]\,\gamma\sin\dfrac{\beta\,y}{l}\,e^{-\gamma y/l}\,d\alpha}{1+4\,(1-\mu)\,\alpha^2\,\gamma^2-(1-\mu)^2\,\alpha^4}$$

$$+\frac{6\,(1+\mu)\,(3-\mu)\,P}{\pi\,(3+\mu)\,h^2}\int_0^\infty \frac{\cos\dfrac{\alpha\,x}{l}\left[2\,\beta^3\cos\dfrac{\beta\,y}{l}+\beta\sin\dfrac{\beta\,y}{l}\right]e^{-\gamma y/l}\,d\alpha}{\beta^2+\gamma^2}\;\ldots(47)$$

in which, as before, α, β, and γ are defined by Eqs. 38.

As was anticipated, σ_c in Eq. 47 is in fact a smooth function without infinite values in the half plane $y \geqq 0$. In the region of small values of x and y the function σ_c may be written with adequate accuracy as a linear function of y in the form:

$$\sigma_c = [\sigma_c]_{x=y=0} + y\left[\frac{\partial\sigma_c}{\partial y}\right]_{x=y=0}\;\ldots\ldots\ldots\ldots(48)$$

In evaluating the constant term in Eq. 48 it is noted that:

$$\int_0^\infty \frac{\beta^3\,d\alpha}{\beta^2+\gamma^2} = \tfrac{1}{4}\;\ldots\ldots\ldots\ldots(49)$$

This leads to the following form of Eq. 48:

$$\sigma_c = \frac{12\,(1+\mu)\,P}{\pi\,(3+\mu)\,h^2}\left(\frac{3-\mu}{4} - B_1 + B_2\,\frac{y}{l}\right)\;\ldots\ldots\ldots\ldots(50)$$

in which B_1 and B_2 are dimensionless constants defined by the formulas:

$$B_1 = 2\int_0^\infty \frac{[1+(1-\mu)^2\,\alpha^2\,\beta^2]\,\beta\,d\alpha}{1+4\,(1-\mu)\,\alpha^2\,\gamma^2-(1-\mu)^2\,\alpha^4}\;\ldots\ldots\ldots\ldots(51)$$

and

$$B_2 = \tfrac{1}{2}\int_0^\infty \frac{[1+\mu-2\,(1-\mu)^2\,\alpha^2\,\beta^2]\,d\alpha}{1+4\,(1-\mu)\,\alpha^2\,\gamma^2-(1-\mu)^2\,\alpha^4}\;\ldots\ldots\ldots\ldots(52)$$

When the load P is distributed over an area A instead of being concentrated at the point x,y, Eq. 45 is replaced by

$$\bar{\sigma} = \frac{12\,(1+\mu)\,P}{\pi\,(3+\mu)\,h^2}\left(K + 0.1159 + \frac{1-\mu}{4}\,S\right)\;\ldots\ldots\ldots\ldots(53)$$

in which K and S are the place coefficients defined by Eqs. 8 and 9; and Eq. 50 is modified by replacing y by the distance $\bar{y}$ from the edge to the center of gravity of the load. Then Eqs. 42, 50, and 53 lead to the following formula for the tensile stress along the bottom of the edge at the point $x = y = 0$ due to the actual load:

$$\sigma_e = \frac{12\,(1+\mu)\,P}{\pi\,(3+\mu)\,h^2}\left[K + 0.8659 - \frac{\mu}{4} - B_1 + \frac{1-\mu}{4}S + B_2\frac{\bar{y}}{l}\right] \ldots (54)$$

in which B_1 and B_2 are defined by Eqs. 51 and 52.

Like the part σ_e of the stress, the deflection z_e at the edge at $x = y = 0$ can be expressed with adequate accuracy as a linear function of the distance $\bar{y}$ from the edge, provided that the loaded area is not too great. Thus one may write

$$z_e = [z]_{x=y=0} + \bar{y}\left[\frac{\partial z}{\partial y}\right]_{x=y=0} \ldots\ldots\ldots\ldots\ldots\ldots (55)$$

or, in terms of two dimensionless constants B_3 and B_4,

$$z_e = \frac{P}{k\,l^2}\left[B_3 - B_4\frac{\bar{y}}{l}\right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots (56)$$

The values of B_3 and B_4 are determined through Eqs. 36 and 55 and are found to be

$$B_3 = \frac{1}{M\sqrt{8}}\left(\frac{M+1-\mu}{\sqrt{2-\mu+M}} + \frac{M-1+\mu}{\sqrt{2-\mu-M}}\right) \ldots\ldots\ldots (57)$$

in which the quantity M is defined as

$$M = \sqrt{(1-\mu)^2 + \mu^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (58)$$

and

$$B_4 = \frac{1}{\pi}\int_0^\infty \frac{[(1+\mu)\,\alpha^2 + 2\,\beta^2]\,d\alpha}{1 + 4\,(1-\mu)\,\alpha^2\,\gamma^2 - (1-\mu)^2\,\alpha^4} \ldots\ldots\ldots (59)$$

in which, as before, α, β, and γ are positive values defined by Eqs. 38.

Numerical values of the constants B_1, B_2, B_3, and B_4, as defined by Eqs. 51, 52, 57, and 59, and computed by members of the staff of the David Taylor Model Basin, United States Navy Department, at Carderock, Md., are given in Table 1. Numerical studies of these values have led to the following formulas through which the four constants are determined with quite satisfactory accuracy within the range of μ, and are given in forms that lend themselves to the final formulas:

TABLE 1.—VALUES OF THE CONSTANTS B_1, B_2, B_3, AND B_4 IN EQS. 54 AND 56 FOR DIFFERENT VALUES OF POISSON'S RATIO μ

μ	B_1	B_2	B_3	B_4
0 . . .	0.9352	0.2952	0.4082	0.3118
0.15. . .	0.9544	0.3822	0.4314	0.3510
0.2 . . .	0.9627	0.4131	0.4406	0.3715
0.3 . . .	0.9830	0.4786	0.4620	0.4106

$$4\,(B_1 - 0.8659) = 0.28 + \tfrac{1}{3}\,\mu + \mu^2 \ldots\ldots\ldots\ldots\ldots (60)$$

$$4\,B_2 = 1.18\,(1 + 2\,\mu) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (61)$$

$$B_3\sqrt{12\,(1-\mu^2)} = \sqrt{2 + 1.2\,\mu} \ldots\ldots\ldots\ldots\ldots (62)$$

$$B_4 = (0.76 + 0.4\,\mu)\,B_3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (63)$$

Substitution from Eqs. 60 and 61 in Eq. 54 leads directly to Eq. 17 which defines σ_e for any shape of the loaded area. Eqs. 12, 13, and 15 are specific forms of Eq. 17, which are derived by use of Eq. 1, by replacing $\log(1 - \mu^2)$ by $-\mu^2$, and by substituting appropriate values of K and S; namely, for Eq. 15 the values in Eqs. 34, and for Eqs. 12 and 13 the following values which apply at the ends of the axis $2\,b$ of the elliptic area:[4]

$$K = \log\frac{2\,l}{a+b} + \frac{a-b}{2\,(a+b)} \qquad \text{and} \qquad S = -\frac{a-b}{a+b} + \frac{2\,a\,b}{(a+b)^2} \,\ldots\ldots(64)$$

It should be mentioned that Eq. 15, which applies when the load is distributed over one half of an ellipse, does not become identical, when $a = b$, to the formula—given elsewhere[4]—for the case of a load distributed over a semicircle.[14,15] The stresses defined by Eq. 15 are greater than those defined by the previous formula.[14,15]

The value of z defined by Eq. 18 when $y = 0$ is derived from Eq. 56 by substitution from Eqs. 62 and 63 and by use of Eq. 1. The second quantity in brackets in Eq. 18, which extends the applicability of the formula to points near the edge, is written so as to make the complete formula conform to the Maxwell theorem of reciprocal deflections. Eqs. 14 and 16 are merely specific forms of Eq. 18.

This completes the verification of the formulas for stresses and deflections at an edge.

C. Stresses and Deflections at a Joint That Has Some Capacity for Load Transfer.—

Assume that the load P is entirely on side A of the joint. For the purpose of the analysis this load can be resolved into two component parts: Component I consists of $\frac{1}{2}\,P$ on side A and $\frac{1}{2}\,P$ placed symmetrically on side B; component II consists of $\frac{1}{2}\,P$ on side A and $-\frac{1}{2}\,P$ on side B. Component I produces the deflections $\frac{1}{2}\,z_e$ on each side. Component II produces equal and opposite deflections on the two sides. According to Eq. 19 these deflections are $\pm\frac{1}{2}\,(1 - j)\,z_e$. This leads to the resultant deflections defined by Eqs. 22 and 23 with $z'_e = 0$. The complete Eqs. 22 and 23 are obtained by superposition of the effects of loads on both sides. Eqs. 20 and 21 which define the stresses are consistent with Eqs. 22 and 23.

COMMENTS ON THE EVIDENCE OBTAINED FROM TESTS AND EXPERIENCE

Since the 1920's experimental evidence has accumulated supporting the claim of usability of the formulas published previously for stresses in concrete highways under loads distributed over a small circular area. The Public Roads Administration—formerly The Bureau of Public Roads—has conducted many of the tests. A comprehensive report in five parts published in 1935, 1936, and 1943 by L. W. Teller and Earl C. Sutherland,[16] Members, ASCE, of

[15] "Analytical Tools for Judging Results of Structural Tests of Concrete Pavements," by H. M. Westergaard, *ibid.*, December, 1933, p. 185, Eq. 5.

[16] "The Structural Design of Concrete Pavements," by L. W. Teller and Earl C. Sutherland, *ibid.*, October, November, and December, 1935; September and October, 1936; and April–May–June, 1943.

the Division of Tests, of the Public Roads Administration, should be mentioned especially. The last part of this report contains extensive and careful comparisons of tests and theory. These include a very satisfactory verification of the relation defined by Eq. 7 between the stresses in the directions of the long and short axes of an oblong footprint of a tire.[17] The new formulas that have been published are derived from the same basic theory as the formulas published previously, and may thus be considered to be supported by the same experimental evidence.

The reasonableness (in the light of general experience) of the sequence of numerical values of stresses and deflections obtained in the six numerical examples may be considered as further evidence in favor of the formulas.

CONCLUSIONS

The formulas that have been presented lend themselves to three purposes: The interpretation of experimental evidence; the interpretation of practical experience with pavements in service; and the forming of judgments from which policies of design may be adopted to meet new conditions such as new types and new magnitudes of the loads.

In relation to the complexity of the problem, which involves a number of significant variables, the formulas are simple to use.

ACKNOWLEDGMENTS

The manuscript from which this paper was prepared was the result of studies made by the writer while serving on active duty at the Bureau of Yards and Docks, United States Navy Department, as Commander, Civil Engineer Corps, United States Naval Reserve. Throughout the studies their use by the Board of Consultants on Airfield Pavements, Office of the Chief of Engineers, United States War Department, was kept in mind. The opinions contained in this paper are the private ones of the writer and are not to be construed as official, or as reflecting the views of the Navy Department or of the Naval Service at large.

The writer is especially indebted to the Staff of the Mathematical Section, Technical Service, of the Navy's David Taylor Model Basin, at Carderock, for supplying the numerical computations of the constants in Table 1.

DISCUSSION

ROBERT HORONJEFF,[18] JUN. ASCE.—The comments presented by the writer are not to be construed as a criticism of the author's presentation but are offered principally to illustrate, to the practicing engineer, the effect in varying the modulus of subgrade reaction, *k*. The paper presented by Professor Westergaard is an important contribution to the science of airfield pavement design.

Normally, the values of Poisson's ratio, μ, and the modulus of elasticity, E, are assumed, but the modulus of subgrade reaction, k, is measured in the field by the so-called "field bearing test." This test normally consists of loading a round 30-in. plate on the subgrade with a total load equivalent to 10 lb per sq in. (7,070 lb) and of recording the deformation in inches with this load. The load is applied almost instantaneously (10 sec) and is held until practically complete deformation has taken place. The modulus of soil reaction $k = \frac{10}{\Delta}$, in which Δ represents the total movement in inches during the application of the load.

In comparison with other routine tests on soils, the field bearing test is expensive. It requires that the load be applied by an hydraulic jack working against a jacking frame. The jacking frame usually consists of two trucks, an anchored steel frame, or any other device, as long as the reactions are at least 8 ft from the bearing plate. The purpose of this discussion is to show that refinements in measuring the modulus of subgrade reaction, k, are unwarranted and that, in most cases, k can be assumed without testing by comparison of the bearing value of the soil in question with similar soils which have already been tested.

To illustrate this point, two curves are presented. Fig. 1(*a*) represents the maximum tensile stresses obtained by substitution in Eq. 4, Case 1, in which the load is applied to the interior of the area of the panel at a considerable distance from any edge or joint. The wheel load, P, used in the example amounts to 60 kips. Poisson's ratio, μ, was assumed to be 0.20, and the modulus of elasticity, E, for concrete, 4,000,000 lb per sq in. The tire imprint area was assumed as an ellipse, the semiaxis, a, being equal to 17 in., and the semiaxis, b, equal to 10 in. As an example, assume that the allowable stress in the concrete is equal to 550 lb per sq in., and that the modulus of subgrade reaction, k, is 100. From the curves in Fig. 1(*a*), the required thickness of concrete is 11 in. If the value of k is 300, the required thickness is 10 in. In other words, for a relatively large difference in the k-value, the required thickness of concrete varies only by 1 in. Fig. 1(*b*) presents the stresses computed from substitution in Eq. 13, Case 3, in which the load is next to an edge or a joint that has no capacity for load transfer. The values of P, μ, E, a, and b are the same as in Case 1, Fig. 1(*a*). Similar comparisons for $k = 100$ and $k = 300$ reveal, again, that large variations of k do not result in large variations in concrete thickness.

---

[18] Chf., Civ. Works Branch, Corps of Engrs., San Francisco, Calif.; Lecturer in Civ. Eng., Univ. of California, Berkeley, Calif.

Engineers who deal with airport design are well aware that a soil whose *k*-value is 100 is considered a relatively poor subgrade, whereas a soil with a *k*-value of 300 is considered a good subgrade. In other words, the *k*-values presented in Fig. 1 represent a range of subgrades from poor to good. The *k*-value for gravel and gravelly soils varies from 200 to 500 whereas it may be as low as 50 for fine-grain soils having high compressibility. Several publications are available[19] which show the approximate range of *k*-values for soil groups classified by either the Public Roads Administration soils classification or the Casagrande soils classification.[20]

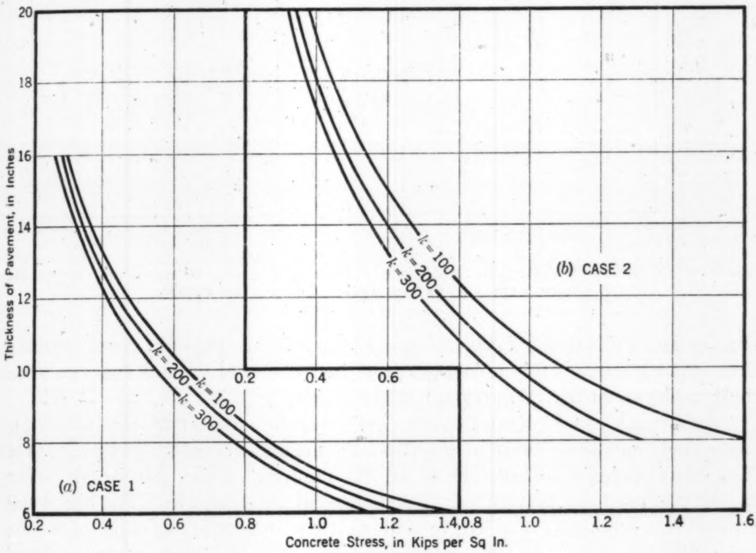

FIG. 1.—SIGNIFICANCE OF RELATIVE *k*-VALUES

This discussion and an examination of Fig. 1 reveal that the establishment of the *k*-value to the nearest 50 units is sufficiently accurate for most design problems, and that the project costs would not be adversely affected. Another conclusion that can be reached is that, for the average case, the engineer will find it more economical to increase the thickness of the pavement, rather than to improve the *k*-value of the subgrade by the addition of a better quality of material.

EVAN P. BONE,[21] ESQ.—The comprehensive formulas given in this paper prove to be very useful in the new design problems of pavements for heavy aircraft. It is possible to predict stresses under conditions not heretofore determinable from purely theoretical analysis. The design curves for rigid pavements given in an engineering manual[22] are based on Eq. 13, inasmuch as it has been determined that edge stress resulting from edge loading is critical for airfield pavements. Eq. 17, which is more general, has been found particularly applicable in the latest design problems of multiple-wheel landing gears.

(*a*) SINGLE FOOTPRINT (*b*) DUAL FOOTPRINT

Fig. 2.—Plan of Slab Showing Ratio of Model Experimental Stress to Westergaard Theoretical Stress, with Arrows Indicating Directions of Stress

By the use of this formula it is now possible to compute the edge stress resulting from the superimposition of stresses from two wheels of various spacing, when both are symmetrical with respect to the y-axis.

As a rough check of the formulas used, experimental strain measurements were made on a scale model at the Rigid Pavement Laboratory of the Corps of Engineers under the direction of R. R. Philippe, Assoc. M. ASCE. The model consisted of a plaster slab on a sponge rubber subgrade. The horizontal dimensions, including the length and width of footprint, spacing of wheels (if multiple wheels), and the "radius of relative stiffness" were all proportioned to scale (approximately 1:20) corresponding to a chosen prototype. The scale value of the "radius of relative stiffness" was secured by use of Eq. 1, in which the terms E, μ, and k were taken as constants of the materials of which the model was constructed. The desired scale value of l was obtained by solving for h, which, for the plaster material used, equaled $\frac{1}{4}$ in. The subgrade modulus, k, of the sponge rubber was evaluated by measuring the volume displacement under a given load. The strains were measured by electrical gages of 1/8-in. active length.

Fig. 2 gives the ratios of the experimental stresses to the theoretical ones. Several items from which the average values were determined refer to different conditions and locations of the respective types of loading, as, for instance, the edge stresses at all four edges of the same model slab. It is observed that the average experimental stresses are lower than the corresponding theoretical stresses. This may be due to experimental error alone, but there are indications that the difference was influenced by the fact that the sponge rubber subgrade acted more as a semi-infinite body than as a liquid support, which defines k.

---

[22] "Ad Interim Engineering Manual for War Department Construction," Corps of Engrs., Office of the Chf. of Engrs., July, 1946, Pt. XII, Chapter 3, p. 16 (published by the War Dept., Washington, D. C.).

Fig. 3 shows a comparison of experimental and theoretical edge stress as the load moves across a joint onto an adjacent panel, the joint having no capacity for load transfer. These experimental stresses are consistently lower than the theoretical ones; yet the similarity of the shapes of the curves and locations of the peak stresses are significant to a distance approximately $2\,l$ from the edge of the slab.

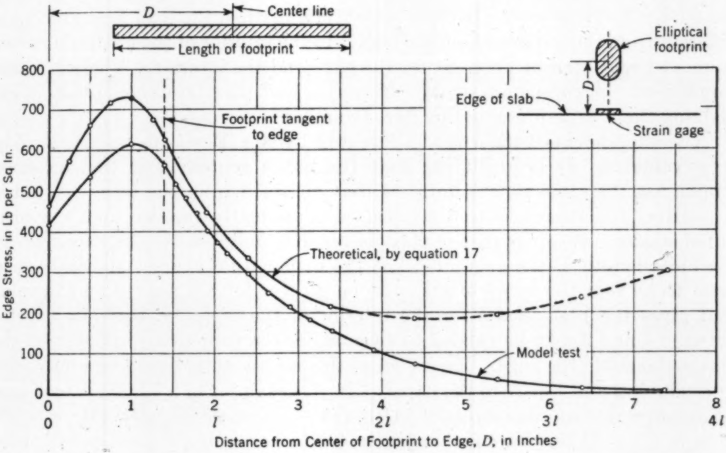

FIG. 3.—COMPARISON OF MODEL TEST SLAB STRESSES WITH WESTERGAARD THEORETICAL STRESSES ($P = 40.42$ LB; $h = 0.265$ IN.; $a = 0.845$ IN.; $b = 1.410$ IN.; $E = 2 \times 10^6$; $\mu = 0.2$; $k = 190$; AND $l = 2.0$ IN.)

Although the model measurements were not performed with a high degree of precision, they may serve to carry convincing verification of the validity of the theoretical analysis.

H. M. WESTERGAARD,[23] M. ASCE.—The curves presented by Mr. Horonjeff serve the useful purpose of showing the numerical meaning of the formulas when applied to a range of practical cases. These curves give renewed emphasis to the fact that the computed values of the stresses are not very sensitive even to fairly great variations of the modulus k of subgrade reaction. The particular test to determine k mentioned by Mr. Horonjeff deserves attention because it is fairly simple, can be made in advance, and has been found to give usable values of k within some range of applications. Outside this range, for example, in the case of very thick pavements, it is probable that values of k obtained directly from this test will require some coefficient of correction.

The fact is that—as has often been stated—the use of a definite value of k is only an empirical makeshift justified by usable results. The modulus k is not a simple mechanical property of the subgrade. The reaction of the subgrade at any one place depends not only on the deflection at that place but on the general pattern of deflections within the surrounding area; and the value of *k* that serves best under given circumstances depends on this pattern as well as on the mechanical properties of the subgrade itself. Therefore *k* becomes a property of the subgrade and the pavement and the character and position of the load. Thus, since the pattern of deflections when the load is at an edge is different from the pattern when the load is in the interior of the area, the proper value of *k* may well be different for the edge and the interior. These remarks supplement the comments by Mr. Horonjeff and may be of some help in explaining the results presented by Mr. Bone in his discussion.

---

[23] Gordon McKay Prof. of Civ. Eng., Graduate School of Eng., Harvard Univ., Cambridge, Mass.

The experiments with a model reported by Mr. Bone are unquestionably very valuable. It is gratifying that the curve representing the measured strains has the same general form as that obtained from the formulas, but it s puzzling that the measured strains are consistently smaller than the computed strains. A minor part of this discrepancy may possibly be explained by the finite length of the gage line, but the explanation nearest at hand would seem to be that the value of *k* should be greater for the edge than the value that gives the best results for the interior of the area. A correction factor between 1 and 2 may be needed to account for the supporting influence of the material outside the edge. To see what this means numerically one may refer to Example 2 and Eq. 27 in the paper. In this example of a 50,000-lb load on a 10-in. pavement an edge stress of 741 lb per sq in. was computed with $k = 200$ lb per cu in. If this *k* were changed to 400 lb per cu in., the computed stress would be reduced to 626 lb per sq in. This reduction is of the order of magnitude indicated by Mr. Bone's results.

Another possibility involves consideration of the energy of shearing stresses near the edge on vertical sections perpendicular to the edge. In the theory this energy was assumed to be relatively negligible. If it is found not to be negligible, this energy may account for a part of the discrepancy. A study of this influence would be difficult, but might prove to be worth undertaking.

BEAM DEFLECTIONS BY SECOND AND THIRD MOMENTS

By Hsu Shih-Chang,[1] Esq.

With Discussion by Messrs. A. Floris, Robert B. B. Moorman, Frank J. McCormick, William A. Conwell, and Hsu Shih-Chang.

Synopsis

The various methods for computing beam deflections may be classified into two main groups—the double-integration method and the moment-area method. In both methods, beam deflection is considered a function of bending moment; and bending moment, in turn, is a function of the force system acting on the beam. In other words, deflection is computed, not directly from the forces acting on the beam, but rather indirectly through the medium of bending moment. Such indirect approach naturally makes the computations lengthy and complicated, and the aim of this paper is to suggest a more direct solution.

Introduction

With the conception of second and third moments of forces and couples, formulas are derived expressing slope deviation as a function of the second moment of forces and couples, and deflection as a function of the second and third moments of forces and couples. Although the fundamental differential equation of beam deflection—

$$\frac{d^2y}{dx^2} = \frac{M}{E\,I} \qquad (1)$$

—must be used in the derivation of such formulas, the final results are free from expressions of bending moment and they have the unique features of simplicity and lucidity.

The method can also be applied to a beam of variable moment of inertia provided that it is segmentally constant and provided that the secondary effects of axial thrust or tension, as well as the effect of the deflection due to shear, are not considered.

Notation.—The letter symbols in this paper are defined where they first appear, in the text or by illustrations, and are assembled alphabetically in the Appendix for convenience of reference.

Note.—Published in March, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

Second and Third Moments of Forces and Couples

Definition of Second and Third Moments.—Unless otherwise modified for a given case, this paper is based on the following assumptions: All forces are perpendicular to the reference line (ON, Figs. 1 and 2), all couples are considered to act at some point on the reference line, and the moment center is always taken on the reference line.

The second moment M'' and the third moment M''' of any force P_A, with respect to any point N taken as the moment center, are defined as the force P_A multiplied by the square and cube, respectively, of the perpendicular distance from the force to point N. Thus (see Fig. 1):

$$M_N = P_A\, a_A; \qquad M''_N = P_A\, a^2_A; \text{ and } M'''_N = P_A\, a^3_A \ldots\ldots (2)$$

in which the point force P_A is considered positive when acting upward and the moment arm a_A (Fig. 1) is positive when point A is on the left of point N.

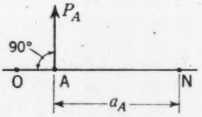

Fig. 1

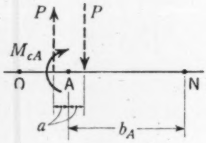

Fig. 2

Fig. 2 shows a couple M_{cA} acting at point A on the reference line ON. This couple can be replaced by two equal and opposite forces:

$$P = \frac{M_{cA}}{2\,a} \ldots\ldots (3)$$

in which the moment arm a is infinitely small. For this case the second moment is written:

$$M''_N = P\,(b_A + a)^2 - P\,(b_A - a)^2 = 2\,(2\,P\,a)\,b_A \ldots\ldots\ldots\ldots (4)$$

In other words,

$$M''_N = 2\,M_{cA}\,b_A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

and the third moment, similarly, is written:

$$M'''_N = P\,(b_A + a)^3 - P\,(b_A - a)^3 = 3\,M_{cA}\,b^2_A \ldots\ldots\ldots (5b)$$

In Eqs. 5 the couple M_c is positive when it acts in a clockwise direction; and the reference distance, or "moment arm" b_A, is positive when point A is on the left of point N. If the couple M_c acts at point N:

$$M_N = M_c;\; M''_N = 0; \text{ and } M'''_N = 0 \ldots\ldots (6)$$

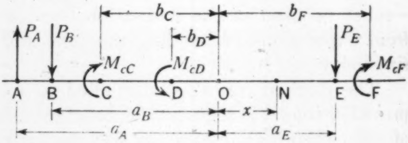

Fig. 3

Characteristics of Second and Third Moments.—Consider the balanced force system shown in Fig. 3, with points O and N, in turn, taken as the moment center. From the conditions of equilibrium:

$$\sum P = P_A - P_B - P_E = 0 \ldots\ldots\ldots\ldots\ldots\ldots (7a)$$

$$M_O = P_A\,a_A - P_B\,a_B + P_E\,a_E + M_{cC} - M_{cD} + M_{cF} = 0 \ldots\ldots (7b)$$

and

$$M_N = P_A\,(a_A + x) - P_B\,(a_B + x) + P_E\,(a_E - x) + M_{eC} - M_{eD} + M_{eF} = 0 \quad \text{(7c)}$$

Taking algebraic signs into consideration, Eqs. 7 can be written in more general terms as follows:

$$\sum_1^n P_n = 0 \quad \text{(8a)}$$

$$M_O = \sum_1^n (P_n\,a_n) + \sum_1^m M_{em} = 0 \quad \text{(8b)}$$

and

$$M_N = \sum_1^n P_n(a_n + x) + \sum_1^m M_{em} = 0 \quad \text{(8c)}$$

The second moments of the balanced force system (Fig. 3) with respect to points O and N, respectively, are:

$$M''_O = \sum_1^n (P_n\,a^2_n) + 2\sum_1^m (M_{em}\,b_m) \quad \text{(9a)}$$

and

$$M''_N = \sum_1^n P_n(a_n + x)^2 + 2\sum_1^m M_{em}\,(b_m + x) = \sum_1^n (P_n\,a^2_n) + 2\sum_1^m (M_{em}\,b_m) + x^2\sum_1^n P_n + 2\,x\left[\sum_1^n (P_n\,a_n) + \sum_1^m M_{em}\right] \quad \text{(9b)}$$

Substituting Eqs. 8 in Eqs. 9:

$$M''_N = \sum_1^n (P_n\,a^2_n) + 2\sum_1^m (M_{em}\,b_m) = M''_O \quad \text{((10a)}$$

or

$$M'' = \text{a constant} \quad \text{(10b)}$$

In Eq. 10*b* the subscript for M'' is unnecessary since the location of the moment center is immaterial. Eq. 10*b* defines the first characteristic of the second and third moments, for forces and couples; thus:

> Theorem I. The second moment of any balanced force system with respect to any point on the reference line is a constant.

Similar to Eqs. 9, the third moments of the balanced force system (Fig. 3) with respect to points O and N, respectively, are:

$$M'''_O = \sum_1^n (P_n\,a^3_n) + 3\sum_1^m (M_{em}\,b^2_m) \quad \text{(11a)}$$

$$M'''_N = \sum_1^n P_n(a_n + x)^3 + 3\sum_1^m M_{cm}\,(b_m + x)^2 = \sum_1^n (P_n\,a^3{}_n)$$
$$+ 3\sum_1^m (M_{cm}\,b^2{}_m) + 3\,x\left[\sum_1^n (P_n\,a^2{}_n) + 2\sum_1^m (M_{cm}\,b_m)\right]$$
$$+ 3\,x^2\left[\sum_1^n (P_n\,a_n) + \sum_1^m M_{cm}\right] + x^3\sum_1^n P_n \,.. \text{(11}b\text{)}$$

Substituting Eqs. 8 and 10 in Eqs. 11:

$$M'''_N = M'''_O + 3\,M''_O\,x = M'''_O + 3\,M''\,x \ldots\ldots\ldots\ldots (12)$$

Eq. 12 defines the second characteristic of second and third moments:

> Theorem II. The third moment of a balanced force system with respect to any point N on the reference line is equal to the third moment of the force system with respect to any other point O on the reference line, plus three times the distance ON multiplied by the second moment of the force system (with respect to any point on the reference line). The value of ON is positive when point N is on the right side of point O.

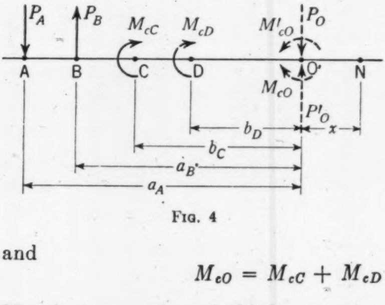

Fig. 4

The next step is to consider the unbalanced force system shown in Fig. 4, consisting of the parallel forces P_A and P_B and couples M_{cC} and M_{cD}. Let the resultant of the unbalanced force system be represented by a force P_O and a couple M_{cO}, both acting at point O; thus:

$$P_O = P_A - P_B \ldots.. (13a)$$

and

$$M_{cO} = M_{cC} + M_{cD} - P_A\,a_A + P_B\,a_B \ldots\ldots\ldots\ldots (13b)$$

The first, second, and third moments of the given unbalanced force system remain unchanged if two equal and opposite forces (P_O and P'_O) and two equal and opposite couples (M_{cO} and M'_{cO}) are introduced, all acting at point O, as shown by dotted lines in Fig. 4. The given unbalanced force system (P_A, P_B, M_{cC}, and M_{cD}), together with its equilibrant (the force P'_O and the couple M'_{cO}) forms a balanced force system. Thus, with any point N on the reference line taken as the moment center: M''_N of the given unbalanced force system (P_A, P_B, M_{cC}, and M_{cD}) is equal to the second moment M''_N of the balanced force system (P_A, P_B, M_{cC}, M_{cD}, P'_O, and M'_{cO}) plus the second moment M''_N of the resultant of the unbalanced force system (P_O and M_{cO}). Since the second moment of a balanced force system is constant (see theorem I and Eq. 10*b*), the second moment M''_N of the balanced force system (P_A, P_B, M_{cC}, M_{cD}, P'_O, and M'_{cO}) is equal to the second moment M''_O of the same balanced force system, which is equal to the second moment M''_O of the given unbalanced force system plus the second moment M''_O of the equilibrant of the given unbalanced force system (P'_O and M'_{cO}).

From Eq. 6, the second moment M''_O of the equilibrant (P'_O and M'_{eO}) vanishes. Hence:

$$M''_N = M''_O + M''_{O,N} \dots\dots\dots\dots\dots\dots (14)$$

Eq. 14 defines the third characteristic of second and third moments:

Theorem III. The second moment (M''_N) of the unbalanced force system with respect to any point N on the reference line is equal to the second moment of the unbalanced force system (M''_O) with respect to any other point O, plus the second moment of the resultant of the unbalanced force system ($M''_{O,N}$) at point O (P_O and M_{eO}) with respect to point N.

Similarly, it can be shown that:

$$M'''_N = M'''_O + 3\, M''_O\, x + M'''_{O,N} \dots\dots\dots\dots (15)$$

which defines theorem IV, as follows:

Theorem IV. The third moment (M'''_N) of the given unbalanced force system (P_A, P_B, M_{eC}, and M_{eD}) with respect to any point N on the reference line is equal to the third moment (M'''_O) of the unbalanced force system with respect to any other point O, also on the reference line, plus three times the product of x and the second moment (M''_O) of the unbalanced force system, with respect to point O; plus the third moment ($M'''_{O,N}$) of the resultant of the unbalanced force system at point O (P_O and M_{eO}) with respect to point N.

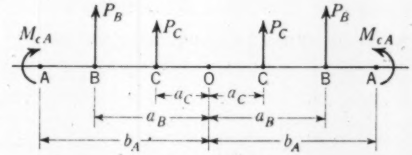

FIG. 5

Finally, for a force system symmetrical about a point O (for example, as shown in Fig. 5), the third moment with respect to point O is:

$$M'''_O = 3\, M_{eA}\, b^2_A + 3\,(-\,M_{eA})\,(-\,b_A)^2 + P_B\, a^3_B + P_B\,(-\,a_B)^3$$
$$+\, P_C\, a^3_C + P_C\,(-\,a_C)^3 = 0 \dots (16a)$$

or

$$M'''_O = 0 \dots\dots\dots\dots\dots\dots (16b)$$

Eq. 16*b* defines the fifth characteristic:

Theorem V. The third moment of any symmetrical force system with respect to the point of symmetry is equal to zero.

SECOND AND THIRD MOMENTS OF FORCE SYSTEMS ACTING ON STRAIGHT BEAMS

A straight beam may be subjected to any system of loading; but, if the secondary effect of axial thrust or tension is neglected, only the couples and transverse loads applied on the beam axis cause flexure; any forces other than these need not be considered. The following typical cases of loading are particularly important in engineering problems.

Case 1. Concentrated Forces and Couples Acting Indirectly on Beam Axis.—For normal forces and couples acting directly on beam axis, use Eqs. 2 to 5, taking the beam axis as the reference line. For oblique or indirect loads, replace the given force system by an equivalent force system acting directly on the beam axis, as shown in Fig. 6.

FIG. 6

Case 2. Uniformly Distributed Load Normal to Beam Axis.—By direct integration (see Fig. 7(*a*)):

$$M''_O = \int_{-l/2}^{l/2} \left(- \frac{W}{l}\, dz \right) z^2 = - \frac{W\, l^2}{12} \ldots\ldots\ldots\ldots (17a)$$

which is numerically equal to the area of the simple beam moment diagram,

(*a*) (*b*) (*c*)

FIG. 7

as shown in Fig. 7(*b*). Since the load is symmetrical about point O (Fig. 7(*a*)), Eq. 16*b* yields:

$$M'''_O = 0 \ldots\ldots\ldots\ldots (17b)$$

By Eq. 14:

$$M''_N = M''_O + M''_{O,N} = - \frac{W\, l^2}{12} - W\, x^2 \ldots\ldots\ldots (18a)$$

By Eq. 15:

$$M'''_N = M'''_O + 3\, M''_O\, x + M'''_{O,N} = - \frac{W\, l^2}{4}\, x - W\, x^3 \ldots (18b)$$

If $x = l/2$:

$$M''_B = - \frac{W\, l^2}{3}; \text{ and } M'''_B = - \frac{W\, l^3}{4} \ldots\ldots\ldots\ldots (19)$$

If $x = -\, l/2$:

$$M''_A = - \frac{W\, l^2}{3}; \text{ and } M'''_A = + \frac{W\, l^3}{4} \ldots\ldots\ldots\ldots (20)$$

Case 3. Triangular Load Normal to Beam Axis.—By integration, referring to Fig. 7(*c*):

$$M''_O = \int_0^l \left(- \frac{2\,W}{l^2}\, z\, dz \right) (\tfrac{2}{3}\, l - z)^2 = - \frac{W\, l^2}{18} \qquad \text{(21}a\text{)}$$

and

$$M'''_O = \int_0^l \left(- \frac{2\,W}{l^2}\, z\, dz \right) (\tfrac{2}{3}\, l - z)^3 = - \frac{W\, l^3}{135} \qquad \text{(21}b\text{)}$$

By Eqs. 14 and 15:

$$M''_N = M''_O + M''_{O,N} = - \frac{W\, l^2}{18} - W\, x^2 \qquad \text{(22}a\text{)}$$

and

$$M'''_N = M'''_O + 3\, M''_O\, x + M'''_{O,N} = - \frac{W\, l^3}{135} - \frac{W\, l^2}{6}\, x - W\, x^3 \qquad \text{(22}b\text{)}$$

For points A and B, assume that $x = -\tfrac{2}{3}\, l$ and $x = +\tfrac{1}{3}\, l$, respectively; thus:

$$M''_A = - \frac{W\, l^2}{2}\,; \text{ and } M'''_A = \tfrac{2}{5}\, W\, l^3 \qquad \text{(23}a\text{)}$$

and

$$M''_B = - \frac{W\, l^2}{6}\,; \text{ and } M'''_B = - \frac{W\, l^3}{10} \qquad \text{(23}b\text{)}$$

Second and third moments for other loading conditions may be computed by integration and substitution into Eqs. 14 and 15.

METHOD OF SECOND AND THIRD MOMENTS FOR COMPUTING BEAM DEFLECTIONS

Defining the x-axis as the undeflected position of the beam axis (which is the "reference line" defined in the preceding section) and the y-axis as the plane normal to the x-axis, with positive directions as shown in Fig. 8, let: δ_A be the vertical deflection at any point A, positive when upward; δ_{BA} be equal to $\delta_B - \delta_A$ and equal to the vertical deflection of point B relative to that of point A; y_{BA} be the vertical deflection of point B measured from the tangent to the elastic curve of the deflected beam axis at point A (positive when upward); θ_A be the angular deflection at point A, which can be taken as equal to $\frac{d\delta}{dx}$ at point A, assuming the same sign as the latter; and θ_{BA} be equal to $\theta_B - \theta_A$ and equal to the angular deflection at point B relative to that at point A. The sign conventions are illustrated in Fig. 8. It follows that:

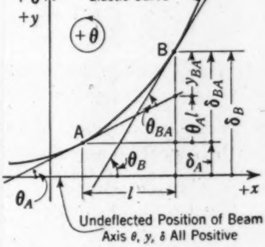

FIG. 8

$$\theta_{BA} = - \theta_{AB}; \text{ and } \delta_{BA} = - \delta_{AB} \qquad \text{(24)}$$

Fig. 9 shows a segment AB of a straight beam with constant flexural rigidity, subject to end shears V_A and V_B; end moments M_A and M_B; transverse loads P_a, P_c, $\cdots$, P_n; and couples M_b and M_d, $\cdots$, M_m.

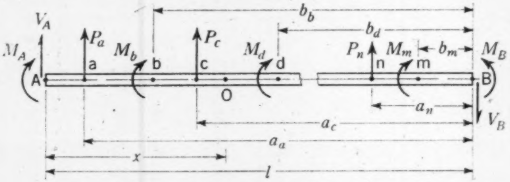

Fig. 9

The well-known differential equation of the elastic curve of the deflected beam axis is

$$\frac{d^2y}{dx^2} = \frac{M}{E\,I} \quad \text{(25)}$$

in which

$$M = M_A + V_A\,x; \quad \text{for} \quad 0 \leqq x \leqq l - a_a \quad \text{(26a)}$$

$$M = M_A + V_A\,x + P_a\,(x - l + a_a); \quad \text{for} \quad l - a_a \leqq x \leqq l - b_b \quad \text{(26b)}$$

$$M = M_A + M_b + V_A\,x + P_a\,(x - l + a_a); \quad \text{for} \quad l - b_b \leqq x \leqq l - a_c \quad \text{(26c)}$$

. . . .

$$M = M_A + \sum_1^m M_m + V_A\,x + \sum_1^n P_n\,(x - l + a_n); \quad \text{for} \quad l - b_m \leqq x \leqq l \quad \text{(26d)}$$

By integration, the angular deflection of point B relative to point A is:

$$\theta_{BA} = \frac{1}{E\,I}\int_0^l M\,dx = \frac{1}{E\,I}\left\{\left(M_A\int_0^l dx + \sum_1^m M_m \int_{l-b_m}^l dx\right) + \left[V_A\int_0^l x\,dx + \sum_1^n P_n \int_{l-a_n}^l (x - l + a_n)\,dx\right]\right\} = \frac{1}{2\,E\,I}\,M''_{AB,\,B} \quad \text{(27)}$$

Since the force system shown in Fig. 9 is in equilibrium and the second moment (with respect to any point on the beam axis) is, therefore, a constant:

$$\theta_{BA} = \frac{1}{2\,E\,I}\,M''_{AB} \quad \text{(28a)}$$

in which M''_{AB} is the second moment of the force system acting on the segment AB, including end moments and end shears; and point B is on the right side of point A. By Eq. 24,

$$\theta_{AB} = -\,\theta_{BA} = -\,\frac{M''_{AB}}{2\,E\,I} \quad \text{(28b)}$$

Thus, the more general expression may be written as

$$\theta_{BA} = \pm \frac{M''_{AB}}{2\,E\,I} \quad \text{(29a)}$$

which takes the positive sign when point B is on the right side of point A.

Referring to Fig. 8:

$$\theta_B = \theta_A + \theta_{BA} = \theta_A \pm \frac{1}{2\,E\,I} M''_{AB} \quad \text{(29b)}$$

which takes the positive sign when point B is on the right side of point A.

Eqs. 29 give the first fundamental theorem of the method of second and third moments, for beam deflections:

> Theorem VI. The angle θ_{BA} measured from the tangent to the elastic curve at any point A to the tangent at any other point B on the right side of point A, in a segment AB of a straight beam of constant flexural rigidity, is equal to the second moment of the force system acting on the segment AB, including end moments and end shears of the segment, taken with respect to any point on the undeflected beam axis, divided by twice the flexural rigidity of the beam (that is, by 2 *E I*).

The deflection of point B from the tangent at point A (Figs. 8 and 9) is:

$$y_{BA} = \frac{1}{E\,I}\int_0^l \int_0^x M\,dx\,dx = \frac{1}{E\,I}\left\{\left(M_A \int_0^l \int_0^x dx\,dx + \sum_1^m M_m \int_{l-b_m}^l \int_{l-b_m}^x dx\,dx\right) + \left[V_A \int_0^l \int_0^x x\,dx\,dx + \sum_1^n P_n \int_{l-a_n}^l \int_{l-a_n}^x (x - l + a_n)\,dx\,dx\right]\right\} = \frac{1}{6\,E\,I} M'''_{AB,\,B} \quad \text{(30)}$$

in which M'''_{AB} is the third moment of the force system acting on the segment AB, including end moments and end shears of the segment, with respect to point B, the latter point (B) being on the right side of point A. The more general form may be written as

$$y_{BA} = \pm \frac{M'''_{AB,\,B}}{6\,E\,I} \quad \text{(31a)}$$

which takes the positive sign when point B is on the right side of point A.

Referring again to Fig. 8, the deflection of point B is:

$$\delta_B = \delta_A + \theta_A\,l + y_{BA} = \delta_A + \theta_A\,l \pm \frac{M'''_{AB,\,B}}{6\,E\,I} \quad \text{(31b)}$$

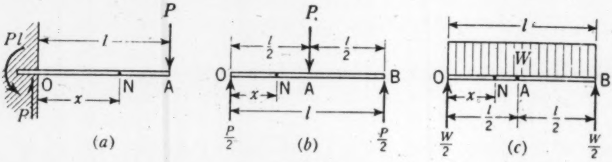
In Eq. 31*b* the positive sign is used when point B is on the right side of point A.

Eqs. 31 give the second fundamental theorem of the method of second and third moments, for beam deflections:

> Theorem VII. The deflection of any point B, measured from the tangent to the elastic curve at point A, of a segment (AB) of a straight beam of constant flexural rigidity, is equal to the third moment of the force system

acting on the segment AB, including end moments and end shears of the segment, taken with respect to point B, divided by six times the flexural rigidity; that is, by $6\,E\,I$.

Theorems VI and VII are similar in nature to theorems I and II of the moment-area method, and lead to identical results. The following examples illustrate the application of theorems VI and VII.



(a) (b) (c)

Fig. 10

Example 1. Cantilever Beam Loaded at Free End.—For the case shown in Fig. 10(*a*), $\theta_O = 0$ and $\delta_O = 0$. From theorem VI or Eq. 29*b*,

$$\theta_N = \frac{1}{2\,E\,I}\,M''_{ON} = \frac{1}{2\,E\,I}\,(P\,x^2 - 2\,P\,l\,x) \dots\dots (32a)$$

and, from theorem VII or Eq. 31*b*,

$$\delta_N = \frac{1}{6\,E\,I}\,M'''_{ON,N} = \frac{1}{6\,E\,I}\,(P\,x^3 - 3\,P\,l\,x^2) \dots\dots (32b)$$

At the free end, A (see Fig. 10(*a*)):

$$\theta_A = -\frac{P\,l^2}{2\,E\,I}\,;\ \text{and}\ \delta_A = -\frac{P\,l^3}{3\,E\,I} \dots\dots (33)$$

Example 2. Simple Beam with a Concentrated Load at Center.—For the case shown in Fig. 10(*b*), as in Fig. 10(*a*), $\theta_A = 0$ and $\delta_O = 0$. Again, from theorem VI or Eq. 29*b*,

$$\theta_A = \theta_O + \frac{1}{2\,E\,I}\,M''_{OA} = \theta_O + \frac{1}{2\,E\,I}\left(\frac{P}{2}\right)\left(\frac{l}{2}\right)^2 = 0 \dots\dots (34a)$$

and

$$\theta_O = -\frac{P\,l^2}{16\,E\,I} \dots\dots (34b)$$

Thus, for $x \leqq l/2$, by Eqs. 29*b* and 31*b*:

$$\theta_N = \theta_O + \frac{1}{2\,E\,I}\,M''_{ON} = \frac{P}{16\,E\,I}\,(4\,x^2 - l^2) \dots\dots (35a)$$

and

$$\delta_N = \theta_O\,x + \frac{1}{6\,E\,I}\,M'''_{ON,N} = \frac{1}{48\,E\,I}\,P\,x\,(4\,x^2 - 3\,l^2) \dots\dots (35b)$$

At the center A, $x = \frac{1}{2}\,l$:

$$\delta_A = -\frac{1}{48\,E\,I}\,P\,l^3 \dots\dots (35c)$$

Example 3. Simple Beam Subject to Uniformly Distributed Load.—By Eq. 29*b* with $\theta_A = 0$ and $\delta_O = 0$ (see Fig. 10(*c*)):

$$\theta_A = \theta_O + \frac{1}{2\,E\,I}\,M''_{OA} = \theta_O + \frac{1}{2\,E\,I}\left[\frac{W}{2}\left(\frac{l}{2}\right)^2 - \int_0^{l/2}\left(\frac{W}{l}\right)x^2\,dx\right]$$

$$= \theta_O + \frac{W\,l^2}{24\,E\,I} = 0 \ldots\ldots (36a)$$

and

$$\theta_O = -\,\frac{W\,l^2}{24\,E\,I} \ldots\ldots (36b)$$

By Eqs. 29*b* and 31*b*:

$$\theta_N = \theta_O + \frac{1}{2\,E\,I}\,M''_{ON} = -\,\frac{W\,l^2}{24\,E\,I} + \frac{1}{2\,E\,I}\left[\frac{W}{2}\,x^2 - \int_0^x\left(\frac{W}{l}\right)x^2\,dx\right]$$

$$= \frac{W}{24\,E\,I}\left(-\,l^2 + 6\,x^2 - 4\,\frac{x^3}{l}\right) \ldots\ldots (37a)$$

and

$$\delta_N = \delta_O + \theta_O\,x + \frac{1}{6\,E\,I}\,M'''_{ON,N} = -\,\frac{1}{24\,E\,I}\,W\,l^2\,x$$

$$+ \frac{1}{6\,E\,I}\left(\frac{W}{2}\,x^3 - \int_0^x \frac{W}{l}\,x^3\,dx\right) = \frac{1}{24\,E\,I}\,W\left(-\,l^2\,x + 2\,x^3 - \frac{x^4}{l}\right) \ldots (37b)$$

For $x = l/2$:

$$\delta_A = -\,\frac{5\,W\,l^3}{384\,E\,I} \ldots\ldots (38)$$

The computation of Eqs. 36 to 38 may be facilitated by using Eqs. 19, substituting $\frac{W}{l}\,x$ for W, and x for l. The second and third moments, referred to point N as moment center, due to uniform load only, are, respectively:

$$M'' = -\,\frac{W\,x^3}{3\,l}\,;\ \text{and}\ M''' = -\,\frac{W\,x^4}{4\,l} \ldots\ldots (39)$$

From which:

$$M''_{ON} = M''_{ON,N} = \frac{W}{2}\,x^2 - \frac{W\,x^3}{3\,l} \ldots (40a)$$

and

$$M'''_{ON,N} = \frac{W}{2}\,x^3 - \frac{W\,x^4}{4\,l} \ldots\ldots (40b)$$

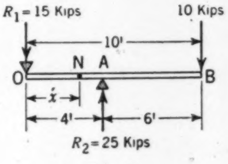


FIG. 11

Example 4. Overhanging Beam Loaded at Free End.—By Eq. 31*b*, with $\delta_O = 0$ and $\delta_A = 0$ (see Fig. 11):

$$\delta_A = \delta_O + \theta_O \times 4 + \frac{1}{6\,E\,I}\,M'''_{OA,A} = \theta_O \times 4 + \frac{1}{6\,E\,I}\left(-\,15 \times 4^3\right) = 0 \ldots (41a)$$

and

$$\theta_O = \frac{40}{E\,I} \qquad \text{(41}b\text{)}$$

For $x \leqq 4$ ft, Eqs. 29*b* and 31*b* yield:

$$\theta_N = \theta_O + \frac{1}{2\,E\,I} M''_{ON} = \frac{40}{E\,I} + \frac{1}{2\,E\,I}(-\,15)\,x^2 = \frac{1}{E\,I}(40 - 7.5\,x^2) \qquad \text{(42}a\text{)}$$

and

$$\delta_N = \delta_O + \theta_O\,x + \frac{1}{6\,E\,I} M'''_{ON,\,N} = \frac{1}{E\,I}(40\,x - 2.5\,x^3) \qquad \text{(42}b\text{)}$$

Similarly, for $x \geqq 4$ ft:

$$\theta_N = \theta_O + \frac{1}{2\,E\,I} M''_{ON} = \frac{1}{E\,I}(240 - 100\,x + 5\,x^2) \qquad \text{(43}a\text{)}$$

and

$$\delta_N = \delta_O + \theta_O\,x + \frac{1}{6\,E\,I} M'''_{ON,\,N}$$

$$= \frac{1}{6\,E\,I}(10\,x^3 - 300\,x^2 + 1{,}440\,x - 1{,}600) \qquad \text{(43}b\text{)}$$

At the free end:

$$\theta_B = -\,\frac{260}{E\,I}\,;\ \text{and}\ \delta_B = -\,\frac{1{,}200}{E\,I} \qquad \text{(44)}$$

in which E is in kips per square foot, and I is in feet^4.

Example 5. Simple Beam Subject to Indirect Loading.—The external load on the beam in Fig. 12(*a*) is replaced by the equivalent force system as shown in Fig. 12(*b*). By Eq. 31*b*, with $\delta_O = 0$ and $\delta_A = 0$:

FIG. 13

$$\delta_A = \delta_O + \theta_O \times 30 + \frac{1}{6\,E\,I} M'''_{OA,\,A}$$

$$= 30\,\theta_O + \frac{1}{6\,E\,I}(1.8 \times 30^3 - 3 \times 10^3 - 3 \times 24 \times 10^2) = 0 \qquad \text{(45}a\text{)}$$

and

$$\theta_O = -\,\frac{640}{3\,E\,I} \qquad \text{(45}b\text{)}$$

for $x \leqq 20$ ft, by Eqs. 29*b* and 31*b*:

$$\theta_N = \theta_O + \frac{1}{2\,E\,I}\,M''_{ON} = -\,\frac{1{,}280}{6\,E\,I} + \frac{1}{2\,E\,I} \times 1.8\,x^2$$

$$= \frac{1}{6\,E\,I}\,(-\,1{,}280 + 5.4\,x^2) \ldots\ldots (46a)$$

and

$$\delta_N = \delta_O + \theta_O\,x + \frac{1}{6\,E\,I}\,M'''_{ON,N} = \frac{x}{6\,E\,I}\,(-\,1{,}280 + 1.8\,x^2) \ldots (46b)$$

For $x \geqq 20$ ft:

$$\theta_N = \theta_O + \frac{M''_{ON}}{2\,E\,I} = -\,\frac{1}{E\,I}\,(0.6\,x^2 - 36\,x + 333.3) \ldots\ldots\ldots (47a)$$

and

$$\delta_N = \delta_O + \theta_O\,x + \frac{1}{6\,E\,I}\,M'''_{ON,N}$$

$$= -\,\frac{1}{6\,E\,I}\,(1.2\,x^3 - 108\,x^2 + 2{,}000\,x + 4{,}800) \ldots\ldots (47b)$$

STRAIGHT BEAMS OF SEGMENTALLY CONSTANT FLEXURAL RIGIDITY

Fig. 13 shows the elastic curve of a beam whose flexural rigidity is $(E\,I)_{AB}$ for segment AB, $(E\,I)_{BC}$ for segment BC, and $(E\,I)_{CZ}$ for segment CZ. By Eq. 29*a*:

$$\theta_{ZA} = \theta_{BA} + \theta_{CB} + \theta_{ZC} = \frac{1}{2(E\,I)_{AB}}\,M''_{AB}$$

$$+ \frac{1}{2(E\,I)_{BC}}\,M''_{BC} + \frac{1}{2(E\,I)_{CZ}}\,M''_{CZ} \ldots\ldots (48a)$$

The general form, therefore, is:

$$\theta_{ZA} = \sum \frac{M''_{AB}}{2(E\,I)_{AB}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48b)$$

Substituting, $M''_{BC} = M''_{AC} - M''_{AB}$; and $M''_{CZ} = M''_{AZ} - M''_{AC}$. In Eq. 48*b*:

$$\theta_{ZA} = \frac{1}{2(E\,I)_{AB}}\,M''_{AB} + \frac{1}{2(E\,I)_{BC}}\,(M''_{AC} - M''_{AB})$$

$$+ \frac{1}{2(E\,I)_{CZ}}\,(M''_{AZ} - M''_{AC}) = \left[\frac{1}{2(E\,I)_{AB}} - \frac{1}{2(E\,I)_{BC}}\right] M''_{AB}$$

$$+ \left[\frac{1}{2(E\,I)_{BC}} - \frac{1}{2(E\,I)_{CZ}}\right] M''_{AC} + \frac{1}{2(E\,I)_{CZ}}\,M''_{AZ} = \Delta\!\left(\frac{1}{2\,E\,I}\right)_B M''_{AB}$$

$$+ \Delta\!\left(\frac{1}{2\,E\,I}\right)_C M''_{AC} + \Delta\!\left(\frac{1}{2\,E\,I}\right)_Z M''_{AZ} = \sum \Delta\!\left(\frac{1}{2\,E\,I}\right)_B M''_{AB} \ldots (48c)$$

in which

$$\Delta\!\left(\frac{1}{2\,E\,I}\right)_B = \frac{1}{2(E\,I)_{AB}} - \frac{1}{2(E\,I)_{BC}} \ldots\ldots\ldots\ldots\ldots (49a)$$

$$\Delta\!\left(\frac{1}{2\,E\,I}\right)_C = \frac{1}{2(E\,I)_{BC}} - \frac{1}{2(E\,I)_{CZ}} \ldots\ldots\ldots\ldots\ldots (49b)$$

and

$$\Delta\left(\frac{1}{2\,E\,I}\right)_Z = \frac{1}{2(E\,I)_{CZ}} - 0 = \frac{1}{2(E\,I)_{CZ}} \quad \text{(49}c\text{)}$$

Eq. 48*b* or Eq. 48*c* may be used, but the latter is the simpler.

Referring to Fig. 13, Eqs. 29*a* and 31*a*:

$$\begin{aligned} y_{ZA} &= \overline{\mathrm{a'Z}} = \overline{\mathrm{a'B'}} + \overline{\mathrm{B'd}} + \overline{\mathrm{db'}} + \overline{\mathrm{b'c'}} + \overline{\mathrm{c'Z}} = y_{BA} + \theta_{BA}\, l_{BZ} \\ &+ \theta_{CB}\, l_{CZ} + y_{CB} + y_{ZC} = \frac{1}{6(E\,I)_{AB}} M'''_{AB,B} + \frac{1}{2(E\,I)_{AB}} M''_{AB}\, l_{BZ} \\ &+ \frac{1}{2(E\,I)_{BC}} M''_{BC}\, l_{CZ} + \frac{1}{6(E\,I)_{BC}} M'''_{BC,C} + \frac{1}{6(E\,I)_{CZ}} M'''_{CZ,Z} \\ &= \frac{1}{6(E\,I)_{AB}} (M'''_{AB,B} + 3\,M''_{AB}\, l_{BZ}) + \frac{1}{6(E\,I)_{BC}} (M'''_{BC,C} + 3\,M''_{BC}\, l_{CZ}) \\ &\qquad + \frac{1}{6(E\,I)_{CZ}} M'''_{CZ,Z} \quad \text{(50)} \end{aligned}$$

By the second characteristic of second and third moments, Eq. 12 yields:

$$M'''_{AB,Z} = M'''_{AB,B} + 3\,M''_{AB}\, l_{BZ} \quad \text{(51}a\text{)}$$

and

$$M'''_{BC,Z} = M'''_{BC,C} + 3\,M''_{BC}\, l_{CZ} \quad \text{(51}b\text{)}$$

Substituting Eqs. 51 in Eq. 50:

$$y_{ZA} = \frac{1}{6(E\,I)_{AB}} M'''_{AB,Z} + \frac{1}{6(E\,I)_{BC}} M'''_{BC,Z} + \frac{1}{6(E\,I)_{CZ}} M'''_{CZ,Z} \quad \text{(52}a\text{)}$$

Therefore, the general formula is:

$$y_{ZA} = \sum \frac{1}{6(E\,I)_{AB}} M'''_{AB,Z} \quad \text{(52}b\text{)}$$

Substituting—

$$M'''_{BC,Z} = M'''_{AC,Z} - M'''_{AB,Z} \quad \text{(53}a\text{)}$$

and

$$M'''_{CZ,Z} = M'''_{AZ,Z} - M'''_{AC,Z} \quad \text{(53}b\text{)}$$

—in Eq. 52*b*:

$$\begin{aligned} y_{ZA} &= \frac{1}{6(E\,I)_{AB}} M'''_{AB,Z} + \frac{1}{6(E\,I)_{BC}} (M'''_{AC,Z} - M'''_{AB,Z}) \\ &\quad + \frac{1}{6(E\,I)_{CZ}} (M'''_{AZ,Z} - M'''_{AC,Z}) = \left[\frac{1}{6(E\,I)_{AB}} \right. \\ &\quad \left. - \frac{1}{6(E\,I)_{BC}}\right] M'''_{AB,Z} + \left[\frac{1}{6(E\,I)_{BC}} - \frac{1}{6(E\,I)_{CZ}}\right] M'''_{AC,Z} \\ &\quad + \frac{1}{6(E\,I)_{CZ}} M'''_{AZ,Z} = \Delta\left(\frac{1}{6\,E\,I}\right)_B M'''_{AB,Z} \\ &\quad + \Delta\left(\frac{1}{6\,E\,I}\right)_C M'''_{AC,Z} + \Delta\left(\frac{1}{6\,E\,I}\right)_Z M'''_{AZ,Z} \\ &\qquad = \sum \Delta\left(\frac{1}{6\,E\,I}\right)_B M'''_{AB,Z} \quad \text{(54)} \end{aligned}$$

in which (compared with Eqs. 49):

$$\Delta\left(\frac{1}{6\,E\,I}\right)_B = \frac{1}{6(E\,I)_{AB}} - \frac{1}{6(E\,I)_{BC}} \quad \text{(55a)}$$

$$\Delta\left(\frac{1}{6\,E\,I}\right)_C = \frac{1}{6(E\,I)_{BC}} - \frac{1}{6(E\,I)_{CZ}} \quad \text{(55b)}$$

and

$$\Delta\left(\frac{1}{6\,E\,I}\right)_Z = \frac{1}{6(E\,I)_{CZ}} \quad \text{(55c)}$$

For beams of variable flexural rigidity, Eqs. 48c and 54 become:

$$\theta_{ZA} = \int_{x=0}^{x=l} M''_{Ax}\, d\left[\frac{1}{2(E\,I)_x}\right] \quad \text{(56a)}$$

and

$$y_{ZA} = \int_{x=0}^{x=l} M'''_{Ax,x}\, d\left[\frac{1}{6(E\,I)_x}\right] \quad \text{(56b)}$$

in which $(E\,I)_x$, M''_{Ax}, and $M'''_{Ax,x}$ are functions of x. Solutions of problems by Eqs. 56 are naturally somewhat complicated. The following examples illustrate the application of Eqs. 48, 52, and 54.

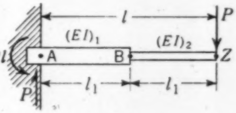

FIG. 14

Example 6. Cantilever Beam with Segmentally Constant Flexural Rigidity.—By Eqs. 48c and 54 (see Fig. 14):

$$\theta_Z = \Delta\left(\frac{1}{2\,E\,I}\right)_B M''_{AB} + \frac{1}{2(E\,I)_2} M''_{AZ} = \left[\frac{1}{2(E\,I)_1} - \frac{1}{2(E\,I)_2}\right](P\,l^2{}_1 - 2\,P\,l \times l_1) + \frac{1}{2(E\,I)_2}(P\,l^2 - 2\,P\,l \times l)$$

$$= -\frac{P\,l^2}{8}\left[\frac{3}{(E\,I)_1} - \frac{1}{(E\,I)_2}\right] \quad \text{(57a)}$$

and

$$\delta_Z = \Delta\left(\frac{1}{6\,E\,I}\right)_B M'''_{AB,Z} + \frac{1}{6(E\,I)_2} M'''_{AZ,Z} = \left[\frac{1}{6(E\,I)_1} - \frac{1}{6(E\,I)_2}\right] \times [P\,l^3{}_1 - 3\,P\,l \times l^2{}_1 + 3\,(P\,l^2{}_1 - 2\,P\,l \times l_1)\,l_1]$$

$$+ \frac{1}{6(E\,I)_2}(P\,l^3 - 3\,P\,l \times l^2) = -\frac{P\,l^3}{24}\left[\frac{7}{(E\,I)_1} + \frac{1}{(E\,I)_2}\right] \quad \text{(57b)}$$

Example 7. Simply Supported Beam with Segmentally Constant Flexural Rigidity and a Load at the Center.—Referring to Fig. 15, Eq. 52b yields:

$$\delta_A = y_{ZA} = \frac{1}{6(E\,I)_1} M'''_{AB,Z} + \frac{1}{6(E\,I)_0} M'''_{BZ,Z}$$

$$= \frac{P\,l^3}{384}\left[\frac{7}{(E\,I)_1} + \frac{1}{(E\,I)_0}\right] \quad \text{(58)}$$

STATICALLY INDETERMINATE BEAMS AND FRAMES

The following examples illustrate the use of the method of second and third moments to analyze statically indeterminate structures.

Example 8. Beam Fixed at One End and Simply Supported at the Other End, With a Concentrated Load at the Center.—Referring to Fig. 16(*a*), with $\theta_O = 0$ and $\delta_A = 0$, Eq. 31*a* yields:

FIG. 16

$$\delta_A = y_{AO} = \frac{M'''_{OA,A}}{6\,E\,I} = 0 \qquad (59)$$

According to Eq. 12:

$$M'''_{OA,A} = M'''_{OA,O} + 3\,M''_{OA}\,l \qquad (60a)$$

and Eq. 10*b*,

$$M''_{OA} = M''_{OA,O} \qquad (60b)$$

Combining Eqs. 60:

$$M'''_{OA,A} = M'''_{OA,O} + 3\,M''_{OA,O}\,l = P\left(\frac{l}{2}\right)^3 - R_2\,l^3 + 3\left[-P\left(\frac{l}{2}\right)^2 + R_2\,l^2\right]l = 0 \qquad (61)$$

From which:

$$R_2 = \tfrac{5}{16}\,P; \quad R_1 = \tfrac{11}{16}\,P; \text{ and } M_1 = \tfrac{3}{16}\,P\,l \qquad (62)$$

Example 9. Beam Fixed at Both Ends But Displaced Vertically through a Distance y, with a Concentrated Load at Center.—Referring to Fig. 16(*b*), with $\theta_{AO} = 0$ and $M''_{OA,A} = 0$:

$$R_1\,l^2 - 2\,M_1\,l - P\,l_a^2 = 0 \qquad (63a)$$

Since $\delta_{AO} = -\,y_A$ and $M'''_{OA,A} = -\,6\,E\,I\,y_A$:

$$R_1\,l^3 - 3\,M_1\,l^2 - P\,l_a^3 = -\,6\,E\,I\,y_A \qquad (63b)$$

Combining Eqs. 63:

$$M_1 = \frac{1}{l^2}\left[P\, l^2_a\,(l - l_a) + 6\,E\,I\,y_A\right] \ldots\ldots\ldots\ldots (64a)$$

and

$$R_1 = \frac{1}{l^3}\,(3\,P\,l^2_a\,l - 2\,P\,l^3_a + 12\,E\,I\,y_A) \ldots\ldots\ldots\ldots (64b)$$

FIG. 18

Example 10. Continuous Frame From the Static Condition of Equilibrium (See Fig. 17).—With $M_B = 0$:

$$12\,V_a - M_a - 12 + 6\,V_d - M_c + 9\,V_c = 0 \ldots\ldots\ldots\ldots (65)$$

From Eqs. 29*a* and 31*a*:

$$\theta_1 = \frac{1}{2\,E\,I}\,M''_{AB,\,B} = \frac{1}{2\,E\,I}\,(V_a \times 12^2 - 2\,M_a \times 12 - 4 \times 3^2)$$

$$= \frac{1}{2\,E\,I}\,(144\,V_a - 24\,M_a - 36) \ldots (66a)$$

$$\theta_2 \doteq \frac{1}{2\,E\,I}\,M''_{BC,\,B} = \frac{1}{2\,E\,I}\,(18\,M_c - 81\,V_c) \ldots\ldots\ldots (66b)$$

and

$$\theta_3 = \frac{y_{DB}}{6} = \frac{1}{36\,E\,I}\,M'''_{BD,\,D} = \frac{1}{36\,E\,I}\,(V_d \times 6^3 - 3 \times V_d$$

$$\times\, 6^2 \times 6) = -\,\frac{1}{2\,E\,I}\,24\,V_d \ldots (66c)$$

When $\theta_1 = -\,\theta_2$, equating Eqs. 66*a* and 66*b* yields $144\,V_a - 24\,M_a - 36 = -\,18\,M_c + 81\,V_c$, which reduces to:

$$8\,M_a - 48\,V_a - 6\,M_c + 27\,V_c = -\,12 \ldots\ldots\ldots\ldots (67a)$$

When $\theta_2 = \theta_3$, equating Eqs. 66*b* and 66*c* yields $18\,M_c - 81\,V_c = -\,24\,V_d$, which reduces to:

$$6\,M_c - 27\,V_c + 8\,V_d = 0 \ldots\ldots\ldots\ldots\ldots\ldots (67b)$$

Therefore, since $y_{BA} = \frac{1}{6\,E\,I} M'''_{AB,\,B} = 0$; and $M'''_{AB,\,B} = V_a \times 12^3 - 3M_a \times 12^2 - 4 \times 3^3 = 0$; or

$$V_a = \tfrac{1}{16} + \frac{M_a}{4} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (68a)$$

Similarly, $y_{BC} = \frac{1}{6\,E\,I} M'''_{BC,\,B} = 0$; and $M'''_{BC,\,B} = V_c \times 9^3 - 3\,M_c \times 9^2 = 0.$

Therefore,

$$V_c = \frac{M_c}{3} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (68b)$$

Substituting Eqs. 68 into Eq. 65:

$$8\,M_a + 24\,V_d + 8\,M_c = 45 \ldots\ldots\ldots\ldots\ldots\ldots (69a)$$

substituting Eqs. 68 into Eq. 67*a*:

$$4\,M_a - 3\,M_c = 9 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (69b)$$

and, substituting Eq. 68*b* into Eq. 67*b*:

$$8\,V_d - 3\,M_c = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (69c)$$

Solving Eqs. 69 simultaneously: $M_c = 1.174$ kip-ft; $M_a = 3.13$ kip-ft; and $V_d = 0.44$ kips. From Eqs. 68 and from static conditions of equilibrium: $V_c = 0.391$ kips; $V_a = 0.844$ kips; and $R = 2.766$ kips.

Example 11. Derivation of the Three-Moment Equation.—Fig. 18 shows a continuous beam of two spans subject to any transverse load. For simplicity, assume that the supports A, B, and C are unyielding, so that $\theta_1 = -\theta_2$. By geometry, $\frac{y_{AB}}{l_1} = -\frac{y_{CB}}{l_2}$; or $\frac{-M'''_{AB,\,A}}{6\,E\,I\,l_1} = -\frac{+M'''_{BC,\,C}}{6\,E\,I\,l_2}$. Simplifying:

$$\frac{1}{l_1} M'''_{AB,\,A} = \frac{1}{l_2} M'''_{BC,\,C} \ldots\ldots\ldots\ldots\ldots\ldots (70a)$$

Eq. 70*a* may be written in the following form:

$$\frac{1}{l_1}(-R_2\,l^3{}_1 - 3\,M_B\,l^2{}_1 + M'''_{\overline{AB},\,A}) = \frac{1}{l_2}(R_3\,l^3{}_2 + 3\,M_B\,l^2{}_2 + M'''_{\overline{BC},\,C}) \ldots (70b)$$

in which $M'''_{\overline{AB},\,A}$ represents the third moment, with respect to point A, of the external loads only, on the span AB, end shears and end moments being excluded; and $M'''_{\overline{BC},\,C}$ represents the third moment, with respect to point C, of the external loads only, on the span BC. Similarly, $M_{\overline{AB},\,A}$ and $M''_{\overline{AB},\,A}$ represent the first and second moments, respectively, with respect to point A, of the external loads only, on span AB. For span AB (Fig. 18(*b*)): $M_{AB,\,A} = M_A - M_B - R_2\,l_1 + M_{\overline{AB},\,A} = 0$; and

$$R_2 = \frac{1}{l_1}(M_A - M_B + M_{\overline{AB},\,A}) \ldots\ldots\ldots\ldots\ldots (71a)$$

For span BC (Fig. 18(c)): $M_{BC,C} = M_B - M_C + R_3 l_2 + M_{\overline{CB},C} = 0$; and

$$R_3 = \frac{1}{l_2}(M_C - M_B - M_{\overline{BC},C}) \ldots\ldots\ldots\ldots\ldots\ldots (71b)$$

Substituting Eqs. 71 in Eq. 70*b*, the three-moment equation is derived, thus:

$$l_1 M_A + 2(l_1 + l_2) M_B + l_2 M_C = \left(\frac{M'''_{\overline{AB},A}}{l_1} - \frac{M'''_{\overline{BC},C}}{l_2}\right) - (l_1 M_{\overline{AB},A} - l_2 M_{\overline{BC},C}) \ldots\ldots (72)$$

Example 12. Continuous Beam.—The problem in Fig. 19 may be solved with the three-moment equation. By Eq. 72, $2(5 + 10) M_B = \left[\frac{500 \times 3^3}{5} - \frac{(-12{,}000) \times 10^3}{4 \times 10}\right] - [5 \times 500 \times 3 - 10 \; (-12{,}000) \times 5] = -304{,}800$ lb-ft; and $M_B = -10{,}160$ lb-ft. For span AB (Fig. 19(c)): $M_{BC,B} = -R_3 \times 10 + 12{,}000 \times 5 - 10{,}160 = 0$. Consequently, $R_3 = 4{,}984$ lb; and $R_2 = 9{,}348$ lb.

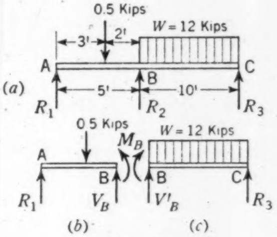

FIG. 19

ACKNOWLEDGMENTS

The writer is indebted to Prof. Fang-Yin Tsai, formerly dean of the College of Engineering, and Prof. T. M. Yu, formerly of the department of civil engineering, both of the National Chung Cheng University, Nanchang, Kiangsi, China, for their invaluable help in the preparation of the paper.

APPENDIX. NOTATION

The following letter symbols, used in the paper and in its discussions, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

a = lever arm of a point force;
b = reference distance to the center of a couple;
E = modulus of elasticity;
I = moment of inertia;
l = span length, or (where stated) equivalent length of a uniform load;
M = moment:
  M'' = second moment;
  M''' = third moment;
  M_c = a couple, or torque;
m = a variable number;

n = a variable number;
P = point force or concentrated load, with appropriate subscripts to denote the point of application;
R = resultant force;
V = vertical shear, or total shear force;
W = total distributed weight, or load;
w = distributed load per unit distance;
x = variable distances parallel to the x-axis;
y = variable distances and deflections parallel to the y-axis;
z = variable distances along a beam, to define the location of an increment dz of distributed load;
δ = vertical deflections (see also y); and
θ = angular deflection.

DISCUSSION

A. FLORIS,[2] ESQ.—By means of his second-moment and third-moment concepts, the author derives formulas for the determination of slopes and deflections, which are used afterward in the analysis of hyperstatic structures. It is stated in the "Synopsis" of this paper that "The various methods for computing beam deflections may be classified into two main groups—the double-integration method and the moment-area method."

The application of the author's second and third moments to statical problems is facilitated by the aid of seven theorems. From these theorems the last two are admittedly similar in nature to those of the moment-area method. The labor involved in these computations is by no means less than the work required by other methods.

In enumerating the various methods for determining slopes and deflections, the author overlooks the principle of virtual displacements and the Castigliano theorems related to it. By the use of this general principle, and with the Müller-Breslau formulas for quick integration involving algebra only,[3] the most rapid results can be obtained in a direct manner.

The slopes and deflections (and hence the hyperstatic quantities) can be determined also by means of a fourth-order differential equation of the elastic curve.[4,5] By using Laplace transforms the tedious process of determining the four constants of integration is eliminated, and the differential equation is transformed into an algebraic equation.[6] Even without the use of the Laplace transformation the problem can be arranged in a manner suitable for practical solution.[7]

The second moment as defined by the author has a physical meaning that he has not utilized. If W is taken as the mass of the system, the second moment is only the moment of inertia of this mass with respect to an axis normal to the center line of the beam. Using the author's notation, M''_O is then the moment of inertia of the system with respect to the normal through point O, the center of gravity of the mass, M''_N is the moment of inertia of the mass with respect to the normal through point N, etc. Some of these values for masses of various shapes are given in reference books.[8]

If the mass is replaced by the loading area, the moment of inertia for area is obtained, which is more familiar to the structural engineer. Conversely, the moments of inertia for mass are derived from the moments of inertia for areas. Mass here is taken as equivalent to load. Of all the moments of inertia, only M''_O needs to be determined by integration. The moments with respect to axes A, B, and N can be found by means of the well-known formula for moments of inertia at points other than the center of gravity. From the values of moments of inertia for few basic loadings, the values of the moment of inertia for a variety of loadings can be obtained by superposition. Table 1 is a sample of second moments for three loadings given by the author.

TABLE 1.—SECOND MOMENTS OR MOMENTS OF INERTIA

Loading	Mass	Area	Axis	Notation	Moment of Inertia: Mass	Moment of Inertia: Area
(a) RECTANGULAR						
	m	$b\,h$	A	I_a	$\frac{m\,h^2}{3}$	$\frac{b\,h^3}{3}$
			O	I_o	$\frac{m\,h^2}{12}$	$\frac{b\,h^3}{12}$
			B	I_b	$\frac{m\,h^2}{3}$	$\frac{b\,h^3}{3}$
			N	I_n	$\frac{m\,h^2}{12}+m\left(\frac{h}{2}+x\right)^2$	$\frac{b\,h^3}{12}+b\,h\left(\frac{h}{2}+x\right)^2$
(b) TRIANGULAR						
	m	$\frac{b\,h}{2}$	A	I_a	$\frac{m\,h^2}{2}$	$\frac{b\,h^3}{4}$
			O	I_o	$\frac{m\,h^2}{18}$	$\frac{b\,h^3}{36}$
			B	I_b	$\frac{m\,h^2}{6}$	$\frac{b\,h^3}{12}$
			N	I_n	$\frac{m\,h^2}{18}+m\left(\frac{h}{3}+x\right)^2$	$\frac{b\,h^3}{36}+\frac{b\,h}{2}\left(\frac{h}{3}+x\right)^2$
(c) TRIANGULAR						
	m	$\frac{b\,h}{2}$	A	I_a	$\frac{m\,h^2}{6}$	$\frac{b\,h^3}{12}$
			O	I_o	$\frac{m\,h^2}{18}$	$\frac{b\,h^3}{36}$
			B	I_b	$\frac{m\,h^2}{2}$	$\frac{b\,h^3}{4}$
			N	I_n	$\frac{m\,h^2}{18}+m\left(\frac{2}{3}h+x\right)^2$	$\frac{b\,h^3}{36}+\frac{b\,h}{2}\left(\frac{2}{3}h+x\right)^2$

Considerable originality is displayed by Mr. Hsu and his interesting paper deserves careful study.

ROBERT B. B. MOORMAN,[9] M. ASCE.—Although the author is to be commended for his efforts to simplify computations for the deflections of beams, the writer feels that the simplification, by introducing second and third moments of the loads, is manifest only in some special cases and cannot be said to be general. The author contends that the use of second and third moments of the loads to compute deflections is a more direct method than that of considering the deflection to be a function of the bending moment. With this the writer cannot agree. Actually the angle changes that occur along the axis of a structure are used in computing the deflections. For beams, columns, or curved members the usual procedure is to assume the angle change equal to the bending moment divided by $E\,I$.

---

[9] Prof., Civ. Eng., Univ. of Missouri, Columbia, Mo.

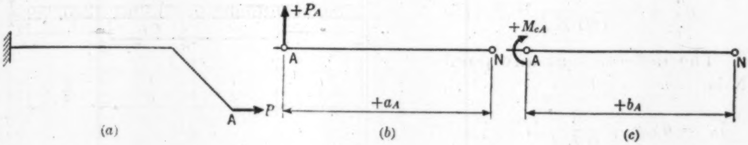

Fig. 20

A direct method of computing deflections should not be limited to straight beams but should also be applicable to a simple arrangement as shown in Fig. 20(*a*). Point O of theorem III should be specified as the point at which the resultant is located on the reference line and not as "any other point O." The same is probably true for theorem IV.

TABLE 2.—Summary of Moment Formulas

Loading	First moment	Second moment	Third moment
Load (see Fig. 20 (*b*)).....	$M_N = P_A\,a_A$	$M''_N = P_A\,a^2{}_A$	$M'''_N = P_A\,a^3{}_A$
Couple (see Fig. 20 (*c*))...	$M_N = M_{cA}$	$M''_N = 2\,M_{cA}\,b_A$	$M'''_N = 3\,M_{cA}\,b^2{}_A$
Balanced force system....	....	$M'' = \text{constant}$	$M'''_N = M'''_O + 3\,M''\,x$
Unbalanced force system (point O at resultant)...	....	$M''_N = M''_O + M''_{O.N}$	$M'''_N = M'''_O + 3\,M''_O\,x + M'''_{O.N}$
Force system symmetrical about point O.........	....	....	$M'''_O = 0$

The usefulness of the paper would probably be enhanced if the information were summarized somewhat as demonstrated in Table 2. Likewise it would be helpful to have the information contained in the section entitled "Second and Third Moments of Force Systems Acting on Straight Beams" extended and tabulated.

That the proposed method can be applied expeditiously to certain deflection problems is illustrated by the following example. Let it be required to determine the equation for the deflection and the equation for the slope at any point for the beam shown in Fig. 21. The deflection at end B is zero, or

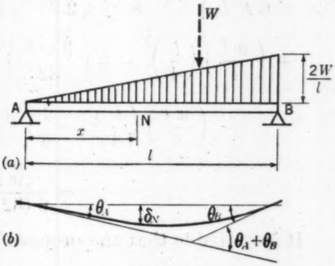

Fig. 21

$$\delta_B = \theta_A\,l + \frac{1}{6\,E\,I}\,M'''_{AB,\,B} = 0 \ldots\ldots\ldots\ldots\ldots (73)$$

Substituting for $M'''_{AB,B}$ in Eq. 73:

$$\theta_A\, l + \frac{1}{6\,E\,I}\left(-\frac{W\,l^3}{10} + \frac{W\,l^3}{3}\right) = 0 \ldots\ldots\ldots\ldots\ldots (74)$$

from which

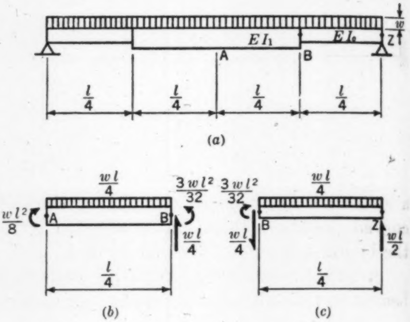
$$\theta_A = -\frac{7}{180\,E\,I}\,W\,l^2 . (75)$$

The deflection at any point N is

$$\delta_N = \theta_A\, x + \frac{1}{6\,E\,I}\,M'''_{AN,N}$$

$$= -\frac{7}{180\,E\,I}\,W\,l^2\,x + \frac{1}{6\,E\,I}\left(\frac{W}{3}\,x^3 - \frac{W\,x^2}{l^2} \times \frac{x^3}{10}\right)$$

$$= \frac{W\,x}{180\,E\,I\,l^2}\,(-3\,x^4 + 10\,x^2\,l^2 - 7\,l^4) \ldots (76)$$



(a)

(b)

(c)

FIG. 22

The slope at any point N is

$$\theta_N = \theta_A + \frac{1}{2\,E\,I}\,M''_{AN} = -\frac{7}{180\,E\,I}\,W\,l^2 + \frac{1}{2\,E\,I}\left(\frac{W}{3}\,x^2 - \frac{W\,x^2}{l^2} \times \frac{x^2}{6}\right)$$

$$= \frac{W}{180\,E\,I\,l^2}\,(-15\,x^4 + 30\,x^2\,l^2 - 7\,l^4) \ldots\ldots\ldots\ldots\ldots (77)$$

To illustrate a case in which the computations for deflection are about the same whether or not the proposed method or the moment-area method is used, consider the beam shown in Fig. 22. Let it be required to determine the deflection at point A, which may be expressed as

$$\delta_A = y_{ZA} = \frac{1}{6\,E\,I_1}\,M'''_{AB,Z} + \frac{1}{6\,E\,I_0}\,M'''_{BZ,Z}$$

$$= \frac{1}{6\,E\,I_1}\left[3\left(\frac{w\,l^2}{8}\right)\left(\frac{l}{2}\right)^2 - \frac{1}{4}\left(\frac{w\,l}{4}\right)\left(\frac{l}{4}\right)^2\left(\frac{3\,l}{8}\right) - \left(\frac{w\,l}{4}\right)\left(\frac{3\,l}{8}\right)^3 + \left(\frac{w\,l}{4}\right)\left(\frac{l}{4}\right)^3 - 3\left(\frac{3\,w\,l^2}{32}\right)\left(\frac{l}{4}\right)^2\right] + \frac{1}{6\,E\,I_0}\left[3\left(\frac{3\,w\,l^2}{32}\right)\left(\frac{l}{4}\right)^2 - \left(\frac{w\,l}{4}\right)\left(\frac{l}{4}\right)^3 - \frac{1}{4}\left(\frac{w\,l}{4}\right)\left(\frac{l}{4}\right)^2\left(\frac{l}{8}\right) - \left(\frac{w\,l}{4}\right)\left(\frac{l}{8}\right)^3\right]$$

$$= \frac{w\,l^4}{6\,(32)^2\,E}\left(\frac{67}{I_1} + \frac{13}{I_0}\right) \ldots\ldots\ldots\ldots\ldots\ldots (78)$$

It is probable that the proposed method will be found useful in simplifying those analyses[10] which involve the moment of the $\frac{M}{E\,I}$-diagram about the support. In a case of this kind the loads can be used in place of the bending moments.

---

[10] "Continuous Frame Analysis by Elastic Support Action," by J. Charles Rathbun and C. W. Cunningham, *Transactions*, ASCE, Vol. 113, 1948, p. 583, Eqs. 16.

FRANK J. MCCORMICK,[11] Assoc. M. ASCE.—A study of this paper reveals that, as defined by the author, the second moment (M'') is equal to twice the area of the bending moment diagram, and the third moment (M''') is equal to six times the moment of that area with respect to one end.

This ingenious substitution of these analytical expressions for the geometrical concepts used in the moment-area and conjugate beam methods is not likely to seem advantageous to most readers, for the invention of these latter methods was an attempt to avoid the mathematical abstractions of the double-integration process in favor of the concreteness of geometrical or physical concepts. In fact, the advantage of being able to visualize the operations involved has led to the invention of many similar substitution methods. Among these are the elastic weight, moment distribution, and column analogy methods in structural analysis, and the membrane, electrical, and hydrodynamical analogies in the field of elasticity. All these represent an effort to simplify the problem, either by replacing the quantities involved by more familiar ones, or by replacing relatively abstract mathematical quantities by analogous concrete physical ones.

Where the conjugate beam method refers the student back to the familiar concepts of shear and bending moment, the method proposed by the author requires the student to learn the new concepts of second and third moments of forces and couples. This could be defended if by so doing less actual labor need be applied for a solution. However, the author has not shown this to be true in the examples presented.

WILLIAM A. CONWELL,[12] M. ASCE.—The scholarly presentation of this paper and its adherence to fundamentals in the approach to the solution of deflection problems make it a definite contribution to engineering literature.

In the "Synopsis," the author states "* * * the aim of this paper is to suggest a more direct solution" and further indicates that it is proposed to solve deflection problems without use of the bending moment. It should be noted that, although the author achieves the elimination of the bending moment, he does not do it without introducing another moment concept—namely, that of second and third moments. There is some question as to whether this substitution is an improvement. If the sign convention is remembered, the second and third moments of a force are readily understood. However, the second and third moments of a moment are not so clearly visualized, inasmuch as they involve a coefficient which has no physical significance and so introduces an element of artificiality. Likewise, the expressions for angle changes and deflections (Eqs. 27 and 30) involve divisors which have no direct physical significance and must, therefore, be remembered if used. Furthermore, if the design computations for the structure are available, the bending moments on which to base deflection calculations are also at hand. In most instances, it would be necessary to compute second and third moments. Still further, the bending moment is intimately associated with the geometry of deflections and thus is an invaluable aid in the visualization of structural action.

---

[11] Associate Prof. of Applied Mechanics, Kansas State College, Manhattan, Kans.

[12] Gen. Engr., Structural Eng. and Design Dept., Duquesne Light Co., Pittsburgh, Pa.

Since the method of this paper has the effect of separating the mind of the designer from the action of the structure, it should offer something to balance this disadvantage. In the use of the column analogy,[13] for instance, the designer's mind is taken up with the computation of stresses in a fictitious column cross section whose stresses are analogous to the bending moments in the structure being analyzed. In the process of computing column stresses, the designer is not thinking in terms of the action of the structure, but at the conclusion of this work he has a good basis for visualizing it. The only excuse for interposing the column analogy in the analysis is that it produces results more quickly in some cases than would otherwise be obtained and, thus, conserves the time of the designer. Whether the same can be stated of the method under discussion will be determined as it is used in competition with other methods.

Practically the entire portent of this paper is carried in theorems VI and VII. Theorems I to V, inclusive, are almost exclusively devoted to definitions. This raises the question as to whether greater emphasis should not be given to theorems VI and VII than is accorded them in the paper at the end of the series of definitive theorems.

From the beginning of his studies in strength of materials, the engineer has been aware that angle changes vary as $\frac{M\,a}{E\,I}$ and deflections vary as $\frac{M\,a^2}{E\,I}$. Accordingly, since M is generally equal to $\Sigma P\,a$, he concluded at an early point in his progress that angle changes vary as $\Sigma\frac{P\,a^2}{E\,I}$ and deflections vary as $\Sigma\frac{P\,a^3}{E\,I}$. It has remained, however, for the author of this paper to employ this general conclusion in such a way as to produce quantitative results. It is, therefore, possible that the method of second and third moments, when used in conjunction with methods more generally employed, will prove to be a valuable tool in determining deflections.

HSU SHIH-CHANG,[14] ESQ.—The purpose of this paper was to simplify the procedure for computing beam deflections, thus eliminating the unnecessary computations involved in other methods. For example, the equation for the deflection at any point N of a cantilever beam that supports a single force P at the free end (Fig. 23(a)) is determined by area moments in three steps as follows:

(1) Construct the bending moment diagram shown in Fig. 23(b);

(2) Compute the area of the bending moment diagram between points A and N—

$$A_m = -P\,(l - x)\,x - \tfrac{1}{2}\,(P\,x)\,x \ldots\ldots\ldots\ldots\ldots (79)$$

---

[13] "The Column Analogy," by Hardy Cross, *Bulletin No. 215*, Eng. Experiment Station, Univ. of Illinois, Urbana, 1930.

[14] Asst., Dept. of Mech. and Elec. Eng., National Chung Cheng Univ., Nanchang, Kiangsi, China.

and

(3) Compute the moment of that area about point N—

$$Q_n = -[P(l-x)\,x]\,\frac{x}{2} - (\tfrac{1}{2}P x^2)\left(\frac{2x}{3}\right) = -\tfrac{1}{6}P x^2(3l - x) \quad \text{..(80)}$$

Eq. 80 is to be divided by $E I$ to obtain the equation of deflection:

$$\delta_N = -\frac{P x^2}{6 E I}(3l - x) \quad \text{.......(81)}$$

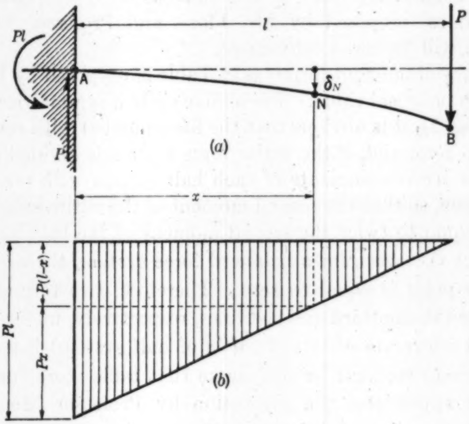


FIG. 23

By the proposed method, it is necessary only to compute the third moment of the reaction P and the couple $P l$ (both at built-in end A) with respect to point N; thus:

$$P x^3 - 3Plx^2 = -Px^2(3l - x) \quad \text{.......(82)}$$

Eq. 82 is divided by $6 E I$ to obtain the equation of deflection—

$$\delta_N = -\frac{P x^2}{6 E I}(3l - x) \quad \text{.......(83)}$$

Although the results are the same, the proposed method simplifies the procedure of computation considerably.

Since the moment center of the second and third moments of any force system, either balanced or unbalanced, may be chosen at any point on the reference line according to the characteristics of second and third moments, the computer can select some convenient points as moment centers to make the calculation simple and easy for any given case. Fig. 28, described subsequently, is an illustration of this procedure. Also, using the proposed method, the designer can formulate the general solutions of angle changes, deflections, and statically indeterminate problems, for a given support condition of beam carrying any loading, expressed as functions of the second and third moments of forces and couples. For any given loading condition, the desired results are obtained quickly from the formulas, which are convenient for practical use. Tables 4 and 5 (explained in detail subsequently) are prepared for this purpose.

Since the bending moment on which the other methods depend is very useful in other fields of structural engineering and is more generally employed, and since the concept of second and third moments, as adapted to the problem of this paper, is new, it is natural that it would be difficult for it to replace other methods immediately. As the concept of the second and third moments becomes more familiar, however, and as its usefulness becomes recognized in other fields of engineering (such as the analysis of hyperstatic structures and continuous frames, proposed by Mr. Floris and Professor Moorman), it is possible that it will be found convenient.

The summary of moment formulas in Table 2, proposed by Professor Moorman, is of much practical value. For a force system symmetrical about point O (referring to Fig. 5), it is obvious that the first moment with respect to point O is also equal to zero; and, if the entire force system is divided into two halves at point O, the second moments of each half system with respect to point O must be the same, so that the second moment of the entire system with respect to point O is equal to twice the second moment of the half force system with respect to point O. Also, for a balanced force system, the first moment with respect to any point is equal to zero. Therefore, two formulas $M = 0$ and $M_O = 0$ inserted in the third and last lines, respectively, under "first moment" in Table 2 and a formula $M''_O = 2$ (M''_O of half system) inserted in the last line under "second moment" would make that table more complete.

The writer appreciates the suggestion by Professor Moorman that the information of second and third moments of loadings be summarized, and has prepared Table 3. If Eq. 54, theorem II, and Table 3 are applied to the example in Fig. 22, the solution can be simplified as follows: Referring to Fig. 24, the deflection at point A may be expressed as

$$\begin{aligned}
\delta_A = y_{ZA} &= \Delta\left(\frac{1}{6\,E\,I}\right)_B M'''_{AB,Z} + \frac{1}{6\,E\,I_0} M'''_{AZ,Z} \\
&= \left(\frac{1}{6\,E\,I_1} - \frac{1}{6\,E\,I_0}\right)\left(M'''_{AB,B} + 3\,M''_{AB}\,\frac{l}{4}\right) \\
&\quad + \frac{1}{6\,E\,I_0} M'''_{AZ,Z} \\
&= \left(\frac{1}{6\,E\,I_1} - \frac{1}{6\,E\,I_0}\right)\left\{3\left(\frac{w\,l^2}{8}\right)\left(\frac{l}{4}\right)^2 - \tfrac{1}{4}\,w\left(\frac{l}{4}\right)^4\right. \\
&\quad \left. + 3\left[2\left(\frac{w\,l^2}{8}\right)\left(\frac{l}{4}\right) - \tfrac{1}{3}\,w\left(\frac{l}{4}\right)^3\right]\left(\frac{l}{4}\right)\right\} \\
&\quad + \frac{1}{6\,E\,I_0}\left[3\left(\frac{w\,l^2}{8}\right)\left(\frac{l}{2}\right)^2 - \tfrac{1}{4}\,w\left(\frac{l}{2}\right)^4\right] \\
&= \frac{w\,l^4}{6(32)^2\,E}\left(\frac{67}{I_1} + \frac{13}{I_0}\right) \quad \text{.......... (84)}
\end{aligned}$$

TABLE 3.—SECOND AND THIRD MOMENTS AT LOADINGS

(Expressed in Terms of Total Load W and Load Intensity w)

[a] Formulas for total load W are omitted in Tables 3(*e*) and 3(*f*).

The advantage of applying Eq. 54 may be further shown by another numerical example. Let it be required to determine the equation for the deflection at any point for the beam shown in Fig. 25. Applying Table 3(*e*) and computing the second and third moments,

$$M'''_{AN,N} = 135\,x^3 - 3 \times 1{,}350\,x^2 - \frac{(4 \times 9 + 9 - 0.3\,x)\,x^4}{20}$$

$$= x^2\,(-\,4{,}050 + 135\,x - 2.25\,x^2 + 0.015\,x^3)\,..(85)$$

Substituting $x = 10$ and $x = 20$, respectively, into Eq. 85, $M'''_{AB,B} = -\,291{,}000$; and $M'''_{AC,C} = -\,852{,}000$; also

$$M''_{AB} = 135 \times 10^2 - 2 \times 1{,}350 \times 10 - \frac{(3 \times 9 + 9 - 0.3 \times 10)\,10^3}{12} = -\,16{,}250$$

and

$$M''_{AC} = 135 \times 20^2 - 2 \times 1{,}350 \times 20 - \frac{(3 \times 9 + 9 - 0.3 \times 20)\, 20^3}{12} = -20{,}000$$

Then, applying Eq. 54, the deflection at any point N is: For $0 \leqq x \leqq 10$ ft—

$$\delta_N = \frac{1}{6\,E\,I_1} M'''_{AN,N} = \frac{x^2}{6\,E\,I_1} (-4{,}050 + 135\,x - 2.25\,x^2 + 0.015\,x^3) \quad (86)$$

and, for $10 \text{ ft} \leqq x \leqq 20$ ft—

$$\begin{aligned}
\delta_N &= \Delta \left(\frac{1}{6\,E\,I} \right)_B M'''_{AB,N} + \frac{1}{6\,E\,I_2} M'''_{AN,N} \\
&= \left(\frac{1}{6\,E\,I_1} - \frac{1}{6\,E\,I_2} \right) [M'''_{AB,B} + 3\,M''_{AB}\,(x - 10)] \\
&\qquad + \frac{1}{6\,E\,I_2} M'''_{AN,N} \\
&= \left(\frac{1}{6\,E\,I_1} - \frac{1}{6\,E\,I_2} \right) [-291{,}000 + 3\,(-16{,}250)\,(x - 10)] \\
&\qquad + \frac{x^2}{6\,E\,I_2} (-4{,}050 + 135\,x - 2.25\,x^2 + 0.015\,x^3) \\
&= \frac{125}{E\,I_1} (262 - 65\,x) + \frac{1}{6\,E\,I_2} (-196{,}500 + 48{,}750\,x - 4{,}050\,x^2 \\
&\qquad + 135\,x^3 - 2.25\,x^4 + 0.015\,x^5) \quad (87)
\end{aligned}$$

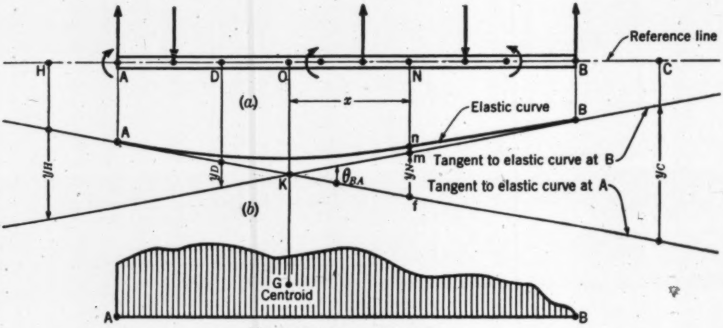
Similarly, for $20 \text{ ft} \leqq x \leqq 30$ ft:

$$\begin{aligned}
\delta_N &= \Delta \left(\frac{1}{6\,E\,I} \right)_B M'''_{AB,N} + \Delta \left(\frac{1}{6\,E\,I} \right)_C M'''_{AC,N} + \frac{1}{6\,E\,I_3} M'''_{AN,N} \\
&= \left(\frac{1}{6\,E\,I_1} - \frac{1}{6\,E\,I_2} \right) [-291{,}000 + 3\,(-16{,}250)\,(x - 10)] \\
&\qquad + \left(\frac{1}{6\,E\,I_2} - \frac{1}{6\,E\,I_3} \right) [-852{,}000 + 3\,(-20{,}000)\,(x - 20)] \\
&\qquad + \frac{x^2}{6\,E\,I_3} (-4{,}050 + 135\,x - 2.25\,x^2 + 0.015\,x^3) \\
&= \frac{125}{E\,I_1} (262 - 65\,x) + \frac{125}{E\,I_2} (202 - 15\,x) \\
&\qquad + \frac{1}{6\,E\,I_3} (-348{,}000 + 60{,}000\,x - 4{,}050\,x^2 \\
&\qquad + 135\,x^3 - 2.25\,x^4 + 0.015\,x^5) \quad (88)
\end{aligned}$$

For the arrangement shown in Fig. 20(*a*), the beam may be cut into two parts at the hip, each part being considered as a straight beam, and solved separately by the proposed method. The writer cannot agree with Professor Moorman's proposal to modify point O of theorem III. By statics, the resultant of an unbalanced force system can be represented by a single force and a couple both acting at any point on the reference line. Therefore, point O of theorem III is an independent point on the reference line similar to that of theorem II, and can be selected at will. In applying theorem III, point O is chosen before computing the resultant at point O.

Mr. Floris suggests that the second moments of loadings are equivalent to the moments of inertia; thus the values of second moments of various shapes of loadings can be obtained from the values of moments of inertia given in reference books. Unfortunately there is no characteristic in the moment of inertia that corresponds to the second moment of a couple, so the analogy of moment of inertia to second moment is only partial. Although the values of second moments of loadings can be taken from reference books by the analogy of moment of inertia to second moment, it is difficult to find a similar analogy to the more important term—third moments. Therefore, it is as well to obtain values of both second and third moments from a separate table, such as Table 3.

The second and third moments of a balanced force system with respect to any point on the reference line have some geometrical significance. Fig. 26(*a*) shows a balanced force system acting on the straight beam AB with the undeflected position of the beam axis as the reference line. Fig. 26(*b*) shows the elastic curve of beam AB, where the two tangents to the elastic curve at ends A and B intersect at point K. Applying theorems I and VI,



(*c*) Bending-moment Diagram

Fig. 26

$$M''_{AB} = 2\,E\,I\,\theta_{BA} = \text{a constant} \ldots\ldots\ldots\ldots\ldots (89)$$

Take any point N on the reference line, and let y_N be the intercept of the vertical line through point N between the two tangents to the elastic curve at points A and B, as shown in Figs. 26(*a*) and 26(*b*). Ordinate y_N will be positive when measured upward from the tangent at point A to the tangent at point B.

Applying theorem VII, Eq. 31*a* gives

$$y_N = \overline{\mathrm{fm}} = \overline{\mathrm{fn}} - \overline{\mathrm{mn}} = y_{NA} - y_{NB} = \frac{M'''_{AN,N}}{6\,E\,I} - \left(- \frac{M'''_{NB,N}}{6\,E\,I} \right)$$

$$= \frac{1}{6\,E\,I}\left(M'''_{AN,N} + M'''_{NB,N}\right) = \frac{1}{6\,E\,I} M'''_{AB,N} \quad \text{(90)}$$

or

$$M'''_{AB,N} = 6\,E\,I\,y_N \quad \text{(91)}$$

Similarly, $M'''_{AB,C} = 6\,E\,I\,y_C$; $M'''_{AB,D} = 6\,E\,I\,y_D$; and $M'''_{AB,H} = 6\,E\,I\,y_H$ —in which the values of $M'''_{AB,D}$ and $M'''_{AB,H}$ must be negative, because y_D and y_H are measured downward. Since $y_O = 0$ at the intersection K, it is obvious that

$$M'''_{AB,O} = 0 \quad \text{(92)}$$

Eqs. 89, 91, and 92 define the geometrical significance of the second and third moments of a balanced force system, acting on a straight beam AB (point B being on the right side of point A), as follows:

(1) The second moment, with respect to any point on the reference line, is equal to the angle between the two tangents to the elastic curve at points A and B, measured from the tangent at point A to the tangent at point B, multiplied by 2 *E I*. Therefore, the second moment is a constant.

(2) The third moment, with respect to any point N on the reference line, is equal to the intercept of the vertical line through point N between the two tangents at points A and B, measured from the tangent at point A to the tangent at point B, multiplied by 6 *E I*.

(3) The third moment, with respect to point O, which is on the same vertical line as the intersection K of the two tangents at points A and B, is equal to zero.

Comparing the elastic curve, Fig. 26(*b*), with the corresponding bending moment diagram, Fig. 26(*c*), since the intersection K and the centroid G of the area of the bending moment diagram occupy the same vertical line,[15] it is interesting to note that the three points—point O which is taken as the moment center of the balanced force system to obtain zero third moment, the intersection K of the two tangents to the elastic curve at points A and B, and the centroid G of the area of the bending moment diagram—are all on the same vertical line. To determine the position of point O, point K, or point G requires the application of theorem II, Eq. 12; thus:

$$M'''_{AB,N} = M'''_{AB,O} + 3\,M''_{AB}\,x \quad \text{(93)}$$

in which x (equal to the distance ON) is positive when point N is on the right side of point O. From Eq. 92, since $M'''_{AB,O} = 0$, Eq. 93 reduces to

$$M'''_{AB,N} = 3\,M''_{AB}\,x \quad \text{(94a)}$$

or

$$x = \frac{M'''_{AB,N}}{3\,M''_{AB}} \quad \text{(94b)}$$

Eq. 94*b* gives the distance from any point N to point O. The position of point O, once determined, may be selected as the origin. Then, from Eq. 94*a*, the third moment of the balanced force system, with respect to any point N on the reference line, can be computed easily as the distance x multiplied by a constant $3\ M''_{AB}$.

---

[15] "Improved Method of Finding Beam Deflections," by Ralph W. Stewart, *Civil Engineering*, February, 1934, p. 88, Fig. 1.

The derivation of Eqs. 52 can be simplified, as follows: Referring to Fig. 27 (which is similar to Fig. 13), Eq. 91 yields

$$y_{ZA} = \overline{\mathrm{aZ}} = \overline{\mathrm{ab}} + \overline{\mathrm{bc}} + \overline{\mathrm{cZ}} = \frac{1}{6\ (E\ I)_{AB}} M'''_{AB,Z} + \frac{1}{6\ (E\ I)_{BC}} M'''_{BC,Z} + \frac{1}{6\ (E\ I)_{CZ}} M'''_{CZ,Z} \ldots (95a)$$

Therefore, the general formula is

$$y_{ZA} = \sum \frac{1}{6\ (E\ I)_{AB}} M'''_{AB,Z} \ldots\ldots\ldots\ldots\ldots\ldots (95b)$$

For the beam with both ends built in and on the same level (in which case the two tangents to the elastic curve at the ends of the beam coincide with each other), Eqs. 89 and 91 make evident the fact that the first moment, second moment, and third moment of the balanced force system acting on the beam, with respect to any point on the reference line, are all equal to zero. Since the moment center of the first, second, and third moments may be taken at any point on the reference line, it is a matter of technique to choose the convenient moment center on the reference line for a given case in order to make the computation as simple and easy as possible. For example, let it be required to determine the two moments M_1 and M_2 at the ends of the beam shown in Fig. 28. The four equations for solving four unknowns M_1, M_2, R_1, and R_2 are

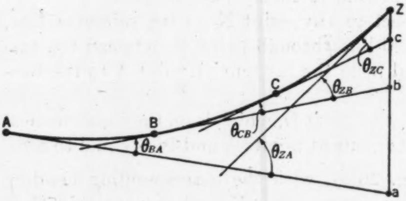


FIG. 27

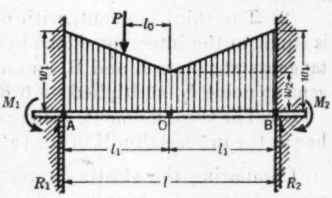

FIG. 28

$$R_1 + R_2 = P + l_1\ (w_1 + w_2) \ldots\ldots\ldots\ldots\ldots (96a)$$

$$M_{AB} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (96b)$$

$$M''_{AB} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (96c)$$

and

$$M'''_{AB} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (96d)$$

in which the subscripts following the subscripts AB in symbols M_{AB}, M''_{AB}, and M'''_{AB} are all unnecessary since the location of the moment center is immaterial. From inspection of Fig. 28, the two trapezoidal loads are symmetrical about point O. Therefore, the first and third moments of the two trapezoidal loads with respect to point O are both equal to zero, and the second moment of the two trapezoidal loads with respect to point O is equal to twice the second moment of one trapezoidal load only with respect to point O. Also, point O is in the center of beam AB. Therefore, the most convenient point of moment center for determining M_1 and M_2 is point O. By Eqs. 96*b* and 96*d*,

TABLE 4.—Formulas of Angle Changes and Deflections[a]

Diagram	Boundary condition	Angle change θ_N of any point N	Deflection δ_N of any point N

Substituting the value of $(R_1 + R_2)$ from Eq. 96*a* into Eq. 99 and simplifying,

$$M_1 + M_2 = \frac{6\,P\,(l^2_1 - l^2_0) + l^3_1\,(3\,w_1 + 5\,w_2)}{12\,l_1} \quad \text{.........}(100)$$

Solving Eqs. 98 and 100 simultaneously,

$$M_1 = \frac{1}{24\,l^2_1}\,[6\,P\,(l_1 + l_0)^2\,(l_1 - l_0) + l^4_1\,(3\,w_1 + 5\,w_2)] \quad \text{....}(101a)$$

and

$$M_2 = \frac{1}{24\,l^2_1}\,[6\,P\,(l_1 + l_0)\,(l_1 - l_0)^2 + l^4_1\,(3\,w_1 + 5\,w_2)] \quad \text{....}(101b)$$

Table 4 gives the formulas for angle changes and deflections in a beam carrying any loading under various given conditions. In applying this table, the origin O can be selected at any point on the elastic curve. The angle change or deflection at point A is given by problem or may be found from the support condition of beam. The angle change and deflection at any point are obtained directly from the formulas. All the formulas in Table 4 can be derived by Eqs. 29 and 31. Since the derivations are somewhat complicated, they are omitted from this discussion.

Table 5 gives the general solutions of statically indeterminate problems for some customary support conditions. The beam must be straight and must possess a constant flexural rigidity. The supports are assumed to be unyielding. The loading on the beam may be any transverse loads and any couples (each of the couples acting at a point on the beam axis, like that shown in Fig. 6(*b*)), where the couples are not shown in the table. Symbol W denotes the total transverse load, the reactions at supports being excluded; and $M_{\overline{AB},B}$, $M''_{\overline{AB},B}$, and $M'''_{\overline{AB},B}$ represent the first, second, and third moments, respectively, with respect to point B, of the external loading only, on span AB—end shears and end moments being excluded. The reactions at supports are assumed positive when they act upward. The statically indeterminate couples are assumed positive when their directions of rotation are as indicated in the table, respectively. The solutions in each case of Table 5 are obtained by solving simultaneous equations. Their derivations are cumbersome and lengthy, and are omitted.

Tables 4 and 5 are advantageous for practical use. For example, let it be required to determine the deflection at the free end D for the beam shown in Fig. 29(*a*). Cut the beam at point C into two parts as shown in Figs. 29(*b*) and 29(*c*). Consider the end shear of 2 kips and the end moment of 8 kip-ft at end C of beam ABC in Fig. 29(*b*) as the external force and couple, respectively. From the solution for R_3 in Table 5(*c*), substitute 8 ft for l_1, 5 ft for l_2, 13 ft for l, 12 kips for W, and zero for $M'''_{\overline{AB},B}$; thus:

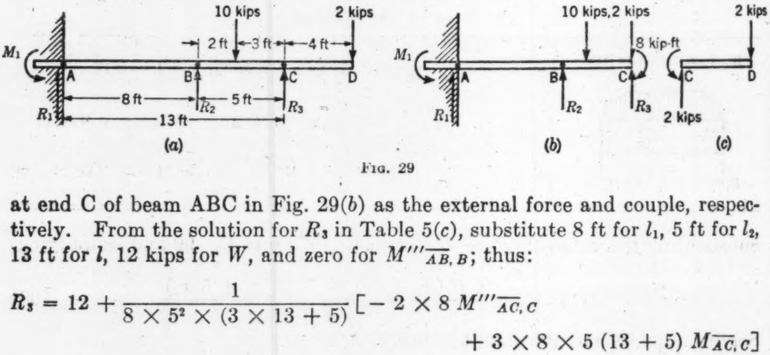

FIG. 29

$$R_3 = 12 + \frac{1}{8 \times 5^2 \times (3 \times 13 + 5)} [- 2 \times 8 \, M'''_{\overline{AC},C} + 3 \times 8 \times 5 \, (13 + 5) \, M_{\overline{AC},C}]$$

$$R_3 = 12 + \frac{1}{8{,}800} [- 16 \, (- 10 \times 3^3) + 2{,}160 \, (- 10 \times 3 + 8)] = 7.09 \text{ kips}$$

In Fig. 29, point C is selected as the origin. From the formula of deflection in Table 4(*b*) for the boundary condition $\delta_A = 0$, substitute C for O, B for A, D for N, 5 ft for l_A, and 4 ft for x; thus:

$$\delta_D = \frac{1}{6 \, E \, I \times 5} (- 4 \, M'''_{CB,B} + 5 \, M'''_{CD,D})$$

$$\delta_D = \frac{1}{30 \, E \, I} \{- 4 \, [10 \times 2^3 - (7.09 - 2) \, 5^3 + 3 \times 8 \times 5^2] + 5 \, (2 \times 4^3 - 3 \times 8 \times 4^2)\} = - \frac{291}{6 \, E \, I} \text{ ft}$$

in which E is in kips per square foot, and I is in feet^4.

The writer is grateful to Mr. Floris, Professor Moorman, Professor McCormick, and Mr. Conwell for their discussions of this paper.

DEVELOPMENT AND HYDRAULIC DESIGN, SAINT ANTHONY FALLS STILLING BASIN

By Fred W. Blaisdell,[1] Assoc. M. ASCE

With Discussion by Messrs. Donald E. Blotcky, M. M. Culp, Paul Baumann, A. J. Peterka, Louis M. Laushey, J. H. Douma, Robert F. Ewald, and Fred W. Blaisdell.

Synopsis

Tests made to develop rules for the design of a stilling basin to dissipate hydrodynamic energy are described in this paper. The energy dissipator has been named the SAF stilling basin, SAF (denoting "Saint Anthony Falls") being a coined word used to differentiate this design from other stilling basin designs. In size, this stilling basin is the smallest known to the writer. The size is reduced through the use of baffles and sills within the stilling basin to assist in the dissipation of the energy of water flowing at high velocities.

The paper begins with a discussion of the reasons for making the tests reported and a brief discussion of previous work on energy dissipators. The scope of the test program is then discussed as are the apparatus and test methods used for each of the three groups or series of tests into which the study is arbitrarily divided. Each element involved in the design of the stilling basin is discussed separately in Section 6; under subheadings each of the various steps leading to the determination of the design equations is discussed; and the pertinent test data are summarized in tables and illustrations. The aim throughout has been to present the data in sufficient detail to permit an independent analysis by the reader so that he can arrive at his own conclusions and discuss the paper intelligently. The results are summarized for convenience of reference so that, after evaluating the design, the reader can obtain all the equations and information essential to the hydraulic design of the SAF stilling basin without "thumbing" through the entire paper.

Note.—Published in February, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] **Project Supervisor, U. S. Dept. of Agriculture, SCS, St. Anthony Falls Hydr. Laboratory, Minneapolis, Minn.**

1. Introduction

Energy dissipators in some form have been made a part of many hydraulic structures throughout the world when the destructive energy in flowing water must be brought under control. Most of these energy dissipators have performed their intended function adequately—particularly those that have received the benefit of model tests. However, some of them have not performed their intended function, with the result that they have been destroyed or the structure of which they were a part has been damaged.

Except in unusual circumstances, only the larger structures are the subjects of individual model studies. However, they ordinarily pay dividends in improved performance and in reduced construction, maintenance, and possible replacement costs. In general, the structures built by the Soil Conservation Service (SCS), United States Department of Agriculture, are of such a size that few of them can justify, economically, the individual model studies that have proved so profitable for the larger structures. However, it becomes economical to make model studies if their costs can be spread over a large number of small structures, as is the case with the SCS where a large number of structures are required to further its soil and water conservation program. For use with certain of these structures it was essential that an efficient and economical stilling basin be developed and that design rules be formulated so that future stilling basins could be designed without recourse to further model studies. For this reason a study of methods of dissipating energy was instigated by the SCS in cooperation with the Minnesota Agricultural Experiment Station at the St. Anthony Falls Hydraulic Laboratory in Minneapolis, Minn.

2. Previous Work

The more important references consulted during the study upon which this paper is based are listed in the Bibliography (see Appendix I). The energy dissipators described in the references cited may be divided into three groups: Those that could be eliminated from further consideration as not being adaptable to the problem at hand (outlets for flumes or chutes and culverts), those that required critical study to evaluate them, and those that required tests to determine their potentialities.

No mention will be made of the first group. Of those that were classified in the second group, the simple stilling basin studied by C. Maxwell Stanley, M. ASCE (1),[2] is outstanding. This energy dissipator consists of a pool in which the energy in the high-velocity flow is dissipated. The pool is frequently formed by a sill or, in the case of high overflow dams, by a secondary low dam. Necessarily, the simple stilling basin is larger than the SAF basin described in this paper for comparable stilling action, since its design does not include the chute and floor blocks which dissipate much of the energy in the SAF basin. The elements and dimensions of the SAF stilling basin are defined in Fig. 1. The tests made to determine the best proportions of each element will be discussed separately in Section 6.

---

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (Appendix I).

Exploratory tests were made on three types of stilling basin that were classified in the third group. The nappe-cutting energy dissipator studied at the Royal Technical University, in Stockholm, Sweden, is described by Wolmar K. A. Fellenius (2*a*). This stilling basin was tested to check the claims made for it. The few tests at Minneapolis did not show any appreciable increase in the energy dissipation when a nappe cutter was used over the energy dissipation when no nappe cutter was used. As a result, no further consideration was given to this type.

FIG. 1.—PROPORTIONS OF THE SAF STILLING BASIN

Armin Schoklitsch (3*a*) has published results of experiments performed on an energy dissipator that is similar to Mr. Stanley's simple stilling basin except that a sill or bucket is used at the basin entrance. This sill causes the water to enter the stilling pool above its floor so that energy dissipation takes place both above and below the jet. A test with the sill removed, making the stilling basin similar to that tested by Mr. Stanley, showed that the use of the sill greatly increased the efficiency of the stilling basin as an energy dissipator. Mr. Schoklitsch has published charts giving the dimensions and performance of this stilling basin for different discharges and heights of dam. The tests on the Schoklitsch energy dissipator at Minneapolis were made after the SAF stilling basin studies were well advanced. At that time the SAF stilling basin was approximately one half of the size of the Schoklitsch dissipator that gave comparable results. Further experimentation on the Schoklitsch energy dissipator was abandoned in favor of the SAF stilling basin study.

Jacob E. Warnock, M. ASCE (4*a*), has described a rectangular stilling basin developed by the Bureau of Reclamation, United States Department of the Interior (USBR). Exploratory tests indicated that this basin was particularly efficient and that its size could be reduced considerably. As a result, additional study was given to a stilling basin of this type, and from this study generalized design rules were formulated for proportioning the SAF stilling basin. Two general views of a stilling basin model are shown in Fig. 2.

3. Test Program

Notation.—The letter symbols used in the paper are defined where they first appear, in the text or by illustrations, and are assembled for convenience of reference in Appendix II.

The studies leading to the development of the SAF stilling basin are conveniently divided into three parts which are listed below in the chronological order of their performance:

(*1*) *The Culvert Outlet Series.*—In these tests the basin dimensions were first determined tentatively. The tests covered a narrow range of the Froude number, **F**.

(*2*) *The Flume Outlet Series.*—These tests covered a wide range of the Froude number and were made to expand the field of application of the SAF stilling basin.

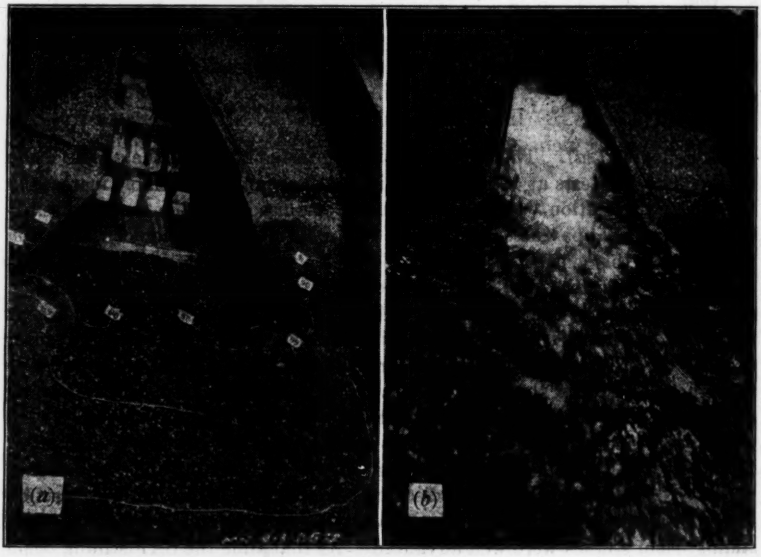

Fig. 2.—Model of SAF Stilling Basin

(*a*) Scour After Running Model 20 Hours; Basin Floor Elevation 88.0; Maximum Scour Elevation 87.4
(*b*) Design Discharge, Tailwater Elevation 93.0

(*3*) *The Turbine Room Series.*—The previous series of tests had shown the end sill height to be a function of the Reynolds number, **R**. The turbine room tests were made to extend the range of the Reynolds number, since its highest value for the culvert and flume outlet series was less than would be obtained for most prototype structures, and to check the equation for the end sill height. The tests also covered a wide range of the Froude number.

The SAF stilling basin design was developed and verified as a result of two hundred seventy-four tests. The number of tests in each series and the range of the variables are given in Table 1. In Table 1, Q is the discharge; V_1 and d_1 are the velocity and depth, respectively, at the entrance to the stilling basin; and d_2 is the theoretical depth after the hydraulic jump. The Froude number is defined by the equation:

TABLE 1.—Range of Test Variables

Series	No. of tests	Q (ft^3/sec)		V_1 (ft/sec)		d_1 (ft)		d_2 (ft)		**F**		**R** × 10^{-3}

$$\mathbf{F} = \frac{V^2_1}{g\, d_1} \qquad (1a)$$

in which g is the acceleration due to the effect of gravity. The Reynolds number is defined by the equation:

$$\mathbf{R} = \frac{V_1\, d_1}{\nu} \qquad (1b)$$

in which ν is the kinematic viscosity.

4. Apparatus and Procedure

Both the culvert and flume outlet series of tests were made in a channel 8 ft long by 18 in. wide by 24 in. deep. Plate glass formed one side of the channel. Water was supplied to the models through a 4-in. pipe line and the rate of flow was controlled by a gate valve. The rate of flow through the model was determined by a calibrated 1-ft type HS-flume (5). Discharge measurements accurate to 1% were readily obtainable.

The channel in which the turbine room series of tests was made is shown in Fig. 3. A glass panel was placed in one side of this channel at the place where the stilling basin models were to be located. The rate of flow to the models was controlled by a gate valve in the 12-in. supply line. Three methods of measuring the flow were used. A calibrated 1.5-ft type H-flume (5) was used for discharges up to 5 cu ft per sec. For discharges greater than 5 cu ft per sec, the pressure drop across an 18-in. by 12-in. reducing flange was calibrated and used to determine the discharge until its calibration became invalid, probably because of rusting at the piezometers. A ½-in. Prandtl (6) pitot tube in the approach to the stilling basin model was then used for measuring the higher discharges.

Previous experiments on outlets (7) have shown that it is impossible to follow, visually, the progress of the erosion under the jet and "white water" in and beyond the end of the stilling basin. Therefore, all models were split along their longitudinal center lines and one half of them were pressed against the glass side of the experimental channel. Check tests (8) showed that, within the limits of experimental error, the results obtained on the half model agreed with the full model. As a result all the tests reported in this paper were made on "half models" in which a glass plate was placed on the longitudinal center line.

Fig. 3.—Test Apparatus, Turbine Room Series

For convenience, the approach to the stilling basin models for the culvert outlet series was considered to be a 3-ft-square culvert built to a scale of 1 in. equals 1 ft. A half section of the culvert barrel, 1.5 in. by 3 in. in section and 7.5 ft long, was placed on a slope of 1% and connected to the 4-in. supply line. An open channel transition section was placed between the culvert and the stilling basin to spread out the water and drop it to the stilling basin floor level. The floor of the transition was given a parabolic shape. The width of the downstream end of the transition was varied to give the desired depth of flow at the stilling basin entrance. In designing the transition, the velocities in the culvert barrel and along the transition were assumed to be identical.

For the flume outlet series, a 3-in.-square pipe, 7.5 ft long, was connected to the 4-in. supply line and a rectangular nozzle 3 in. wide with an adjustable lid was placed on a slope of 1 on 2 (a flatter slope was used for a few tests) and was used to control the depth of approach at the stilling basin entrance. The open channel between the nozzle and the stilling basin was 3 in. wide and its slope was 1 on 2.

The approach to the stilling basin model for the turbine room series is shown in Fig. 3. The gate for controlling the depth of flow at the entrance to the model is at the downstream end of the cone connected to the 12-in. supply line. As it left the gate, the stream was ordinarily well distributed across the channel leading to the model stilling basin. However, at the larger gate openings and at the larger discharges, the disturbances existing in the cone persisted and the depth distribution across the channel section was not satisfactory. Accordingly, an adjustable steel "float" was placed downstream from the gate to insure satisfactory flow conditions at the entrance to the stilling basin. This "float" was used for all tests in this series.

FIG. 4.—GATE SEAL AND AIR LINE DETAILS, TURBINE ROOM SERIES

The velocities obtained during the turbine room tests were such that the water would ordinarily entrain air. However, it was not possible to provide as long a channel between the depth control gate and the stilling basin as would have been desirable. For this reason there was insufficient distance for the water to entrain the air that would ordinarily be present in high-velocity flows. An arrangement for entraining air artificially was therefore incorporated in the design. A detail of this arrangement is shown in Fig. 4. The air flow was measured by a square-edged orifice using equations and coefficients published by H. S. Bean, E. Buckingham, and P. S. Murphy (9).

Stop logs were used in both test channels for tailwater control. Water levels and stream-bed contours were measured with the aid of point gages mounted on carriages in such a way that levels anywhere in the test channel could be obtained readily. These gages were also used in setting the models in their correct positions.

All models were of the "movable bed" type; the stream bed downstream from each stilling basin was formed in commercial concrete sand. The water leaving the model stilling basin was permitted to erode the stream bed until the scour-hole dimensions had become stabilized. This action required about 30 min for the culvert and flume outlet series and 2 hours for the turbine room series. The size of the scour hole was taken as an indication of the effectiveness of the stilling basin (1*a*)(8).

The method of testing the models was as follows: The stilling basin was installed and the stream bed was filled with sand to an elevation higher than the anticipated elevation of the eroded stream bed. The stream bed was then flooded so that the initial rush of water through the stilling basin would not erode the stream bed excessively. The gate valve in the supply line was then opened to give the desired discharge and the tailwater level was adjusted to the correct depth. The discharge, tailwater depth, and water-surface profiles were recorded near the end of each test run. The stream bed was drained at the conclusion of each test. For the culvert and flume outlet series, the center-line profile of the eroded stream bed was recorded on data sheets. For the turbine room series, a contour map of the eroded stream bed was also obtained. Elevations of the stream bed at selected points near the stilling basin were also obtained and recorded.

Photographs were taken during many of the tests (see Fig. 2(*b*)). Motion pictures were also obtained for selected typical conditions.

5. HYDRAULIC JUMP

All the SAF stilling basin dimensions are related either directly or indirectly to the hydraulic jump. The theoretical equation for the hydraulic jump is

$$d_2 = -\frac{d_1}{2} + \sqrt{\frac{2\,V^2_1\,d_1}{g} + \frac{d^2_1}{4}} \qquad \text{(2a)}$$

The derivation of Eq. 2*a* can be found in most books on hydraulics (10*a*). Numerous experiments have proved the validity of this equation which can be simplified to

$$d_2 = \frac{d_1}{2}\left(-1 + \sqrt{8\,\mathrm{F} + 1}\right) \qquad \text{(2b)}$$

6. TEST RESULTS

(*a*) *Length of Basin.*—As noted in Section 2, the SAF stilling basin was developed from the rectangular stilling basin described by Mr. Warnock (4*a*). The single rectangular stilling basin tested had a design length L_B of 3.75 d_2 although Mr. Warnock used 3.00 d_2. This basin was designed for a flow of Q = 275 cu ft per sec and a depth d_1 = 1.0 ft. The dimensions of this stilling basin (shown in Fig. 5) are in terms of the prototype, assuming the linear scale ratio to be 12 to 1. The results of the tests on this stilling basin under approximate design flow conditions are presented in Fig. 6(*a*) and Table 2, test C3. The profile shown in Fig. 6(*a*) is taken along the channel center line. Note that the toe of the roller is not at the upstream end of the basin. This test indicated that the stilling basin was much longer than was necessary to secure adequate energy dissipation, although it was entirely satisfactory from a purely hydraulic point of view.

[a] Elevation of maximum depth of scour, in feet, on the channel center line near the end of the stilling basin.

[b] Elevation of the stilling basin floor.

[c] Symbols denoting criteria for stilling basin performance, as follows:

G = good; maximum depth of scour only slightly below top of end sill and downstream bed level gradually rising as in Fig. 6(*c*).

S = satisfactory; no scour deeper than floor of stilling basin with the downstream bed level gradually rising.

F = fair; maximum depth of scour slightly below floor of stilling basin, or secondary scour holes, as in Figs. 6(*a*), 6(*f*), and 8(*d*) (structure not in danger of being undermined).

P = poor; maximum depth of scour considerably below floor of stilling basin and a large scour hole as in Fig. 6(*b*) (structure in danger of being undermined).

The next step in the investigation of length was to shorten the basin sufficiently to bring the toe of the roller back to the upstream end. The results of this shortening are presented in Fig. 6(*b*) and test C12, Table 2. The performance of the basin was not affected by this length reduction and, surprisingly, the maximum depth of the scour hole at the end of the stilling basin was reduced by 0.4 ft. Because these findings were encouraging, the basin length was reduced progressively with the results shown in Fig. 6 and Table 2.

The maximum depth of the scour hole decreased with a decrease in basin length until a length of 1.5 d_2 was reached. Further reduction in the basin length resulted in an increased depth of scour. However, the maximum depth of scour did not reach the elevation of the stilling basin floor until the length had been reduced to 0.98 d_2.

FIG. 5.—PROPORTIONS OF THE RECTANGULAR STILLING BASIN ON WHICH MODEL TESTS WERE MADE

The floor blocks and end sill cause a hump or "boil" to form above the tailwater surface elevation. The height of this boil is a measure of the required height of stilling basin side wall if overtopping is to be prevented. The height of boil, determined for each test run, remained constant at about 1 ft above the tailwater surface elevation until the basin length was reduced to 0.98 d_2. For this length of basin the boil height increased to more than 2 ft. For $L_B = 0.69\, d_2$ the boil height reached 3 ft above the tailwater elevation. This increase in boil height required no higher side walls since the maximum boil height occurred downstream from the end of the stilling basin. However, the large size of the scour hole for $L_B = 0.98\, d_2$ was an indication that the energy dissipation was poor. A study of the data obtained from this series of tests resulted in the decision tentatively to select 1.25 d_2 as the best length of stilling basin.

After this length was selected, the study of basin lengths was deferred until the dimensions and spacing of the floor blocks and chute blocks, end sill height, and basin shape had been investigated and tentative conclusions had been derived from the investigation. When the study of basin length was resumed, tests were planned to broaden the scope of the previous work. The principal dimensions of these basins and a summary of the results are given in Table 2.

As a result of these tests it was found, unfortunately, that the length of the stilling basin for discharges other than 275 cu ft per sec could not be predicted assuming that $L_B = 1.25\, d_2$. The stilling basins for smaller discharges were too short and those for higher discharges were longer than necessary. To determine the best length of basin for each discharge, L_B was decreased from run to run until the capability of the stilling basin to dissipate the energy became unsatisfactory.

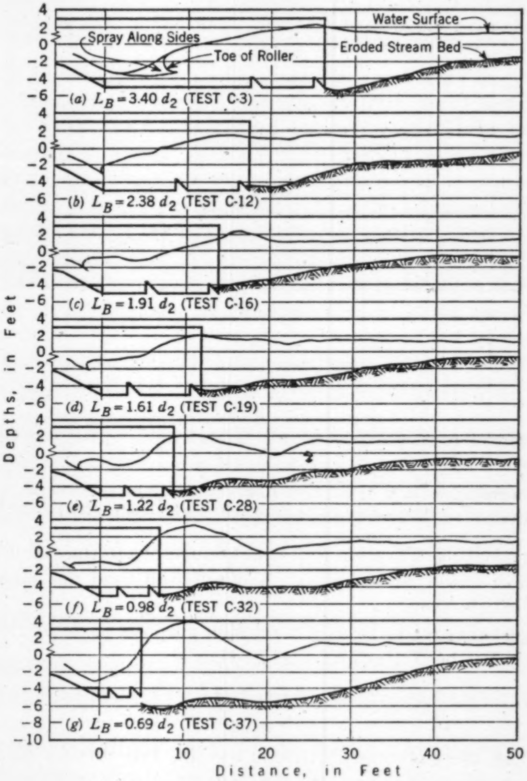

FIG. 6.—EFFECT OF LENGTH OF RECTANGULAR STILLING BASIN ON CENTER-LINE BED AND WATER-SURFACE PROFILES (SEE TABLE 2)

After the data obtained for each test were studied, the composite performance of each length of stilling basin was placed in one of the four categories listed in Table 2, Col. 14, and the performances were plotted in Fig. 7. For satisfactory performance the length of the stilling basin in terms of d_2 is shown to be considerably greater for the lower values of **F** than it is for the higher values of **F**. However, the data should be sufficient to permit a satisfactory determination of the basin length for all values of **F** between 3 and 150. In this connection it should be noted that a rating of "fair" was given to performances resulting in erosion that is not dangerous to the stability of an outlet when a short cutoff wall is used. A cutoff wall need not be used when the rating is "satisfactory."

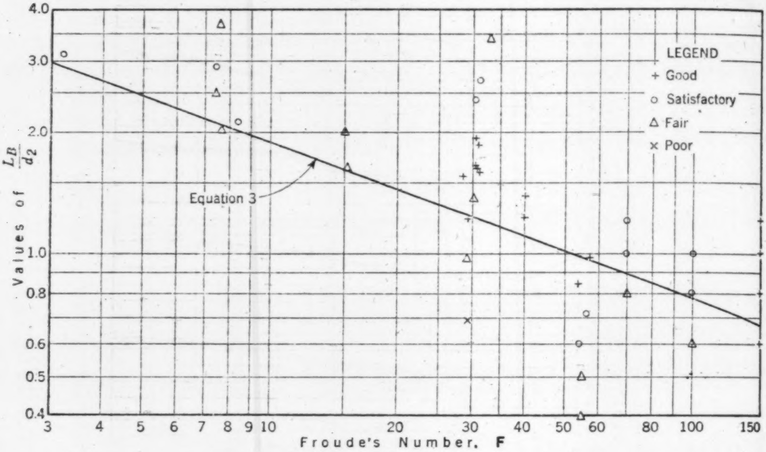

FIG. 7.—DIMENSIONLESS PLOT OF STILLING BASIN PERFORMANCE AS AFFECTED BY BASIN LENGTH
(Correction: Add a point at $\mathbf{F} = 3.18$, $L_B/d_2 = 2.11$)

A suggested curve to be used for design purposes in determining the length of the basin has been drawn in Fig. 7—that is:

$$\frac{L_B}{d_2} = \frac{4.5}{\mathbf{F}^{0.38}} \quad \text{(3)}$$

Of course, there is some latitude in locating this curve. Eq. 3 is suggested as being conservative but not to the extent that the material in the outlet is wasted. Eq. 3 was developed for a range of the Froude number from 3 to 150 but was later used to design experimental stilling basins for the turbine room series having values of **F** as high as 288. Although no test in the turbine room series was designed specifically to check the equation for the length of the stilling basin, the results of the turbine room tests indicate that the original design equation is entirely satisfactory and that no change in either its form or constants is indicated.

(*b*) *Chute Blocks.*—The chute blocks at the entrance to the stilling basin serve to increase the effective depth of the entering stream, break it up into a number of small jets, and help to create the turbulence required for effective energy dissipation.

The height of the chute blocks was originally assumed to be d_1 and their width and spacing 0.75 d_1 at the downstream end. Their tops were made horizontal and their sides vertical. In plan they decreased in width with distance upstream to take into account the decrease in transition width (see Fig. 5). No change was made in the chute blocks until the basin dimensions had been tentatively selected and the floor blocks had been tentatively located. A test was then made on a solid chute block such as is used in the Schoklitsch energy dissipator (3*a*). Tests made on this change, when compared to tests made on the original chute block design, showed that there was less energy dissipated, that flow conditions in the channel downstream from the stilling basin were not as good, and that the height of the boil was greater. The chute blocks were next made 1.75 d_1 high at their downstream end and the top was sloped 1 on 3 so that the jet leaving the top of the chute blocks was directed at the base of the floor blocks. The result of this change was an increase in the depth of erosion near the end of the stilling basin over that obtained for the chute blocks originally used.

Chute blocks with the original dimensions were replaced on the transition. However, they were rectangular in plan instead of following the arrangement shown in Fig. 5; and their sides were placed parallel to the transition center line. Little difference was found between the rectangular and trapezoidal chute blocks—the advantage, if any, accruing to the rectangular blocks. The chute blocks used in all subsequent tests had a height of d_1 and a width and spacing of approximately 0.75 d_1. Throughout the tests made from Froude numbers of 3 to 288, no reason was found for making a change in these dimensions.

In making the subsequent tests, sometimes a block and sometimes a space were placed next to the side wall. Apparently, it makes no difference in the performance of the stilling basin whether a chute block or a space is next to the side wall as long as the blocks are symmetrical about the center line of the outlet.

(*c*) *Floor Blocks.*—The function of the floor blocks is to create the turbulence through which energy is dissipated. Energy is also removed from the water by impact against these blocks.

Longitudinal Position.—No particular attention was given to the location of the floor blocks during the first length-of-basin tests. After a length equal to 1.25 d_2 had been tentatively selected as the best, the longitudinal spacing of the floor blocks was investigated. The results of these tests are presented in Table 3(*a*) and Fig. 8. When the floor blocks were placed at a distance of $L_B/5$ from the upstream end of the basin (Table 3(*a*), test C41, and Fig. 8(*a*)), there was insufficient distance between them and the chute blocks to permit the turbulence caused by the chute blocks to become fully effective in dissipating energy. This condition is shown by the greater depth of erosion and slightly higher boil, for example, than in the case of test C28 in which the distance to the floor blocks is $L_B/3.2$ (Table 3(*a*), test C28, and Fig. 8(*b*)). On the other hand, when the distance to the floor blocks was 2 $L_B/3$ (Table 3(*a*), test C40, and Fig. 8(*d*)), there was insufficient distance between the floor blocks and the end sill to permit the turbulence caused by the floor blocks to become fully effective in dissipating the energy. This condition is also shown by the greater depth and volume of erosion than for runs having a somewhat lesser distance to the floor blocks. The boil was higher than for any other run of this group because the floor blocks and end sill seemed to act together in deflecting the stream upward. The maximum depths of erosion for the two extreme floor block locations were approximately the same, indicating that it is as bad to have too little distance between the chute blocks and the floor blocks as it is to have the floor blocks and end sill too close together.

[a] Elevation of maximum depth of scour, in feet, on the channel center line near the end of the stilling basin. [b] Distance from upstream end of stilling basin to floor blocks. [c] Height of floor blocks. [d] Floor blocks are in line with chute blocks. Compare with test C28 in which floor blocks are in line with spaces between chute blocks. [e] Percentage of stilling basin width occupied by floor blocks.

Both the depth of erosion and the scour pattern are nearly identical when the floor blocks are located $L_B/3.2$ and $L_B/2$ from the upstream end of the basin (Table 3(*a*), tests C28 and C39, and Figs. 8(*b*) and 8(*c*)), and it is impossible to state definitely which spacing is the better from the standpoint of scour. However, the boil is 1 ft higher for test C39 and therefore the longitudinal floor block spacing of $L_B/2$ was eliminated from further consideration.

The floor blocks were placed $L_B/3$ from the upstream end of the stilling basin for all subsequent tests. Although the subsequent tests covered a range of the Froude number from 3 to 288, no reason was discovered for changing the longitudinal floor block location.

Height.—The height of the floor blocks for the first length-of-basin tests was assumed to be $5\ d_1/4$. During these tests the floor block height was reduced to d_1 with no apparent adverse effects. When the floor block height was investigated, a further reduction to $3\ d_1/4$ was made. The result of this test (Table 3(*b*)) was an increase in both the height of boil and depth of scour.

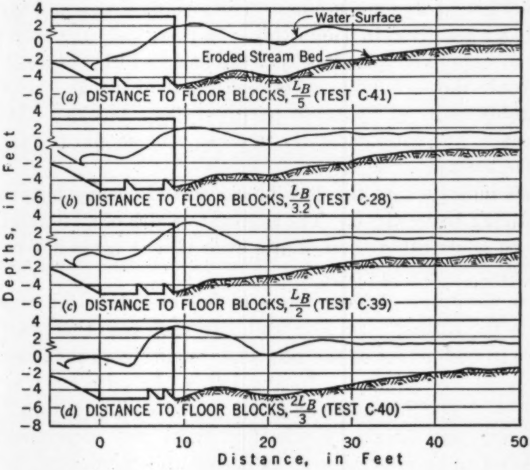

Fig. 8.—Effect of Floor Block Locations on Center-Line Bed and Water-Surface Profiles

The result of increasing the height of the floor blocks to $3\ d_1/2$ was the same—an increase in both the height of boil and depth of scour over that for a block height of d_1. Accordingly, a floor block height equal to d_1 was used for all subsequent tests.

Width and Spacing.—The width and spacing of the floor blocks was ordinarily made equal to those of the chute blocks. However, for the stilling basins that diverged in plan (see Fig. 1 and Section 6(*h*)), the floor block width and spacing were increased in proportion to the increase in stilling basin width at the floor block location.

Arrangement.—Ordinarily, the floor blocks were opposite the spaces between the chute blocks to intercept and break up the stream issuing through these spaces. To test the effectiveness of this arrangement, a single test was made with the floor blocks in line with the chute blocks. The results of this test (C42) are given in Table 3(*c*). They may be compared with the results of test C28, although the tabulated data do not give the complete story since a bad whirl developed along the side of the downstream channel for test C42 that caused considerable bed erosion and bank erosion. For all subsequent tests the floor blocks were alined with the spaces between the chute blocks.

Aggregate Floor Block Width.—Insufficient water can pass between the floor blocks if they occupy too much of the stilling basin width; they then act more like a sill than like individual blocks. This fact was demonstrated vividly when a test was made on a narrow stilling basin with a higher value of d_1 than had been used prior to that time. The floor blocks, when 3 $d_1/4$ wide, obstructed 67% of the stilling basin width (Table 3(*d*), test C73). The boil caused by these wide blocks was very high and overtopped the basin side wall. (In all previous tests, where the floor blocks had obstructed 43% of the basin width, the boil height was much less.) The results of two additional tests on this stilling basin are given in Table 3(*d*). In these tests the floor block width was reduced to occupy 56% and 44% of the basin width, respectively, so that more water could flow around and between the floor blocks. The boil height was considerably reduced by these narrower floor blocks. The scour was slightly increased, but not sufficiently to cause concern since it did not extend lower than the basin floor level.

These tests indicate that the floor blocks should occupy between 40% and 55% of the stilling basin width. The aggregate width of all floor blocks, therefore, should be held within these limits even if it is necessary to reduce the width of the floor blocks to do so.

Transverse Position.—A floor block of full or half width was sometimes placed next to the stilling basin side wall. In each case this practice resulted in an increase in boil height at the side wall, requiring an increase in side-wall height to prevent overtopping. To avoid this, the criterion was established that no floor block should be placed closer to the stilling basin side wall than 3 $d_1/8$. The side-wall height (see Section 6(*f*)) was determined with this criterion in mind and no deviation from it should be permitted.

(*d*) *End Sill.*—The end sill, at the downstream end of the stilling basin (see Fig. 1), deflects the bottom currents upward and away from the stream bed. In addition, a ground roller is generated under the deflected jet. This ground roller transports bed material upstream and deposits it at the end of the stilling basin.

Originally, before much thought had been given to the problem, the end sill height was assumed to be d_1. This assumption proved satisfactory for the first runs of the culvert outlet series in which case Q, d_1, and d_2 were constant. Toward the end of series C (culvert outlet tests) a few tests were made on basins designed for indifferent values of Q and d_2 but with the same value of d_1. During these tests it was discovered that the end sill caused a high boil when d_2 was low and the end sill blocked off a large part of the stilling basin exit area—that is, when the ratio of end sill height c to d_2 was high. The height of the end sill was therefore made proportional to d_2 rather than to d_1. A little thought shows this to be more logical. The function of the end sill is to deflect the bottom currents upward and in doing so, the entire stream leaving the stilling basin is deflected. To have the same degree of deflection for all depths of water at the end of the basin, the height of the end sill should vary with d_2. The satisfactory height of end sill used in the first few tests was (in terms of d_2) equal to $d_2/7$. Therefore, this end sill height was used with entirely satisfactory results until the tests of the flume outlet series, which were made at higher values of **F**, showed that further changes were required.

The design conditions and results of the flume outlet tests made to determine the best end sill height are summarized in Table 4. The tests were made by holding all variables constant for each Froude number with the exception of the height of end sill. Tests were made at that end sill height which, in the judgment of the observer, would give the best results. Additional tests were made using higher and lower end sills to check the assumed value of c.

[a] Elevation of maximum depth of scour, in feet, on the channel center line near the end of the stilling basin. The basin floor is at El. 0.

The plotted center-line profiles of the water surface and the eroded sand beds were studied to determine the best end sill height. The height judged best on this basis is noted in Table 4. Ordinarily, a low end sill did not deflect the jet upward sufficiently to prevent stream-bed erosion close to the outlet and to permit the formation of a ground roller under the jet. On the other hand, a high end sill caused the jet to shoot into the air. Thus, a higher side wall was required ordinarily and the landing stream eroded a large hole some distance downstream from the stilling basin. In Table 4, the terms "second hole" and "high boil" indicate the same condition; because of the test setup the second hole did not always appear and the term "high boil" is substituted as a synonomous term.

The flume outlet series was completed by making tests to check the over-all performance of the stilling basin. The results of these tests are summarized in Table 5. The end sill heights used in designing the stilling basins for these tests were found to be entirely satisfactory.

Considerable study was given to the problem of reducing the end sill height observations of the culvert and flume outlet series to a single curve before a successful solution was obtained. Plotting c/d_2 versus **F** did not reduce the data to such a form that a single curve could be used. Studies of this plot indicated that the variation was a function of the discharge per unit width of stilling basin. Plotting the product of c/d_2 and the discharge per unit width versus **F** produced a very satisfactory curve which was used in designing end sills for the tests listed in Table 5. The equation of this curve was not dimensionless, and it was therefore necessary to devise a method of making the equation generally applicable. Although two methods were used to accomplish this result, only the simpler and most straightforward method will be described. In the Reynolds number, defined in Eq. 1*b*, the term $V_1 d_1$ is the discharge per unit width. The kinematic viscosity, ν, can be considered constant for design purposes. For this condition the Reynolds number is proportional to the discharge per unit width. Since **R** is dimensionless, it does not have the undesirable dimensional properties of the equation first developed for the height of end sill. A consideration of the previously developed equation indicated that **F** had little influence on the determination of the end sill height. Therefore, the Froude number was tentatively eliminated from further consideration and c/d_2 was plotted against **R**. The curve drawn through these data was quite well defined and had the equation,

$$\frac{c}{d_2} = \frac{24}{\sqrt{\mathbf{R}}} \qquad (4)$$

Unfortunately, the experimental data did not cover the complete range of Reynolds numbers that may be expected in designing field structures—because the models were operated in accordance with the Froude model law (gravitational forces controlling) whereas the prototype-model relationship for the end sill height developed from the culvert and flume outlet series of tests requires that the model be operated in accordance with the Reynolds model law (viscous forces controlling). Since the two model laws require different and incompatible operating conditions, it is not possible to operate a model in such a way as to fulfil the requirements of both laws simultaneously.

The end sill heights computed from Eq. 4 are unbelievably low for the Reynolds numbers within the range of practical application. This condition led to the suspicion that the form of Eq. 4 might be incorrect, although nothing occurred during the culvert and flume outlet series to indicate that Eq. 4 could not be safely extrapolated, and showed the advisability of making additional tests at higher values of **R**. The turbine room series of tests was designed

wall (Col. 13). [b] Basin dimensions or controllable flow conditions not as recommended in this paper. [c] Washout primarily to determine whether or not the end sill height equation originally proposed (Eq. 4) can be extrapolated beyond the range of the Reynolds numbers for which it was derived to those Reynolds numbers that are to be expected in full-size structures. These tests confirm the opinion that the extrapolated heights of end sill appear to be far too low. The results of the sixty-three tests made as part of the turbine room series are summarized in Table 6. The tests have been listed in order of increasing Reynolds numbers and grouped according to constant Froude numbers. The individual tests in each group have different amounts of air entrainment or different heights of end sill or different tailwater depths.

Typical scour patterns for several different heights of end sill are presented in Fig. 9. The height of end sill computed from Eq. 4 was used to obtain the results shown in Figs. 9(*a*), 9(*f*), and 9(*i*). The results of tests made with the end sill height recommended as a result of the turbine room series of tests are shown in Figs. 9(*b*), 9(*f*), and 9(*h*). The results presented in Figs. 9(*a*) to 9(*d*) and 9(*e*) to 9(*g*), inclusive, are for approximately the same Froude numbers (37 and 42, respectively), but at different Reynolds numbers; the tests in the latter group have a Reynolds number more than three and one-half times that of the first mentioned group (717,000 versus 200,000). The results shown in Figs. 9(*h*) and 9(*i*) are for a Froude number near the upper limit of what may be expected in a prototype structure (261) whereas the Reynolds number has a moderate value (710,000).

The 6-ft width of test channel was too narrow for many of the tests, with the result that certain features of the eroded sand bed are not indicative of what is to be expected in the prototype. These nontypical erosion patterns are shown in Figs. 9(*e*) to 9(*i*) near the downstream end and on the outside edge where a depression has been eroded along the side of the test channel. Typical erosion patterns are presented in Figs. 9(*a*) to 9(*d*). The tailwater depth for these latter tests was such that a stream bank could be maintained between the stream and the outside edge of the test channel. In the former tests the tailwater was so high that the stream bank could not be maintained and the disturbance caused by the water striking the vertical side of the channel resulted in the erosion of a depression along the channel wall.

Those tests of the turbine room series that have Reynolds numbers within the range covered by the tests of the culvert and flume outlet series check the previous conclusions. However, a study of the data obtained for Reynolds numbers beyond the range covered by the previous tests shows that the scour near the stilling basin is much less if an end sill height equal to 7% of the theoretical tailwater depth is used. Further study of the data shows that the height of the end sill relative to the tailwater depth (c/d_2) is independent of both the Froude and the Reynolds numbers. The data obtained during the flume and culvert outlet series were then re-analyzed and it was found that entirely satisfactory scour patterns were obtained for an end sill height equal to 7% of the theoretical tailwater depth. Admittedly, the end sill height as given by Eq. 4 resulted in slightly better scour patterns to $\mathbf{R} = 118{,}000$, where $c/d_2 = 0.07$, but the difference is so small as not to warrant the use of a separate equation for the lower Reynolds numbers. As a result of all tests made to determine the height of end sill, the recommended equation is

$$\frac{c}{d_2} = 0.07 \quad \text{(5)}$$

FIG. 9.—EFFECT OF END SILL HEIGHT, REYNOLDS NUMBER, AND FROUDE NUMBER ON SCOUR PATTERN

End sill heights as given by both Eqs. 4 and 5 were used for a few tests until it became certain that Eq. 4 would be eliminated from the final list of recommended design equations and Eq. 5 would be substituted for it. Subsequent tests were made simply to verify Eq. 5.

(*e*) *Tailwater Depth.*—A certain depth of tailwater above the stilling basin floor is required to prevent the hydraulic jump from being washed out of the stilling basin. This depth can ordinarily be computed from Eqs. 2. However, the use of the floor blocks and of the end sill makes it possible to reduce the actual tailwater depth d'_2 below the theoretical tailwater depth d_2 given by Eqs. 2. Mr. Warnock (4*b*) suggests a 15% reduction, or

$$\frac{d'_2}{d_2} = 0.85 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6a)$$

This tailwater depth was used in making the tests of the culvert and flume outlet series.

It is expected that the design tailwater elevation will be such that the surface roller on the hydraulic jump will never be washed out of the stilling basin. However, it is possible that the actual conditions will be somewhat different from those assumed at the time the structure was designed. Therefore, the stilling basin was tested at tailwater depths both greater and less than normal to determine what would happen under these conditions. The results of these tests are presented in Table 7. Water-surface and bed profiles are shown in Fig. 10 for normal and lowered tailwater levels. The surface roller was washed out of the basin when the tailwater level was reduced to 5.00 ft (normal tailwater level was 6.00 ft). There was no increase in the depth of scour at the end of the stilling basin, however, although the volume of erosion downstream from the basin was greatly increased. Even if no cutoff wall is used, the stability of the structure is not endangered for this tailwater level, although the stilling basin action is impaired. If the tailwater depth falls below this level, however, it is absolutely necessary that a cutoff wall be used.

[a] Elevation of maximum depth of scour, in feet, on the channel center line near the end of the stilling basin.
[b] Surface roller on hydraulic jump washed out of stilling basin.

The following brief explanation will define the term "air-jet" boundaries, in Fig. 10. The turbulence at the entrance to the stilling basin causes much air to be entrained at that point. In addition, the water in the channel approaching the stilling basin may contain entrained air. The vigorous turbulence in and beyond the stilling basin prevents the ready separation of this entrained air. Therefore, the presence of air in the water may be taken as an indication that the flow is very turbulent and, conversely, the absence of air may be assumed to indicate that the turbulence is insufficient to maintain the air in the "suspended" state. The lower boundary of the "air jet" shown in Fig. 10 is the lower limit of air entrainment and therefore indicates the lower limit of extreme turbulence as defined. The upper boundary of the "air jet" is taken as the lower boundary of the roller normally associated with the hydraulic jump. Much entrained air is also found in this roller.

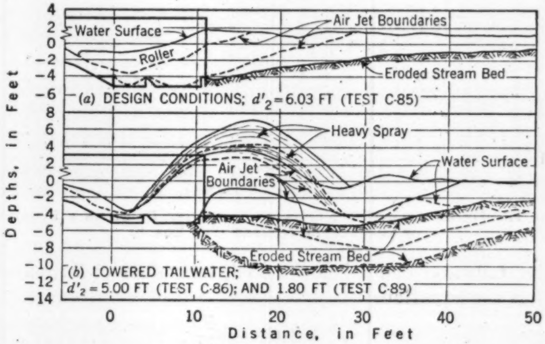

FIG. 10.—CENTER-LINE BED AND WATER-SURFACE PROFILES FOR NORMAL AND SUBNORMAL TAILWATER DEPTHS

Unfortunately, in making a check of the stilling basin design during the flume outlet series, it was found that the roller ordinarily present on the hydraulic jump was washed out of the stilling basin at values of the Froude number of less than about $\mathbf{F} = 30$. Several methods were available to overcome this difficulty: The tailwater depth could be increased, the end sill height could be increased, or the stilling basin could be lengthened. Increasing the end sill height increased the height of the boil caused by the end sill and increased the depth of scour near the end of the stilling basin. The increase required in the length of the stilling basin to insure its proper functioning was so great as to be uneconomical. The method finally adopted was to increase the tailwater depth. The equation for that part of the tailwater depth curve between $\mathbf{F} = 3$ and $\mathbf{F} = 30$ was therefore changed to

$$\frac{d'_2}{d_1} = 1.10 - \frac{\mathbf{F}}{120}, \qquad (6b)$$

to insure the proper functioning of the stilling basin at the lower Froude numbers. This curve and the data on which it is based are shown in Fig. 11.

For many runs of the turbine room series the tailwater depth was slowly lowered until the roller was washed out of the stilling basin. The object of this procedure was to determine the relative tailwater depth at which the basin would cease to function as was assumed in the design and to determine the safety factor for this part of the stilling basin. The results of these tests are presented in Table 6 and Fig. 11. They indicate that d'_2 can be reduced below $0.85\ d_2$ when the Froude number is high—that is, when $\mathbf{F} > 120$. A curve based on the turbine room tests has been added to Fig. 11 to permit a lowering of the relative tailwater depth below $0.85\ d_2$ for values of **F** greater than 120. This curve has the equation,

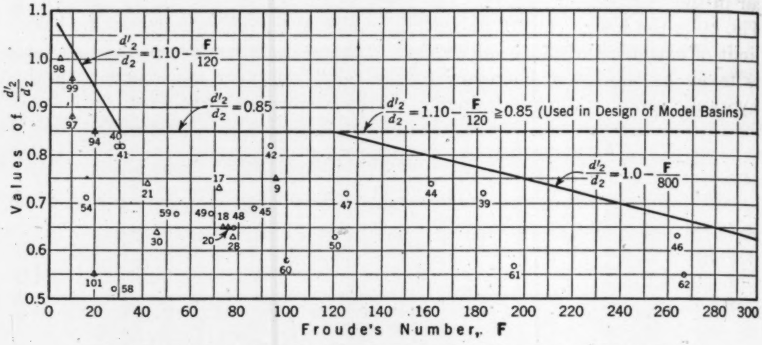

FIG. 11.—DIMENSIONLESS PLOT SHOWING TAILWATER DEPTH AS A FUNCTION OF THE FROUDE NUMBER (SEE EQS. 6)

$$\frac{d'_2}{d_2} = 1.00 - \frac{\mathbf{F}}{800} \qquad (6c)$$

The difference between the curve and the plotted points of Fig. 11 is the safety factor which insures that the stilling basin will perform as anticipated by the designer. The safety factor is small, but it is felt to be sufficient since a tailwater level somewhat lower than the design value will not endanger the basin, although the roller will be washed out of it. For this condition the floor blocks and end sill deflect the stream into the air and break it up as is shown by Fig. 10(*b*) where the tailwater depth is reduced to 5 ft (the design depth being 6 ft). This statement is inserted not as a justification for using a tailwater depth below that recommended but to show that an unanticipated lowering of the design tailwater depth or a discharge greater than that for which the outlet is designed will not endanger the outlet structure. (In Fig. 11, the plotted points are identified as follows: The triangles refer to the tests of the flume outlet series, the circles to the turbine room series, and the numbers to the test numbers.)

During the culvert outlet series a few tests were made in which the tailwater level was held at a constant elevation while the discharge was increased until the roller was washed out of the stilling basin. These tests were made to determine what would happen if the tailwater level were lower than was assumed by the designer or the actual discharge were greater than that assumed for design purposes. Conversely, the discharge was increased for several different tailwater elevations to wash the roller out of the stilling basin and then was decreased until the roller reappeared. The results of these tests indicate the maximum discharge at which the basin will continue to function properly for any tailwater depth. It is apparent from Fig. 12 that the stilling basin on which these tests were made would function properly for the design tailwater depth until a discharge equal to about 118% of the design value was reached. Similarly, for the design discharge, the basin would function properly until the tailwater depth was reduced to 90% of the design value or 76% of the theoretical value. When the tailwater depth was increased to 7.20 ft or 120% of the design (102% of the theoretical) value, the roller could not be washed out of the stilling basin even though the discharge was increased to 598 cu ft per sec or 217% of the design discharge.

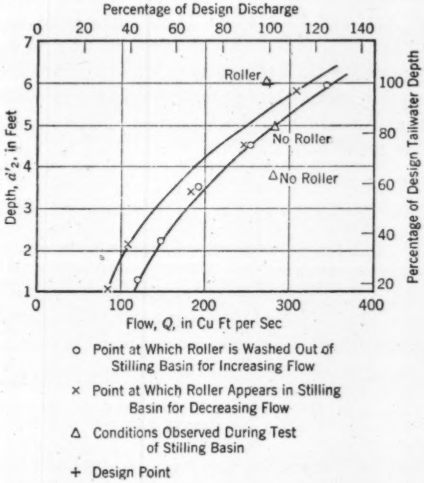

FIG. 12.—EFFECT OF VARIATIONS IN DISCHARGE AND TAILWATER DEPTH ON STILLING BASIN PERFORMANCE

(*f*) *Side-Wall Height.*—The flow in the stilling basin is very turbulent and the water surface is rough so that some freeboard above tailwater level is necessary if overtopping of the side walls is to be prevented. In addition to the surface roughness, the standing wave or boil, caused by the floor blocks and end sill, requires freeboard above the tailwater level. For Froude numbers less than about $\mathbf{F} = 20$ the crest of the standing wave is in the stilling basin whereas for higher Froude numbers the crest occurs downstream from the end of the basin and its full height need not be considered in designing the side-wall height.

Average profiles of the water surface in the stilling basin were obtained for all series, but the maximum height of splash was obtained only for the turbine room series. From the latter tests the height of the side wall is determined. The maximum height of the splash z_m in the stilling basin was divided by d_2. Both z_m and z_m/d_2 are shown in Table 6. Although there is considerable scatter to the data, z_m/d_2 is apparently independent of $\mathbf{F}$. The maximum value of z_m/d_2 for those tests of the turbine room series in which the recommended design conditions exist is 0.31; and the minimum, -0.02. The maximum value of z_m/d_2 occurs at the exit end of the stilling basin. A study of the data shows that, if the height of the stilling basin side walls z above the maximum tailwater level is given by the equation—

$$z = \frac{d_2}{3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

—the freeboard will be sufficient to keep the splash in the stilling basin. Because of the scatter in the data, the freeboard provided by this equation will be greater, in some cases, than is necessary to protect the structure adequately, but the safety factor is not excessive for the average case. Two values of z_m/d_2 were obtained from motion pictures made during the culvert and flume series of tests (series C and F). These observations substantiate the results of the turbine room tests (series T).

Frequently the elevations of the tailwater and stream bed at the time the stilling basin is constructed are much higher than those that are ultimately expected and for which the stilling basin is designed. In this case the height of the side wall must be based on the maximum expected tailwater level. If the side walls are constructed so low that water will pour over them into the stilling basin, the basin must handle, in effect, a quantity of water greater than that for which it was designed. The result is the large increase in the size of the scour hole shown in Fig. 13. This condition occurs because the "air jet," leaving the stilling basin is not deflected upward by the end sill as much as if no water entered the basin over the top of the side walls. Consequently, the side walls should always be high enough to extend above the maximum tailwater level.

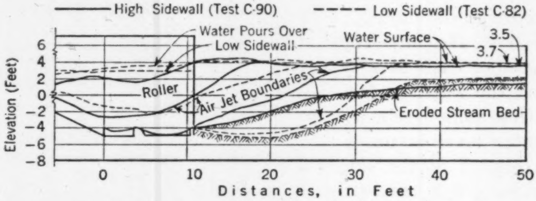

FIG. 13.—EFFECT OF WATER POURING OVER LOW SIDE WALLS INTO STILLING BASIN ON CENTER-LINE BED AND WATER-SURFACE PROFILES

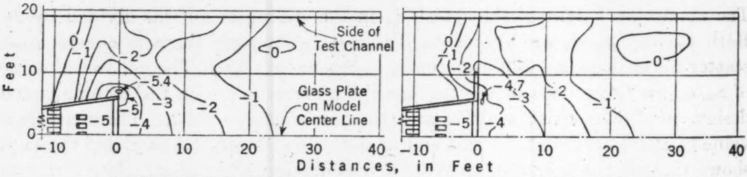
(*g*) *Wing Walls.*—The SAF stilling basin was developed mainly for use in connection with earth dams. For this type of dam, wing walls are used at the end of the stilling basin to protect the toe.

Shape of Wing Walls.—The wing walls used in the past have been rectangular in downstream elevation. During the culvert outlet series (C) tests were made to determine the best length of this wing wall. During runs made with stilling basins having no wing walls it was observed that there was considerable scour at the toe of the dam and that the deepest scour occurred close to the end of the stilling basin side walls, as shown in Fig. 14(*a*). The principal



(*a*) NO WING WALL (TEST C-46) (*b*) WING WALL 4.5 FT. LONG (TEST C-47)

FIG. 14.—EFFECT OF RECTANGULAR WING WALL ON SCOUR PATTERN

cause of the scour is an eddy along the side of the channel which is set in motion and is driven by the water that flows along the center of the downstream channel after it leaves the stilling basin. The upstream end of this eddy causes the scour at the toe of the dam. The wing wall has a twofold function: It calms the water in back of it and prevents the eddy from extending as far upstream as it would if the wing wall were absent; and it lessens the concentration of flow at the end of the stilling basin. The use of a wing wall results in a decreased depth of scour at the end of the stilling basin (Fig. 14(*b*)), although it has little or no effect on the scour at the channel center line.

The results of the tests made to determine the best length of rectangular wing wall are presented in Table 8. Too short wing walls are ineffective in preventing scour and there is nothing to be gained by making the wing walls too long. As a result of these tests, it was suggested that the minimum length of wing wall be 40% of the stilling basin side-wall height. Lengths longer than this do not change the hydraulic performance significantly.

TABLE 8.—EFFECT OF WING-WALL LENGTH ON DEPTH OF SCOUR; SERIES C

($L_r = 12$; $b_1 = 9$ Ft; $Q = 275$ Cu Ft per Sec; $d_1 = 1$ Ft; $d_2 = 7.13$ Ft; $d'_2 = 6$ Ft (Which Equals El. + 1.0); $L_B = 8.75$ Ft; $c = 1$ Ft; $F = 29$; $d'_2/d_2 = 0.84$; $L_B/d_2 = 1.23$; $c/d_2 = 0.14$; and Stilling Basin Floor Elevation = − 5.0 Ft)

[a] Length of the wing wall expressed as a percentage of the side-wall height. [b] Depth of scour, in feet, on the channel center line near the end of the stilling basin.

This rectangular wing wall was not entirely satisfactory since the depth of scour at its end was sufficient to cause some concern. It was felt that the concentration of flow lines at the end of the wing wall caused this scour. A submerged extension of the wing wall to keep the concentrated streamlines above the stream bed was tried. The height of this extension above the stilling basin floor was 0.5 d'_2 and the length was 0.6 times the side-wall height. The results were excellent in that the depth of scour at the end of the wing wall and (what is just as important) the erosion in back of the wing wall were considerably decreased. The results of this test are shown in Fig. 15(*b*). The results of a comparable test made with the originally proposed wing-wall length are presented in Fig. 15(*a*) for purposes of comparison. Subsequent to this test an additional test was made in which the top of the wing wall was sloped. The slope used was 1 on 1 beginning at the top of the stilling basin side wall. The results of this test (see Fig. 15(*c*)) were such that this wing-wall shape was used for all subsequent tests and has been shown in Fig. 1 as the recommended wing-wall shape.

Location of Wing Walls.—In the past, the wing walls used on most outlets built by the SCS have been placed perpendicular to the center line of the outlet structure. As a result, this arrangement was used throughout the test program. However, after the SAF stilling basin design had been released, questions were raised as to whether the wing wall should be perpendicular, parallel, or at some intermediate angle to the basin center line. Tests were made to answer these questions.

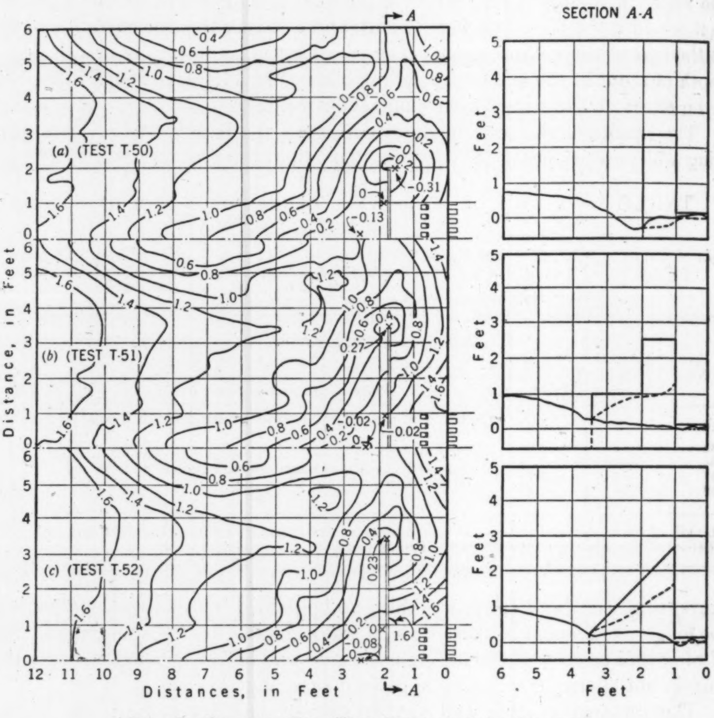

Fig. 15.—Effect of Wing-Wall Slope on Scour Pattern

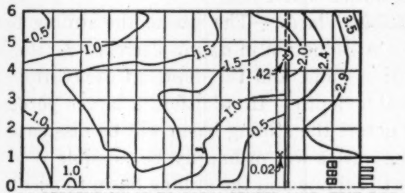
The stilling basin used in this group of tests had the dimensions shown in Table 6 for test T63. The stilling basin model had deteriorated somewhat in the fifteen months since test T63 was made, and the turbine room test setup had been partly dismantled. As a result, no attempt was made to measure the discharge, although the same valve setting was used for each of the tests in this series. It is believed that the flow was somewhat greater than that for test T63. Less sand was also available for the movable bed than was desirable. Therefore, the test results are only comparable among themselves. Plan views of each of the stilling basins and wing-wall arrangements tested are shown in Fig. 16. The top of the wing wall was sloped at 1 on 1 in all cases.

The results of the tests made on three different positions of the wing wall are given in Fig. 16. The boil height for test T66 was satisfactory ($z_m/d_2 = 0.10$) and the scour pattern (Fig. 16(*a*)) was similar to that for other tests made with the wing wall placed perpendicular to the basin center line. The maximum boil height for test T64 was 0.6 ft greater at the end of the stilling basin ($z_m/d_2 = 0.23$) than for test T66, but was still below the top of the basin side wall. The scour pattern was changed somewhat (Fig. 16(*b*)) and in general was improved. Erosion of the dam fill beside the stilling basin was decreased by a foot or more. The boil height for test T65 was the highest observed in this group of tests ($z_m/d_2 = 0.34$). This boil height occurred at the very end of the stilling basin. The high boil did, however, cause a deeper secondary scour hole than for the other two tests of this group. The scour pattern (Fig. 16(*c*)) for this test was also satisfactory. In no tests of this group did the scour descend to the elevation of the stilling basin floor, although the rise in the bed elevation along the channel center line downstream from the basin was less as the wing wall was brought nearer the outlet center line. For tests T64 and T65 there was an opening between the stilling basin wall and the wing wall that was not noticed until the tests had been completed. Water passed through this opening and caused an erroneous scour pattern at this point on the outside of the



(*a*) PERPENDICULAR TO BASIN CENTER LINE (TEST T-66)

(*c*) PARALLEL TO BASIN CENTER LINE (TEST T-65)

FIG. 16.—EFFECT OF TRIANGULAR WING-WALL POSITION ON SCOUR PATTERN

basin wall. Contours believed to be erroneous have been omitted from Figs. 16(*b*) and 16(*c*).

These tests indicate that the wing wall may be extended parallel to the basin center line if field conditions make it necessary to do so although the boil height is considerably increased. The wing wall perpendicular to the stilling basin center line produces entirely satisfactory flow and scour conditions, but the best over-all conditions were obtained when the wing wall was set at an angle of 45° to the outlet center line.

(*h*) *Shape of Stilling Basin.*—The size of the stilling basin varies with the initial flow depth. A reduction in d_1 will decrease d_2, the length of the basin, the height of the side walls, and the depth of excavation necessary to secure the required tailwater depth. In addition, a larger percentage of the energy in the water as it enters the stilling basin will be dissipated. A saving in the over-all cost of the outlet will ordinarily be possible if a transition is placed between the culvert or flume and the stilling basin to accomplish this reduction in d_1. In cases where a transition is used, a diverging transition side wall can be extended to form the stilling basin walls, as is shown on a half plan of Fig. 1. The limiting basin side-wall divergence is unknown but is probably as large as can be used on the transition.

A few tests were made on a trapezoidal-shaped stilling basin as part of the culvert outlet series. The stilling basin was designed for flow conditions at its entrance and the width and spacing of the floor blocks were multiplied by the ratio b_2/b_1 to compensate for the increase in width of the stilling basin at their location. (The widths b_1 and b_2 are defined in Fig. 1.) All blocks had their axes parallel to the center line of the basin. Flow conditions in the downstream channel were somewhat improved through the use of the trapezoidal stilling basin, as a result of the lower velocity of exit from the basin and because the stream spreads out to fill the downstream channel and reduces the size of the eddies that are formed along the sides of the channel near the stilling basin.

(*i*) *Cutoff Wall.*—A cutoff wall is used at the end of the stilling basin to prevent scour from undermining the basin. The depth of the cutoff wall, therefore, must be greater than the maximum depth of scour at the end of the stilling basin.

Serious erosion near the end of the stilling basin is prevented by the end sill which deflects the jet upward as it leaves the basin. A ground roller under the jet brings material upstream and further aids in preventing erosion. During the tests of the recommended design the scour sometimes reached an elevation slightly below the floor of the stilling basin but never reached a depth at the end of the basin greater than the thickness of a floor slab that might be used. Therefore, a cutoff wall of only nominal depth need be used at the end of the stilling basin.

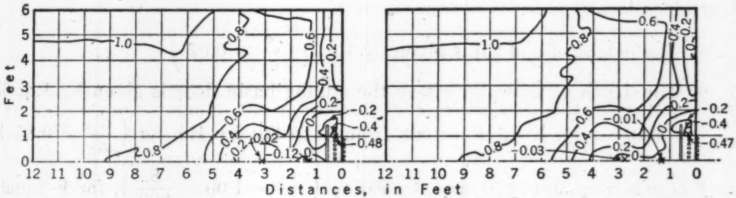
(*j*) *Effect of Air Entrainment.*—Air is ordinarily entrained by the water flowing in channels laid on a steep slope—resulting in a greatly increased depth of flow of the mixture. However, no air was naturally entrained during the model tests because of the low velocities or short length of test channel. Therefore, five runs were made in which from 10% to 117% of air was mixed with the water. The results of these tests and their parallel runs made without air entrainment are summarized in Table 6.

It was intended that the quantity of air mixed with water as it passed under the depth control gate (see Fig. 3) be computed from the equation:

$$Q_a = 0.2\, Q \sqrt{\mathbf{F}_{aw}} - Q \dots\dots\dots\dots\dots\dots\dots (8)$$

in which Q_a is the air flow at atmospheric pressure and Q is the water flow, both in cubic feet per second, and $\mathbf{F}_{aw}$ is the Froude number for the air-water mixture. Eq. 8 is an average of the equations derived by Warren DeLapp, Jun. ASCE (11*a*), from an analysis of the data published by L. Standish Hall, M. ASCE (11). However, an error was made in the solution of the equation and the actual quantities of air used are somewhat different from those intended. Nevertheless, the qualitative results give an indication of what may be expected when air is entrained with the water.

In designing the test basins, it was assumed that the velocity of the water would be unchanged by entrained air. The initial depth of flow was increased, therefore, to compensate for the larger total quantity of mixture flowing in order to keep the velocity constant. The result is a lowering of the Froude number for the flow of mixture below that obtained for water flow alone. The stilling basin was designed for the higher Froude number obtained when there was no air entrainment and the same basin was used for the test with air entrainment. In either case the tailwater depth is the same whether or not air entrainment occurs since the downstream velocities are low enough that the air separates from the water after leaving the stilling basin. No increase in side-wall height is necessary when the water transports entrained air. The results of a typical test are given in Fig. 17(*b*) where the percentage of air used was 117—that is, the air flow was greater than the water flow. The results presented in Fig. 17(*a*) were obtained on the same stilling basin when no air was entrained in the water.



(*a*) F = 264; R = 99000; $\frac{Q_a}{Q} = 0.00$ (TEST T-46) (*b*) F = 125; $\frac{Q_a}{Q} = 1.17$ (TEST T-47)

FIG. 17.—EFFECT OF ENTRAINED AIR ON SCOUR PATTERN

(Correction: In caption (*a*) R should be boldface, denoting the Reynolds number.)

These tests show that the effect of air entrainment can be neglected in the design of the SAF stilling basin. The resulting structure will safely handle any flow in which air is entrained.

7. SUMMARY

The following conclusions are reached as a result of the tests made to develop and verify the SAF stilling basin design.

1. The length of the stilling basin for Froude numbers between **F** equals 3 and **F** equals 300 is determined by Eq. 3 $\left(\frac{L_B}{d_2} = \frac{4.5}{\mathbf{F}^{0.38}}\right)$.

2. The height of the chute blocks and floor blocks is d_1 and the width and spacing are approximately $\frac{3}{4}\,d_1$.

3. The distance from the upstream end of the stilling basin to the floor blocks is $\frac{L_B}{3}$.

4. No floor block should be placed closer to the side wall than $\frac{3}{8}\,d_1$.

5. The floor blocks should be placed downstream from the openings between the chute blocks.

6. The floor blocks should occupy between 40% and 55% of the stilling basin width.

7. The widths and spacings of the floor blocks for diverging stilling basins should be increased in proportion to the increase in stilling basin width at the floor block location.

8. The height of end sill is given by Eq. 5 $\left(\frac{c}{d_2} = 0.07\right)$.

9. The depth of tailwater above the stilling basin floor is given by Eq. 6*b* $\left(\frac{d'_2}{d_2} = 1.10 - \frac{\mathbf{F}}{120}\right)$, for **F** equals from 3 to 30; by Eq. 6*a* $\left(\frac{d'_2}{d_2} = 0.85\right)$, for **F** equals from 30 to 120; and, by Eq. 6*c* $\left(\frac{d'_2}{d_2} = 1.00 - \frac{\mathbf{F}}{800}\right)$, for **F** equals from 120 to 300.

10. The height of the side wall above the maximum tailwater depth to be expected during the life of the structure is given by Eq. 7 $\left(z = \frac{d_2}{3}\right)$.

11. Wing walls should be equal in height to the stilling basin side walls. The top of the wing wall should have a slope of 1 on 1.

12. The wing wall should be placed at an angle of 45° to the outlet center line.

13. The stilling basin side walls may be parallel (rectangular stilling basin) or they may diverge as an extension of the transition side walls (trapezoidal stilling basin).

14. A cutoff wall of nominal depth should be used at the end of the stilling basin.

15. The effect of entrained air should be neglected in the design of the stilling basin.

8. REMARKS

The safety factor incorporated in the design of the SAF stilling basin is low but it is felt to be adequate. As more exact methods of analysis are applied to the design of a structure, it is possible to reduce the safety factor, with increased assurance that the structure will perform as intended by the designer. The SAF stilling basin is based on a large number of tests and knowledge of its performance is such that the safety factor can be safely reduced to a minimum. In addition, the tests show that, although a discharge somewhat higher than the design discharge might wash the roller out of the basin, this action would do little or no damage. A lowering of the tailwater somewhat below the design level would have the same effect and result.

Throughout the tests it was observed that the performance of the SAF stilling basin was excellent at discharges less than the design value. For the design conditions, the SAF stilling basin provides an economical method of dissipating energy and preventing dangerous and uncontrolled stream bed erosion. The hydraulic design of the SAF stilling basin is simple; only the depth and velocity of the flow approaching the basin are needed before entering a design chart (12) or solving the design equations.

9. ACKNOWLEDGMENTS

The work covered in this paper was performed at the St. Anthony Falls Hydraulic Laboratory of the University of Minnesota where the Office of Research of the SCS and the Minnesota Agricultural Experiment Station are cooperating in the solution of problems pertinent to the activities of the SCS. The work was done under the administrative direction of M. L. Nichols, chief, Office of Research, and under the technical direction of C. E. Ramser, M. ASCE, research specialist in hydrology. The tests were largely performed by Charles A. Donnelly, senior engineering aide, under the direction of the writer. Albert N. Huff was project supervisor at Minneapolis during these investigations. From him and from Donald A. Parsons much constructive criticism was forthcoming. The writer also wishes to acknowledge the most helpful, constructive criticism offered by the anonymous (to the writer), expert reviewers to whom the paper was submitted by the Society's Committee on Publications.

APPENDIX II. NOTATION

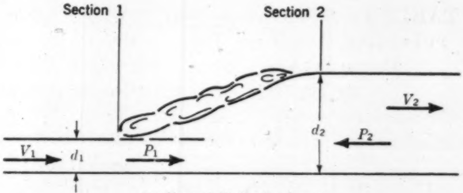
The following letter symbols, adopted for use in this paper and for the guidance of discussers, conform essentially to American Standard Letter Symbols for Hydraulics (ASA—Z10.2—1942), prepared by a Committee of the American Standards Association, with Society representation and approved by the Association in 1942. In addition, the symbols of linear concepts are defined by Fig. 1.

b = stilling basin width:
  b_1 = at the entrance;
  b_2 = at the floor block location;
  b_3 = at the exit;
c = height of end sill;
d = flow depth:
  d_1 = at the stilling basin entrance (lower conjugate depth for the hydraulic jump);
  d_2 = upper conjugate depth for the hydraulic jump (see Eq. 2*b*);
  d'_2 = tailwater depth, measured above the stilling basin floor;
  d''_2 = tailwater depth at which the hydraulic jump was washed out of the stilling basin;
$\mathbf{F}$ = the Froude number (Eq. 1*a*); $\mathbf{F}_{aw}$ = the Froude number when air is entrained;
g = acceleration due to the effect of gravity;
L_B = length of the stilling basin;
L_r = assumed linear scale ratio between prototype and model;
Q = rate of flow of water; Q_a = rate of flow of air;
$\mathbf{R}$ = the Reynolds number (Eq. 1*b*); $\mathbf{R}_m$ = the Reynolds number for the model;
V_1 = velocity of flow at stilling basin entrance;
z = height of stilling basin side walls above maximum tailwater level:
  z_a = average maximum boil height above tailwater level;
  z_m = maximum boil height in stilling basin above tailwater level; and
ν = kinematic viscosity.

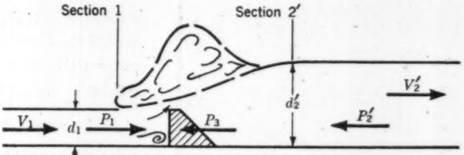
DISCUSSION

Donald E. Blotcky,[3] Assoc. M. ASCE.—Criteria for design of the Saint Anthony Falls (SAF) stilling basin (Minneapolis, Minn.) are based on scour conditions considered satisfactory in the movable bed model. Because of the limited knowledge of the mechanics of energy dissipation, empirical equations must be used. However, it is desirable to submit such equations to a rational analysis, thus striving toward the goal of explaining all hydraulic phenomena by rational methods.

It is the writer's belief that use of the theoretical equation for the hydraulic jump (Eqs. 2) is undesirable where formation of the jump is aided by blocks and sills.



(a) Normal Hydraulic Jump



(b) Hydraulic Jump Complicated by Floor Blocks

Fig. 18.—Velocity, Depth, and Pressure Relationships in Hydraulic Jumps

Energy dissipation can be divided into two categories as far as stilling basin action is concerned: First, that in which the energy is dissipated due to impact of water on water; and, second, that in which energy

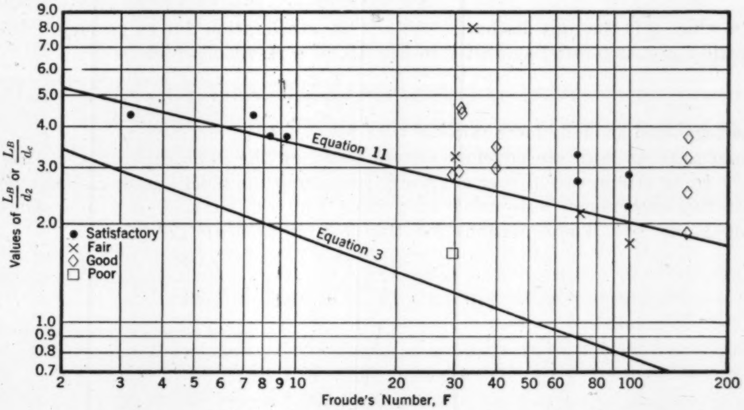


Fig. 19.—Dimensionless Plot of Stilling Basin Performance for Comparison of Eqs. 3 and 11

is dissipated due to impact of water on a submerged solid object and the impact of water on water.

In the first case, exemplified by the hydraulic jump, the degree of energy loss is well known (27). In the analytical solution of the hydraulic jump (Fig. 18(*a*)), the phenomenon starts at the toe of the jump, at Section 1, and has a theoretical end of jump at Section 2, which is located at the point of maximum d_2. It should be noted that the jump acts from Section 1 to Section 2 without interference. Eqs. 2 relates the various parts of the jump as shown in Fig. 18(*a*). The second case (Fig. 18(*b*)) is usually a hydraulic jump with floor blocks added, and will hereinafter be called a "block jump" as distinct from a normal hydraulic jump. The addition of blocks, which cause additional unknown energy losses, invalidates Eqs. 2. In place of d_2, the writer suggests that d_c, the critical depth, be used in presenting the design equation for the length of basin. Since the following equalities are true,

$$f(d_c) = \psi(d_2) = \alpha(d_1) = \theta(\mathbf{F}) \quad \text{....(9)}$$

any one of the equal functions can be substituted and the result will be changed in form only. It would, perhaps, be even more desirable to present the equation for L_B as a function of **F** and d'_2. In Table 9, values of d_c are given for various runs as computed from

$$d_c = \sqrt[3]{q^2/g} \quad \text{..........(10)}$$

in which q is the unit discharge and g is the acceleration due to gravity. The ratio L_B/d_c is plotted against **F** in Fig. 19, as a result of which

$$L_B/d_c = \frac{6.2}{\mathbf{F}^{0.25}} \quad \text{..........(11)}$$

is suggested as being more rational than Eq. 3. It is, however, no more exact, inasmuch as both are envelope curves based on the same experimental data.

In an attempt to further analyze the action of the block jump, various runs of the experiment were used as a basis for computation of values shown in Table 10. The equations for the computations are (27*a*):

$$\epsilon_j = \frac{(d_2 - d_1)^3}{4\, d_2\, d_1} \quad \text{..........(12)}$$

$$\epsilon_1 = d_1 \left(1 + \frac{\mathbf{F}_1}{2} \right) \quad \text{..........(13)}$$

$$\epsilon'_2 = d'_2 + \frac{q^2}{2\, g\, (d'_2)^2} \quad \text{..........(14)}$$

$$\epsilon_2 = (\epsilon_1 - \epsilon_j) \quad \text{..........(15)}$$

$$\epsilon_{bj} = (\epsilon_1 - \epsilon'_2) \quad \text{..........(16)}$$

$$\epsilon_b = (\epsilon_{bj} - \epsilon_j) \quad \text{..........(17)}$$

In these equations, ϵ_j, ϵ_{bj}, and ϵ_b represent energy loss due to the hydraulic jump, the block jump, and the blocks alone, respectively; d'_2 is the depth of flow at section $2'$; ϵ_1, ϵ_2, and ϵ'_2 represent the specific energy at section 1, section 2, and section $2'$, respectively; and $\mathbf{F}_1$ is the Froude number at section 1.

T37	1.157	1.66	0.441	0.50	0.059	0.27	10.68	0.05	80.8
T42	2.405	3.340	0.801	0.93	0.129	0.24	11.06	0.05	93.7

The values in Col. 8, Table 10, when plotted (Fig. 20) against the corresponding Froude numbers, result in the equation

$$\frac{d'_2}{d_1} = 1.05\,\mathbf{F}^{0.522} \quad \ldots\ldots\ldots\ldots\ldots (18)$$

which is comparable to Eqs. 6 and is in a more desirable form.

In the hydraulic jump, $\mathbf{F} = 3$ is the theoretical transition point between the direct jump and the undulated jump. It has been noted (15*a*) that observed values of d_2 within the undulated jump zone are in excess of those computed by Eq. 2. It has also been stated (15*b*) that the actual transition point between the direct jump and the undulated jump is at about $\mathbf{F} = 4$. It is interesting to note that the undular jump also occurs in the block jump. This is evident because the ratio d'_2/d_2 is greater than 1 for small values of **F**, and has occurred for values of **F** as high as 15. For this reason Eq. 18 should not be used for values of **F** less than 15. Further experimentation is necessary to locate the probable range of values for the undulated jump in the block jump.

Col. 6 of Table 10 gives the actual head loss caused by the blocks; Col. 9 gives the ratio of the efficiency of the blocks as compared to that of the hydraulic jump. It should be noted that the blocks are most effective, compared to the hydraulic jump, at low values of **F**.

Fig. 21 is a plot of the values of Cols. 7 and 8, Table 10, against **F**. Study of the manner in which the plotted points follow the curves for the hydraulic jump causes speculation as to the actual nature of the relationship between parts of the block jump. It is apparent that the ratios are comparable to those in a hydraulic jump and thus might be susceptible of an analytical solution based on change of momentum.

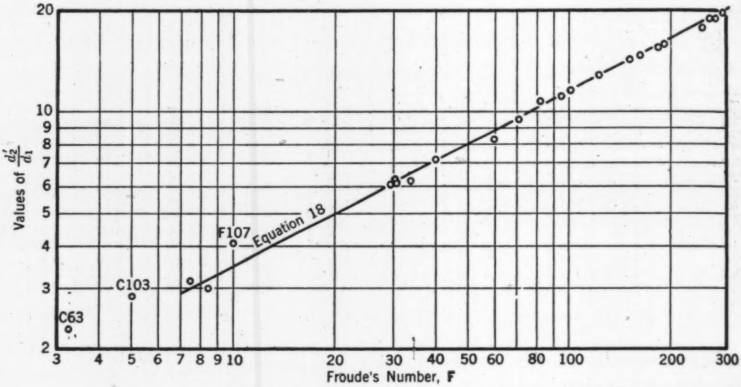

FIG. 20.—RELATION BETWEEN DEPTH RATIO AND FROUDE NUMBER FOR BLOCK JUMP

A schematic picture of the conditions obtaining in the block jump is given in Fig. 18(*b*). Applying the momentum theorem, P_3 is the only new force involved over that in the solution for the hydraulic jump. Change of momentum may then be expressed by

$$P'_2 + P_3 - P_1 = \frac{Q\,w}{g}\,(V_1 - V'_2) \ldots\ldots\ldots\ldots\ldots (19)$$

in which $P_1 = A_1\,w\,\bar{y}_1$; $P'_2 = A'_2\,w\,\bar{y}'_2$; A is the area at any section; w is the unit weight of water; $\bar{y}$ is the depth to the center of gravity at the section; and V'_2 is the velocity at section 2′. To determine P_3, recourse must be had to the analysis of forces acting on a flat plate perpendicular to flow and completely submerged in the fluid (see Fig. 22(*a*)). It can be shown by dimensional analysis (28)(29) that the force acting on the flat plate is

$$F = \theta(R)\,\rho\,V^2\,A_p \ldots\ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

in which $\theta(R) = C_f\,\frac{1}{2}$; $\rho = \frac{w}{g}$; V is the velocity of approach; A_p is the area of the plate; and C_f is a coefficient of form.

Thus,

$$F = C_f\,w\,A_p\,\frac{V^2}{2\,g} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

FIG. 22.—RELATIONSHIP OF QUANTITIES IN FLOW AROUND FLAT PLATES AND BLOCKS

If $F = P_3$ is substituted in Eq. 19,

$$A'_2 \, w \, \bar{y}'_2 + C_f \, w \, A_p \frac{V^2}{2 \, g} - A_1 \, w \, \bar{y}_1 = \frac{Q \, w}{g} (V_1 - V'_2) \ldots\ldots (21a)$$

or

$$\frac{(d'_2)^2}{2} + C_f \frac{A_p}{b} \frac{V^2}{2 \, g} - \frac{d^2_1}{2} = \frac{q}{g} (V_1 - V'_2) \ldots\ldots\ldots\ldots (21b)$$

from which

$$d'_2 = \sqrt{\frac{2 \, q}{g} (V_1 - V'_2) + d^2_1 - C_f \frac{A_p}{b} \frac{V^2}{g}} \ldots\ldots\ldots\ldots (21c)$$

Eq. 21*c* is dimensionally and dynamically correct; it is only in its application that troubles arise.

If it is assumed that

$$A_p = W \, d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22a)$$

$$W = k \, b \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22b)$$

and

$$V'_2 = q/d'_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22c)$$

in which W is the width of plate; d, the depth of plate; and k, the percentage of basin width covered by blocks; then Eq. 21*c* may be rewritten

$$d'_2 = \sqrt{\frac{2 \, q}{g}\left(V_1 - \frac{q}{d'_2} \right) + d^2_1 - C_f \frac{k \, V^2}{g} d} \ldots\ldots\ldots\ldots (23)$$

Eq. 23 is an implicit equation which cannot, by any simple means, be solved into an explicit function. For this reason Eq. 23 must be solved by trial and error. As an original value for d'_2, the value of d_2 can be used. The third solution will generally give the final value of d'_2. In the foregoing analysis it has been assumed that the resistance P_3 is caused by a flat plate. Since this is not true, it must be shown that the general conditions still prevail. Fig. 22(*b*) shows the approximate pressure bulbs on a flat plate under the conditions required by the analysis (30). By bringing the flat plate in contact with a solid boundary (30*a*) the pressure distribution is altered approximately as shown in Fig. 22(*c*). By changing the plate to the form of a floor block the pressure bulbs are again varied to the approximate shapes shown in Fig. 22(*d*). In analyzing C_f the assumption can be made that the skin friction is negligible and that, for all practical purposes,

$$C_f = C_d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

in which C_d is the coefficient of form drag. Rewriting Eq. 20*b*,

$$\frac{F}{A_p} = p = C_d \, w \frac{V^2}{2 \, g} \ldots\ldots\ldots\ldots\ldots\ldots (25a)$$

or

$$\frac{p}{w} = C_d \frac{V^2}{2\,g} \qquad (25b)$$

It is noted that the coefficient C_d is actually a nondimensional number, shown to vary with **R**, which, when multiplied by the velocity head of stagnation, gives the pressure head caused by the stagnation of flow. Referring to Fig. 22(a), the pressure under ideal circumstances would be the pressure due to stagnation of flow and thus equal to $\frac{V^2}{2\,g}$ or $\frac{V^2_s}{2\,g}$. Since the streamlines of flow are approximately zero in width at the point of separation the velocity V_s must be greater than V, the velocity of approach. For this reason, the negative pressure bulb is greater than the positive pressure bulb; C_d can then be written as

$$C_d = J_+ + J_- \qquad (26)$$

in which J_+ is the coefficient in $J_+ \frac{V^2}{2\,g}$ to represent the plus pressure on the front of the plate and J_- is the coefficient in $J_- \frac{V^2}{2\,g}$ to represent the negative pressure on the back of the plate caused by the velocity V_s. The true physical nature of J is shown in Fig. 22(e), where it is shown to be the average height of the pressure bulb over the area of the plate.

In two-dimensional flow, J is one side of a plane rectangle; in three-dimensional flow it is the height of a rectangular solid. Thus, by measuring the pressure bulbs on the back and front of a block, the value of C_d is obtainable. Distinction should be made for the C_d of a single block and the C_d for a block group, since interference would cause a change in value. In studies pertaining to cavitation on baffle piers the coefficient J_- was determined to be equal to 0.68 for a single cubical pier (31).

As another approach to C_d, Eq. 23 can be rewritten as

$$C_d = \frac{\frac{2\,q}{g}\left(V_1 - \frac{q}{d'_2}\right) + d^2_1 - (d'_2)^2}{k\,d\,\frac{V^2}{g}} \qquad (27)$$

By assuming k equal to 0.5, d equal to d_1, and V equal to V_1, the value of C_d can be computed for various runs of the experiments. Included in the foregoing assumptions is the inherent fact that the chute blocks will not dissipate any appreciable amount of energy and thus are ignored. The computed values of C_d based on these assumptions are plotted against **R** in Fig. 23.

Up to about $\mathbf{R} = 10^6$, the value of C_d is practically constant, which indicates that C_d is independent of **R** for this range. However, one point (T58) with $\mathbf{R} = 1.45 \times 10^6$ and with $\mathbf{F} = 28.2$ is definitely below the values of the other runs. Two possibilities can explain the reason for this change. First, if the range of undulated jumps extends to as high a value of **F** as 28.2, then the observed d'_2 would be too high, and consequently the run could not be used in an equation based on change of momentum. Second, the value of $\mathbf{R}_{crit}$ has

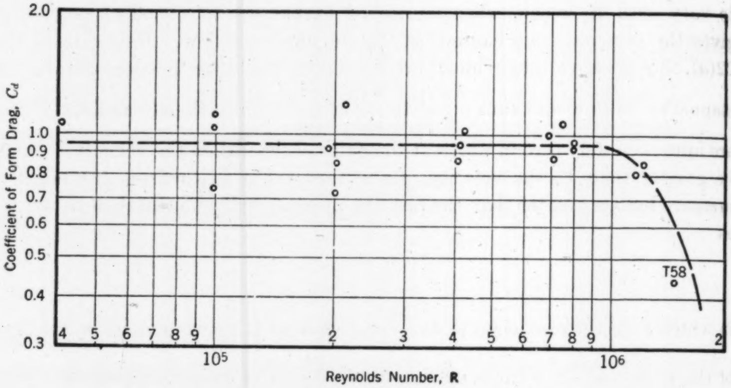

FIG. 23.—PLOT OF C_d VERSUS R FOR BLOCK JUMP

been reached, in which the boundary layer adjacent to the block has changed from laminar to turbulent flow. Whether a solid, streamlined as slightly as is the block, can exhibit this characteristic is as yet unknown. Other experimenters have made tests to determine C_d for a body similar to the floor block, but so far have given as a result only that C_d was constant and a value. No attempt was made to correlate the value of C_d to **R** and no mention is made of the range of **R** (32). It is entirely possible for the smooth blocks used in the experiments to exhibit this characteristic, but if so the value computed for C_d cannot be used in application to a prototype. In prototype flow it would be almost impossible for a laminar boundary layer to exist next to a surface as rough as a concrete block.

In a model controlled by the Froude number the value of **R** is different for the model and prototype. However, it has been stated that "* * * the Froude number refers to flow with a free surface, and actually has no relationship whatever with the inner mechanism of confined flow * * *" (33). Since the foregoing derivations are based on the premise that the blocks are completely submerged this quotation will hold and **R** will be the same, as regards C_d, for model and prototype. The confined flow is between a solid boundary and a streamline which has a pressure greater than zero and which is not affected by surface disturbances. If the submergence is not sufficient to satisfy these conditions the water would be deflected into the air and a free surface of flow would then affect the flow around the blocks.

The author has given aid to designers from two standpoints: (*a*) By presenting design equations the designer has at hand a reasonable method to use;

and (*b*) perhaps of more importance, the designer may use a standardized method so that prototype structures may be compared in action after construction.

M. M. Culp,[4] **Assoc. M. ASCE.**—Early gully control work involving the use of chutes and drop inlet spillways has demonstrated the need for some mechanical device to assist in the dissipation of hydrodynamic energy at the outlet end of such spillways. Erosion damage below several drop inlets and chutes led to field inspections and study of the problem. It seemed that the principal factors involved were:

1. Tailwater elevation;
2. Soil condition in the gully bottom and banks;
3. The stability of the channel grade below the spillway (which affects tailwater);
4. The magnitude, duration, and frequency of discharge through the spillway; and
5. Vegetative growth or other protective cover in the immediate vicinity of the outlet.

Where damage occurred it was obviously the result of eddies produced by a high velocity jet of water emerging from the spillway. Severe damage, requiring extensive repair, has occurred at the outlet of several spillways. For example, Fig. 24 shows the outlet of a twin 6-ft by 6-ft reinforced concrete drop inlet. The outlet apron had been undermined and so badly cracked that it had to be completely removed during repair operations.

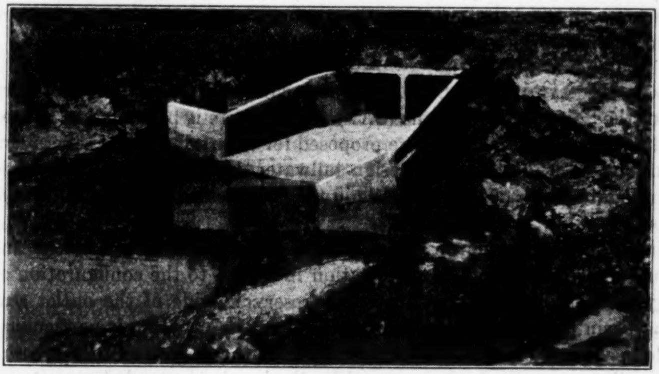

Fig. 24.—Failure of Apron on Twin 6-Ft by 6-Ft Drop Inlet Culvert Due to Undermining and Scouring

---

[4] Civ. Engr., Head, Design and Construction Section, Regional Eng. Div., SCS, U. S. Dept. of Agriculture, Milwaukee, Wis.

Several spillways constructed with Saint Anthony Falls (SAF) outlets during the past two years have not been subjected to a real test, as yet, and final conclusions cannot be drawn. However, several flows of less than design capacity have occurred, and the short experience to date indicates that the SAF outlet will function satisfactorily.

The designer of this type of outlet is confronted with the problem of constructing a stage-discharge curve for the natural channel below the spillway. Associated with this problem is the determination of the probable grade and cross section of a stable channel below the spillway. It is a well-recognized fact that natural channels tend to degrade when the bed load is removed by deposition in a reservoir. The problem is complicated further by variations in channel roughness with the stage, and by nonuniform flow conditions that may exist. The problem may be simplified, however, by the construction of a low drop spillway in the channel below the SAF outlet. Such a spillway provides a control from which backwater computations lead to reasonably correct tailwater elevations.

The writer sugggests that Mr. Blaisdell give consideration to the use of the word "chute," in lieu of "flume," to describe the high velocity open spillway shown in Fig. 3. This suggested nomenclature conforms to the definition given in the ASCE *Manual of Engineering Practice No. 11*, "Letter Symbols and Glossary for Hydraulics."

Mr. Blaisdell is to be complimented on a clear presentation of a long, tedious, and difficult program of hydraulic tests of a generalized nature. The writer is confident that the results of his work, as reported in the paper under discussion, will have continued and increasing use, especially in the field of upstream engineering.

Paul Baumann,[5] **M. ASCE.**—An abundance of information on the model tests of the Saint Anthony Falls (SAF) stilling basin is presented in this paper, and simple empirical formulas are proposed for determination of several critical dimensions. In addition, the design tailwater depth, d'_2, as compared to d_2, the conjugate depth of the hydraulic jump, is expressed in terms of the Froude number, **F**.

Since the primary purpose of a stilling basin is the dissipation of energy, it would have been helpful if information in regard to the configuration of the energy gradient between the upstream (reservoir) side of the outlet and the stilling basin proper had been presented. Such information is particularly desirable in view of the fact that the depth d_1 at the upper end of the basin and of the roller, respectively, is governed by the loss in energy between it and the reservoir surface (assuming the energy line to coincide with the reservoir surface for small velocity of approach). The coefficient ϕ to be applied to the factor $\sqrt{2\,g\,h}$ must be determined experimentally for each problem. Values of ϕ determined on models therefore furnish valuable information for those who must prepare stilling basin designs without the aid of model tests.

In general, it has been found that ϕ does not drop much below 0.9 for supercritical flow of water under rounded gates, although, for water discharging over ogee sections of considerable height, ϕ may drop to 0.5 and lower, depending on the smoothness of the surface, the curvature of the ogee section as well as that of the apron, and the transition between the crest and the stilling basin. Such a loss in head, and therefore in energy, is reflected in the depth d_1, which may be considerably in excess of the depth that would be established without such loss. The conjugate depth, d_2, derived from Eq. 2*a*, is necessarily affected correspondingly.

---

[5] Asst. Chf. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

It is an interesting fact in hydraulics that Eq. 2*a*, which is derived from the condition that the sum of the static and dynamic pressure above the jump equals the sum of the static and dynamic pressure below the jump, leads to a loss in energy without the application of any empirical factors. The validity of this equation has been confirmed on models as well as on prototypes. This equation may, with close approximation, be written

$$d_2 = 0.45 \left(v_1 \sqrt{\frac{d_1}{3.28}} - d_1 \right) \dots\dots\dots\dots\dots\dots (28)$$

In contradistinction, the equation for the depth d_1 must always include the empirical factor ϕ and must read

$$d^3_1 - d^2_1 H_0 + \frac{q^2}{\phi^2\, 2\, g} = 0 \dots\dots\dots\dots\dots\dots (29)$$

in which H_0 is the vertical distance from the floor of the stilling basin to the upstream energy line (reservoir surface); and q is the discharge per unit width of stilling basin. Since ϕ appears in the second power, it is readily conceivable that its influence on the value of d_1 is significant.

In discussing the paper, "Baffle-Pier Experiments on Models of Pit River Dams" (34), the writer (34*a*) attempted to determine the most efficient design depth (d'_2) based on the concept that the dissipation of energy (the transformation of kinetic into heat energy) is due to the roller and that the rise in temperature of the roller should be a maximum for the design depth d'_2. The equation for d'_2 so derived is, after simplification and correction,

$$(d'_2)^3 = \frac{q^2}{g} \left(2 - \frac{d'_2}{2\, H} \right) \dots\dots\dots\dots\dots\dots (30)$$

in which H is the vertical distance between the upstream energy line (reservoir surface) and the stilling basin water surface for design depth d'_2. In arriving at this equation, the empirical formula—

$$V_B = \alpha\, Q \sqrt{\frac{H}{g}} \dots\dots\dots\dots\dots\dots (31)$$

—was used for the volume of the roller. In Eq. 31, V_B is the volume of the roller; α is a coefficient; and Q is the total discharge ($= q\, b$).

The difference between the conjugate depth d_2 and the values for d'_2 resulting from Eq. 30 is demonstrated by Fig. 25, which indicates that d_2 is considerably in excess of d'_2. This is particularly noticeable with an increase in head. The values, however, would tend to become reconciled if d_2 were determined by the use of a proper coefficient ϕ with the value of d_1 as previously discussed.

To demonstrate the relation between values for d'_2 determined by Eq. 30 and by the author, respectively, Fig. 12, an important part of the paper, is

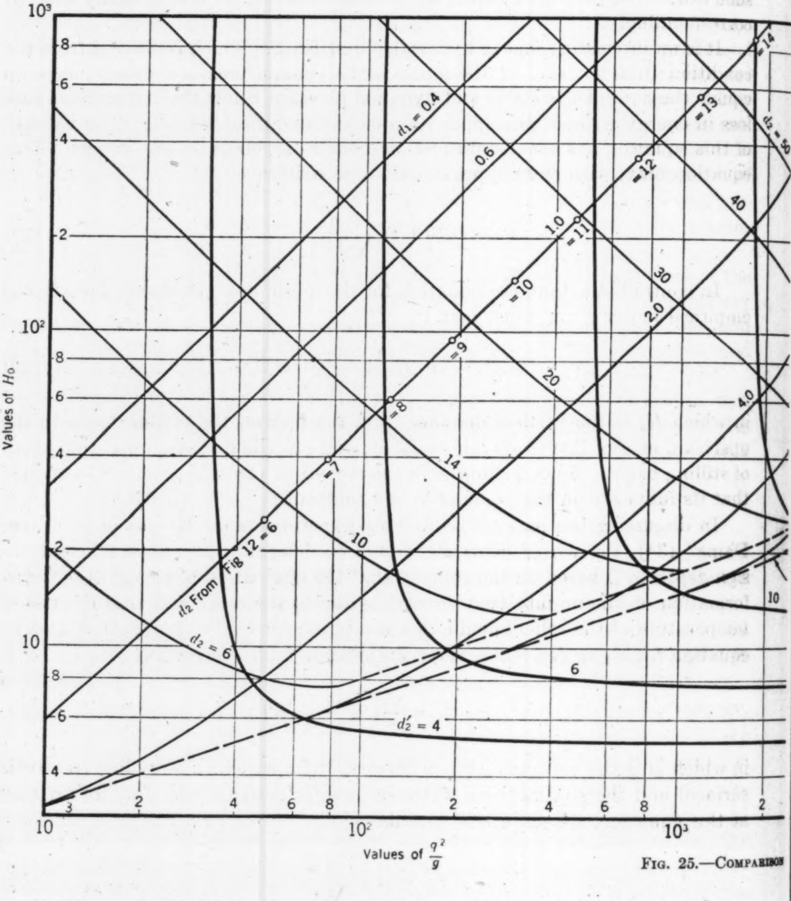

FIG. 25.—COMPARISON

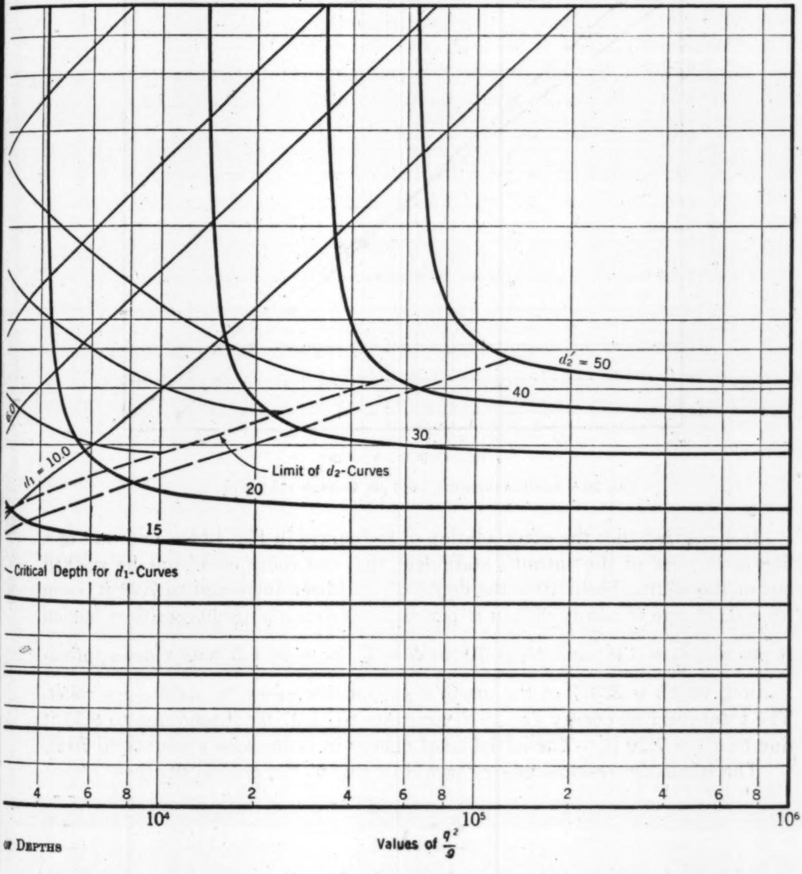
used. It was derived from the series of culvert outlet tests which are not shown in the paper.

For $d_1 = 1$ ft and $b_1 = 9$ ft, Eq. 29 may be rewritten

$$H_0 = 1 + \frac{q^2}{\phi^2 \, 2\, g} \quad \text{.......................(32)}$$

in which $q = \frac{Q}{b_1}$.

The curves shown in Fig. 12 plot as straight lines on semilogarithmic paper. They may, therefore, be extrapolated so as to cover depths d'_2 considerably in excess of 7 ft, as shown in Fig. 26. The two curves intersect and therefore have a common point, whose approximate coordinates are: $Q = 540$ cu ft per sec and $d'_2 = 7.9$ ft. The two curves would be expected to merge into one beyond this point. Hence, this point would coincide with a break in the curves. Only the curve through points at which the roller was washed out of the basin for increasing flow is used. Points for d'_2-values, as plotted in Fig. 25, naturally fall on the curve for $d_1 = 1$ ft for a unit value of ϕ. It may be noted that, despite the d'_2-values so determined being considerably at variance with the d'_2-values from Eq. 30 for small values of Q $\left(\text{that is, } \frac{q^2}{g} \text{ and } H_0\right)$, they ap-



of Depths

proach each other with an increase in Q and H_0, and coincide for $d'_2 = 13$ ft±. Below this point the model tests indicate that a greater design depth is necessary; above this point a design depth equal to or smaller than that resulting from Eq. 30 is required.

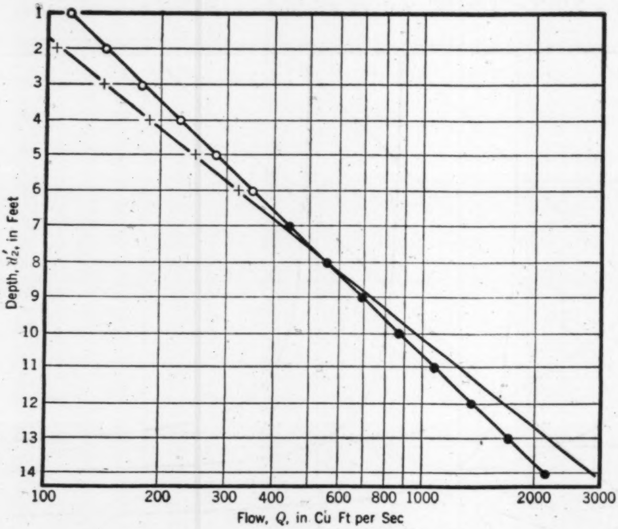


FIG. 26.—SEMILOGARITHMIC PLOT OF CURVES FROM FIG. 12

It is realized that the extrapolation of the curves in Fig. 12 is somewhat of a liberty in view of the author's statement that the roller could not be washed out of the stilling basin after the depth d'_2 had been increased to 7.20 ft, even for a discharge of nearly 600 cu ft per sec. For such a discharge ($Q = 598$ cu ft per sec; $\frac{q^2}{g} = 138$; and $H_0 = 70$ for $\phi = 1$), $d_2 = 16.1$ ft with close approximation, which is 223% of the depth d'_2 found necessary to maintain a roller. The total residual energy due to d_2 amounts to 16.37 ft; it amounts to 8.53 ft due to $d'_2 = 7.20$ ft. The initial total energy in both cases amounts to 70 ft.

The minimum residual energy would be due to the critical depth—

$$d_c = \sqrt[3]{\frac{q^2}{g}} \qquad (10)$$

—which establishes itself for $d'_2 = 2\,H$ in Eq. 30. However, the critical depth in the stilling basin is not compatible with its purpose, which is stilling action to minimize downstream scour.

A. J. PETERKA,[6] ASSOC. M. ASCE.—General studies of the type reported in this paper have been needed for some time. Designers in particular have seized every available scrap of information that would ease the problem of designing small stilling basins that will operate for the first time as prototype structures, or larger basins that will be submitted to a laboratory for refinement of features. Unfortunately, in most hydraulic laboratory investigations, it is not possible to concentrate on general solutions since funds are usually available only to solve the problems for a specific installation. Because of this situation only a limited amount of information is available for general solutions.

---

[6] Hydr. Engr., Bureau of Reclamation, U. S. Dept. of Interior, Denver, Colo.

The author is to be complimented for his approach to a problem that is difficult in many ways. His results, no doubt, will serve the purpose for which they were intended. However, there will be a tendency for designers to use this material for purposes beyond its range of reliability and the intent of this discussion is to indicate some of these limiting factors rather than to criticize, adversely, the excellent treatment given by the author.

The stilling basin operation, indicated by Fig. 6, appears to be greatly dependent on the chute blocks, baffle blocks, and end sill. It also appears that the configuration of the movable bed downstream from the apron had some effect in determining the length of the basin. Since at the start of each test the bed was molded above the elevation of the apron, there was probably some resistance offered to the flow that could favorably affect the performance of a short apron. Without a high bed, somewhat different action might take place, as the result of a different distribution of velocities.

The stilling basin profiles indicate that for L_B less than about 2 d_2 very little energy is dissipated on the apron. Thus, the basin becomes a distributor rather than a dissipator. The high-velocity flow entering the basin is deflected upward toward the surface, and the hydraulic jump acts merely to distribute the energy over a greater area with most of the dissipation occurring in the channel downstream from the apron. If the energy is not to be dissipated on the apron, the writer feels that it would be more economical to dispense with the apron accessories, consisting of chute blocks and baffle piers, and to adopt a curved deflector bucket to "throw" the water away from the structure. This method has been used successfully by others. A special application of this type of energy distributor was used successfully on the Fontana Dam spillway in the Tennessee Valley (35).

The advisability of relying primarily on such relatively fragile structures as chute blocks and baffle piers for satisfactory apron performance is questioned by the writer. If the prototype apron is submerged, as many of them are, underwater inspection and repair of blocks and piers are difficult. If the apron accessories should become damaged or lost, for any reason, the safety of the entire structure is endangered. As a precaution against undermining the apron, it might prove enlightening in future tests to determine the necessary depth of cutoff wall with some or all of the apron accessories removed. The resulting erosion pattern would also indicate the importance of keeping close watch on the condition of these same accessories if a deep cutoff wall is not used.

The main criterion for evaluating apron efficiency, during the author's tests, was the extent of the erosion in the model, and no mention of wave action below the apron is made. From Figs. 2(*a*) and 6, it appears that considerable wave action and resulting surface roughness occurred. The destructive effect of these waves is often as important as the scour of the channel bottom. If the basin discharged into an unlined canal or steep banked stream with soft or overhanging sides, some type of bank protection would be necessary. The prevalence of high surface velocities below the apron, if they existed, might also be of concern.

FIG. 27.—STILLING BASIN PROFILE, HORSETOOTH OUTLET WORKS

No mention was made by the author of any changes in the transition parabola during the tests and it is assumed that the same parabola was used throughout. During hydraulic model studies for Horsetooth Dam outlet works, in Colorado (Fig. 27), made in the Hydraulic Laboratory of the Bureau of Reclamation under the writer's supervision, it was found that the shape of the parabola had considerable effect on the stability of the hydraulic jump. Steeper slopes at the point of entry into the basin resulted in improved basin efficiency, lower waves in the downstream canal, and more uniform velocity distribution at the end of the basin as shown in Fig. 28. Apron accessories were not used in this stilling basin.

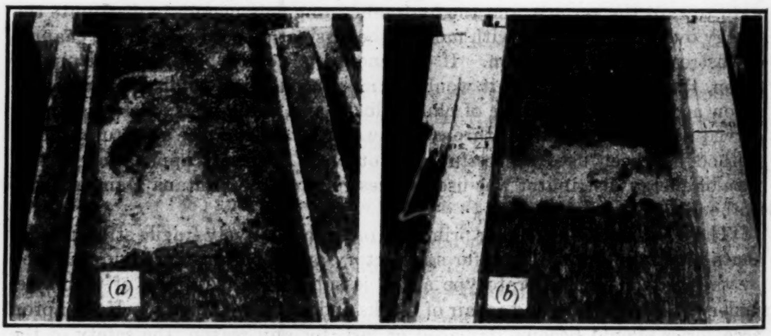

FIG. 28.—STILLING BASIN, HORSETOOTH OUTLET WORKS (SEE CURVES IN FIG. 27)

(a) Unsymmetrical Jump with Trajectory Curve No. 1
(b) Symmetrical Jump with Trajectory Curve No. 2

During tests, supervised by the writer, on the Enders Dam spillway, in Nebraska, which also makes use of a transition parabola (Fig. 29), the value of the proposed chute blocks, d_1 in height, was not readily apparent. Subsequent tests, and check tests, both with and without chute blocks indicated that, in this case at least, erosion was greater with the blocks in place. Removal of the blocks decreased the extent and depth of the erosion of the sand bed below the apron, as shown in Fig. 30. Furthermore, observations indicated no change in the appearance of the operation when the blocks were removed. Use of the blocks, however, did increase the amount that the tailwater elevation could be reduced without causing the jump to wash out of the apron. Finally, it was shown that the same range of useful tailwater could be produced by increasing the height of the dentated end sill from 9 ft to 12 ft, as shown in Fig. 29.

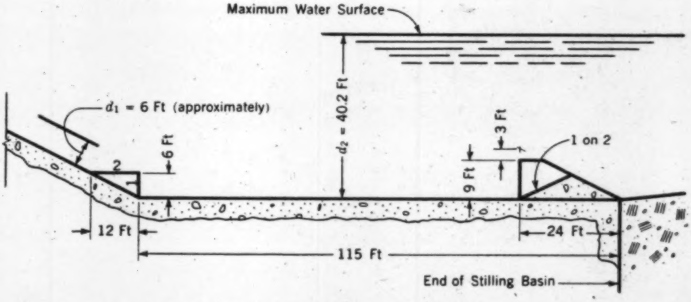

Fig. 29.—Stilling Basin Profile, Enders Spillway

The explanation of the action of these particular chute blocks, offered by the writer, is pure conjecture but may be of some value. Although the Enders spillway chute blocks were equal in height to d_1, as proposed by the author, they were not sufficiently tall. Because of the steep transition profile, the top length of the chute blocks was relatively short. Thus, the directional effect given to the water leaving the top surfaces was negligible, and the flow continued downward much as if the chute blocks were not in place. Had the stilling basin approach been flatter, the top length of the chute blocks would have been proportionately longer, giving greater directional effect to the water and inducing energy dissipating eddies to form. It appears that, if the transition profile is to be varied from one structure to another, the top length of the blocks is of greater importance than the block height.

The author's conclusions regarding the lateral spacing of the floor blocks are in good agreement with results of tests made by the writer on Kentucky Dam in the Tennessee Valley, and on some of the larger structures of the Bureau of Reclamation. A good over-all estimate for design purposes is 50%. Model tests of certain specific installations may show a need for increasing the block area more than 50% to provide flow stability on the apron, but this increase also produces a more concentrated boil. Reducing the block area substantially below 50% results in less turbulence but does not take full advantage of the possibilities.

The 45° wing wall shown by the author has also proved a satisfactory solution to a vexing problem. In most stilling basins the erosion below the downstream corners of the basin is somewhat greater than at any other location, because the downstream channel is wider than the stilling basin, creating a dead-water area at each side of the basin just beyond the end sill. The water leaving the end sill is directed upward, inducing a current from the dead-water area to

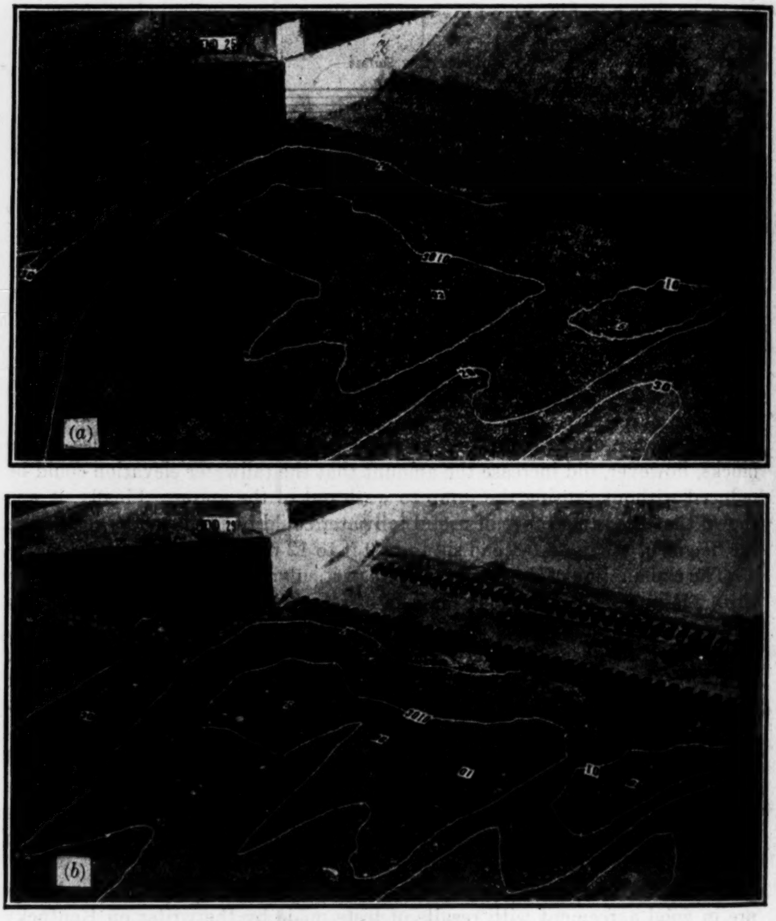

FIG. 30.—EFFECT OF CHUTE BLOCKS ON THE SCOURING BELOW THE SPILLWAY BASIN, ENDERS DAM (45° WING WALL)

(a) Blocks Removed
(b) Blocks Installed

flow laterally under the main flow as it leaves the end sill. This circulation results in excessive erosion at the apron corners even if surface velocities appear to be low. Addition of the 45° wing wall reduces the amount of circulation and the resulting erosion considerably, as shown by comparison of Figs. 30(*b*) and 31. If the dead-water area is large, or if it extends behind the wing wall, special treatment at the corners of the apron may be necessary.

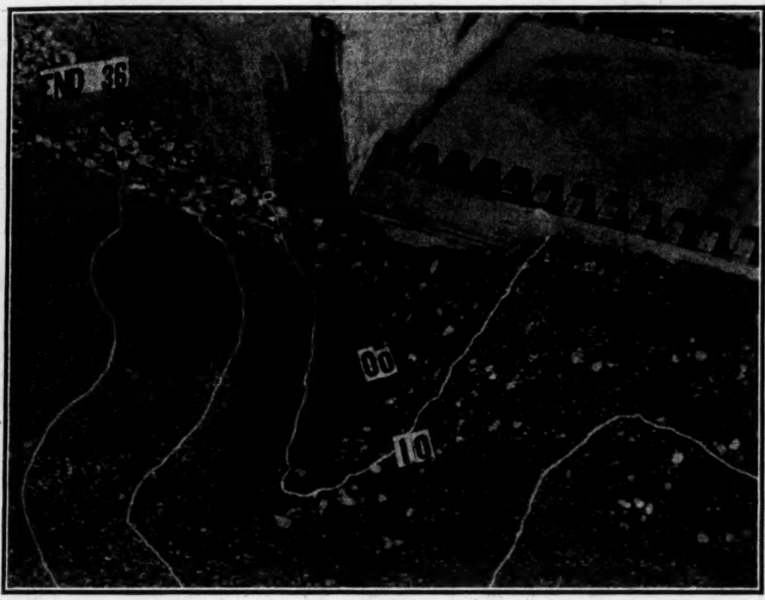

FIG. 31.—EROSION AT APRON CORNER WITH 90° WING WALL

Louis M. Laushey,[7] **Jun. ASCE.**—The results reported in this paper lead one step closer to the economical design of stilling basins. During 1946 and 1947 the writer conducted somewhat similar tests to determine the effects of a rectangular end sill on the hydraulic jump in a level, rectangular channel. Emphasis was concentrated on the tailwater depth required to form a jump, the proportioning of the height of sill, and the length of the basin required to accommodate the jump. It is interesting to compare the results of these tests with a rectangular end sill in a rectangular basin to those obtained on the Saint Anthony Falls (SAF) basin which uses both a sill and an array of blocks to dissipate the kinetic energy.

The tests on end sills of various heights were conducted in a level, steel flume 12 in. wide and 40 ft long. Water was circulated by a centrifugal pump, and was measured by a calibrated venturi meter. The depth of flow was con-

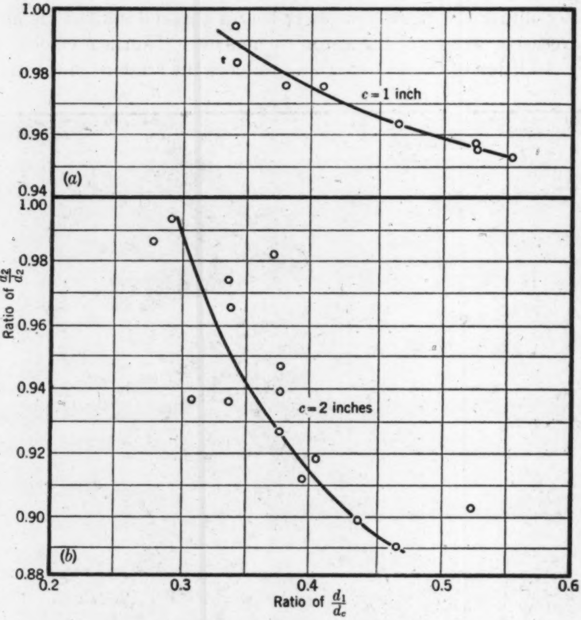

FIG. 32.—DIMENSIONLESS PLOT SHOWING TAILWATER DEPTH RATIOS AS A FUNCTION OF THE RATIO d_1/d_c FOR TYPICAL SILLS

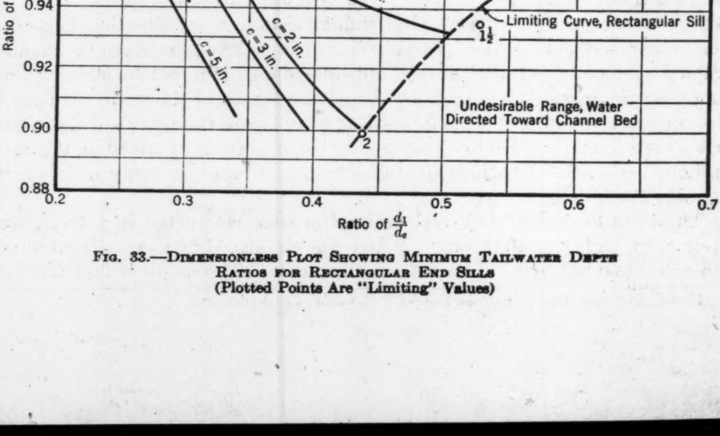

FIG. 33.—DIMENSIONLESS PLOT SHOWING MINIMUM TAILWATER DEPTH RATIOS FOR RECTANGULAR END SILLS (Plotted Points Are "Limiting" Values)

trolled at the upper end of the flume by raising or lowering a sluice gate hinged to a horizontal steel plate, 6 ft long, to guide the water parallel to the channel bottom. The jump was formed on the test section representing the apron, the downstream end of which was 8 ft from the outfall end of the flume. Sills were introduced at the end of the apron. Depths of flow were controlled by an adjustable tail gate at the end of the flume, and were measured in open manometers. Seven pressure openings were drilled at 2-ft intervals along the center line of the channel; four openings were on the apron, and three were downstream. The sills were made of $\frac{1}{4}$-in. steel plate, 12 in. long, with heights varying from $\frac{1}{2}$ in. to 5 in. The maximum dimensions of the flume in the reach below the jump were 12 in. wide, 20 in. deep, and 8 ft long.

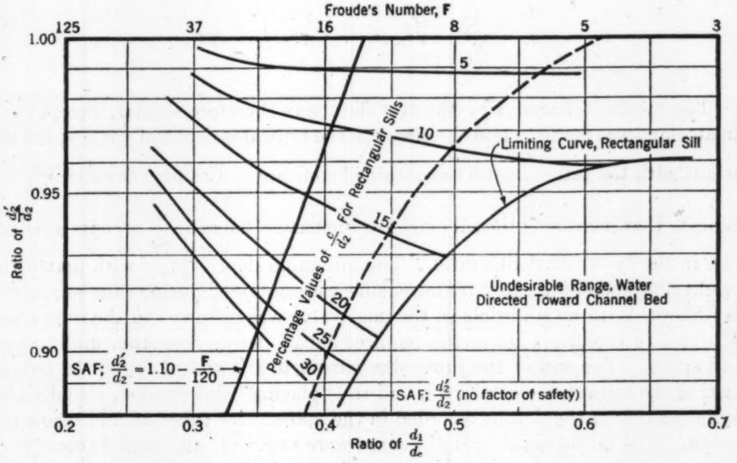

FIG. 34.—COMPARISON OF TAILWATER DEPTH RATIOS FOR THE SAF BASIN AND THE END SILL BASIN

Comparison of Tailwater Depths Required.—Results of the tests to determine the tailwater depth required for a jump in a basin with an end sill are shown in Figs. 32, 33, and 34. The curves in Fig. 32 are typical curves for sills 1 in. and 2 in. high, the points having been plotted to show the precision attained. The ordinates, values of $\frac{d'_2}{d_2}$, are the same ratios as those used in the SAF analysis, but the dimensionless ratio $\frac{d_1}{d_c}$ was chosen for the abscissa. This is the ratio of initial depth to critical depth before the jump, and it is helpful in visualizing the flow characteristics at the toe of the spillway. It is a function of the head on the dam and the height of the dam above the water surface on the apron. For example:

$$\frac{d_1}{d_c} = \frac{\dfrac{Q}{V_1}}{\dfrac{Q^{\frac{2}{3}}}{g^{\frac{1}{3}}}} = \frac{Q^{\frac{1}{3}}\, g^{\frac{1}{3}}}{V_1} = \frac{(32.2)^{\frac{1}{3}}\, C^{\frac{1}{3}}\, (H^{\frac{3}{2}})^{\frac{1}{3}}}{(64.4)^{\frac{1}{2}}\, (H + h)^{\frac{1}{2}}} = 0.396\, C^{\frac{1}{3}} \left(\frac{H}{h + H}\right)^{\frac{1}{2}} \quad \ldots\ldots(33)$$

In Eq. 33, C is the spillway coefficient of discharge; H is the head on the dam, in feet; and h is the height of crest above water surface on the apron, in feet. Eq. 33 has the following significance: (a) When $\frac{d_1}{d_c} = 1.0$, the flow is at critical depth and the height of the jump is zero; (b) when $\frac{d_1}{d_c} > 1.0$, flow is tranquil and no jump can form; and (c) when $\frac{d_1}{d_c}$ approaches zero, the height of the jump approaches infinity. However, it can be shown that $\frac{d_1}{d_c}$ is a function of the Froude number, which was used in the SAF tests, and is equal to:

$$\frac{d_1}{d_c} = \frac{d_1}{\frac{Q^{\frac{2}{3}}}{g^{\frac{1}{3}}}} = \frac{g^{\frac{1}{3}}\, d_1}{V^{\frac{2}{3}}{}_1\, d^{\frac{2}{3}}{}_1} = \left(\frac{g\, d_1}{V^2{}_1}\right)^{\frac{1}{3}} = \frac{1}{\mathbf{F}^{\frac{1}{3}}} \dots\dots\dots\dots\dots (34)$$

The method of analyzing the test data was therefore similar, except that an attempt was made to find the effect on the tailwater depth of varying the sill height with the ratio $\frac{d_1}{d_c}$ (or **F**) maintained constant. Results shown in Fig. 33 indicate that increasing the sill height or increasing the ratio $\frac{d_1}{d_c}$ permits a reduction in the tailwater depth ratio. The minimum depth ratios with maximum height sills, and depth ratios for lower sills, were obtained during runs conducted as follows: With no sill in place, the inlet valve was opened and the inlet plate adjusted to produce a jet of the required initial depth, free from undulations and spray. The end of the jump was moved to the end of the apron by adjusting the tailwater control gate, and the "placing" was checked visually and by inspection of the depths recorded in the manometer tubes on and below the apron. The initial depth and discharge were measured and used to compute a theoretical depth d_2 which had to check the observed depth at the end of the jump. Without changing the discharge and initial depth, sills of increasing height were placed, successively, at the end of the apron. The most accurate values of d'_2 were obtained by starting with too low a tailwater depth, and raising it slowly. When the water was too shallow, a frothy fringe of water formed just below the sill. This fringe moved upstream as the tailwater was raised, and disappeared when all depths downstream from the sill were the same. When the tail gate was raised too far, the jump moved upstream on the apron.

Fig. 34 shows the comparison of the limiting curve of tailwater depth ratios to that proposed for the SAF basin. The variable ratio $\frac{c}{d_2}$ is the parameter linking the main variables $\frac{d'_2}{d_2}$ and $\frac{d_1}{d_c}$, whereas this parameter has been made equal to 0.07 in the SAF basin. The ratios $\frac{c}{d_2 - d_1}$, $\frac{c}{d'_2 - d_1}$, $\frac{c}{\frac{V^2{}_1}{2g}}$, and $\frac{c}{d'_2}$ were also tried to reduce the scatter resulting in the plot, but without profit. To obtain a comparison, the actual test points (without a factor of safety) from the SAF data in Fig. 11 were plotted as well as Eq. 6*b*. Results are in close agreement for the two basins, although the height of the rectangular sill for a given value of **F** would produce variable results.

Comparison of Height of End Sill.—Fig. 34 shows that, as the Froude number is increased, sills larger than 0.07 d_2 can be used safely without blocks in a rectangular basin. From Table 4 of the SAF tests, best results were obtained at $\mathbf{F} = 40$ with $\frac{c}{d_2} = 0.15$. The ratio of $\frac{d'_2}{d_2}$ for this sill height would be about 0.97 in the end sill basin, which is much higher than the value of 0.85 recommended for the SAF basin. However, the difference might be explained by the effectiveness of the blocks at the higher Froude numbers.

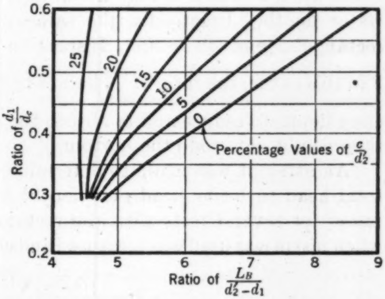

FIG. 35.—LENGTH OF JUMP TO HEIGHT OF JUMP RATIOS FOR RECTANGULAR END SILLS

The maximum height of end sill that could be used safely was obtained by increasing the height of sill, with the discharge and initial depth constant, until sufficient height was reached to make the sill begin to act as a control. The limit was reached when all depths downstream could not be made the same because of the drop down curve, which indicated water was directed toward the bottom.

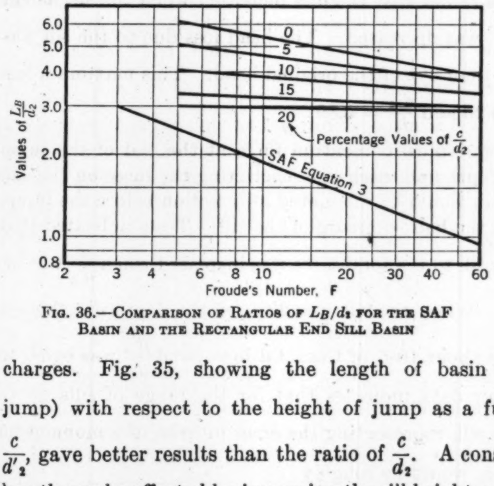

FIG. 36.—COMPARISON OF RATIOS OF L_B/d_2 FOR THE SAF BASIN AND THE RECTANGULAR END SILL BASIN

Comparison of Length of Basin.—The difficulty of expressing the basin length as a function of d_2 for all values of **F** was mentioned by the author when $L_B = 1.25$ d_2 gave results too short for small discharges and too long for higher discharges. Fig. 35, showing the length of basin (taken equal to length of jump) with respect to the height of jump as a function of $\frac{d_1}{d_c}$ (and **F**) and $\frac{c}{d'_2}$, gave better results than the ratio of $\frac{c}{d_2}$. A considerable reduction in basin length can be effected by increasing the sill height, using Figs. 35 and 36. This condition is especially true at the low Froude numbers where an almost 50%

reduction is possible because of the sill. Referring to Fig. 36, the SAF basin requires considerably less length, although with high rectangular end sills the lengths become more nearly the same. Floor and chute blocks therefore appear to be effective devices in reducing the length of jump.

Other Comparisons.—It was noted during the rectangular end sill tests that a boil formed over the sill for ratios of $\frac{d_1}{d_c} \leqq 0.32$ (equivalent to $\mathbf{F} \geqq 30$). This is interesting because in the SAF basin the roller was washed out of the stilling basin when $\mathbf{F}$ was less than about 30. The solution was to increase the tailwater depth. Practically the same procedure had to be followed for the rectangular end sill basin. Inspection of Fig. 34 shows that, with values of $\mathbf{F}$ in this range, the ratio of $\frac{d'_2}{d_2}$ had to be increased to almost unity to create sufficient depth to reduce and to absorb the downward velocity components so that they would not erode the bottom.

An attempt was made to determine the head loss created by the sill. The total head (velocity head plus depth) at the initial and final depths was computed for several tests with the rectangular sill. The head loss in the jump when no sill was used was measured and checked by the Stevens equation (36)(37),

$$i = \frac{6.25\,(\sqrt{1 + 16\,r} - 3)^3}{(1 + r)\,(\sqrt{1 + 16\,r} - 1)} \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

in which i is the percentage of original head lost in the jump; and r is the ratio of velocity head to depth before the jump. The difference between the measured loss with a sill and that without a sill was expressed as a ratio of the original total head. It was found that the loss increased when the sill height was increased and when $\frac{d'_2}{d_2}$ was decreased. The head loss due to the sill was small, and was never more than 6% of the original head. This maximum loss was obtained when $\frac{c}{d'_2} = 0.25$ and $\frac{d'_2}{d_2} = 0.89$.

Calculation of the pressure-plus-momentum force at the end of the jump from the measured initial depth and discharge, neglecting the force on the sill, will give a smaller value than would be calculated at a section before the jump. The difference results from the back pressure of the sill. Tests indicated that the ratio of the force on the sill to the total force was increased when $\frac{c}{d'_2}$ was increased and $\frac{d'_2}{d_2}$ decreased. When the sill was 20% of the depth d'_2, the apparent force on the sill was about 10% of the total force, and $\frac{d'_2}{d_2}$ was equal to 0.90. Analysis of the other data indicates that for the range of sills up to $\frac{c}{d'_2} = 0.25$ the force on the sill, representing the error in using the momentum equation without correction, would be roughly

$$(P + M)_e = \left(1 - \frac{d'_2}{d_2}\right)(P + M)_1 \ldots\ldots\ldots\ldots\ldots (36)$$

in which $(P + M)_s$ is the force on the sill, in pounds; and $(P + M)_1$ is the pressure plus momentum force before the jump, in pounds.

The author is correct in stating that the SAF basin can be built shorter than the rectangular end sill type. For values of Froude numbers up to $\mathbf{F} = 30$, little difference seems to exist in the tailwater depth required for a jump. The indication is, however, that for the higher Froude numbers and the low tailwater depths, with a height of sill that would ordinarily be used, the rectangular basin would be inferior to one designed according to the SAF dimensions.

J. H. Douma,[8] Assoc. M. ASCE.—Although the detailed data and rules presented are for the design of stilling basins for small drop and spillway structures (used principally by the Soil Conservation Service of the United States Department of Agriculture in its soil and water conservation program), much of the author's discussion and some results of the Saint Anthony Falls (SAF) stilling basin tests are applicable to large stilling basins for flood-control and multiple-purpose projects.

In this discussion the author's data will be compared to model studies conducted in 1939 by the writer at the hydraulic laboratory of the Bureau of Reclamation, United States Department of the Interior. Hereinafter, these studies are called the USBR tests. The tests were conducted for the purpose of developing the rectangular stilling basin referred to in the paper and described by Jacob E. Warnock, M. ASCE (4). Comparisons also will be made with the current practice in stilling basin design for flood-control and multiple-purpose projects. The USBR tests are reported in an unpublished memorandum from the writer to the chief designing engineer of the Bureau of Reclamation on the subject, "Model Study of Wickiup Dam Outlet Works, Deschutes Project, Oregon," dated June 30, 1939.

The author has chosen to relate stilling basin dimensions to the hydraulic jump by means of the d_2-depth and a dimensionless term, $\frac{V^2_1}{g\,d_1}$, corresponding to the high-velocity flow at the stilling basin entrance. In the USBR studies, expressions were developed for stilling basin dimensions solely in terms of d_2. Others have expressed stilling basin dimensions in terms of either the height of jump,

$$d_j = d_2 - d_1 \qquad (37)$$

or the ratio,

$$J = d_2/d_1 \qquad (38)$$

As J. C. Stevens, Past-President, ASCE, has pointed out (15c), there are only two independent characteristics of the hydraulic jump—the initial depth, d_1, and the velocity, V_1—at the stilling basin entrance. From them are derived the initial energy head, the final depth, the final velocity, and the final energy head, as well as the lost energy head, the empirical characteristic length of jump, and the Froude number corresponding to the initial depth and velocity.

---

[8] Senior Hydr. Engr., Office, Chf. of Engrs., Washington, D. C.

All forms of the published formulas for stilling basin dimensions are functions of the two independent characteristics of the hydraulic jump; therefore, equally satisfactory criteria for the dimensions of a stilling basin could be obtained by use of any one of the forms, provided that appropriate constants were determined to reflect the various stilling basin conditions and the desired degrees of energy dissipation. For example, the variation of stilling basin lengths, as computed from published formulas, reflects the widely varying conditions. This results from the differences in the profiles of individual stilling basins, the relation of the provided tailwater depth to the d_2-depth required by momentum relations, and the ability of the foundation to withstand erosion downstream from the individual stilling basins. The nature of the stilling basin, whether for normal or emergency operation, and whether isolated or adjacent to a main structure, as well as the conception and judgment of the designer, also has some bearing on the final choice of stilling basin dimensions.

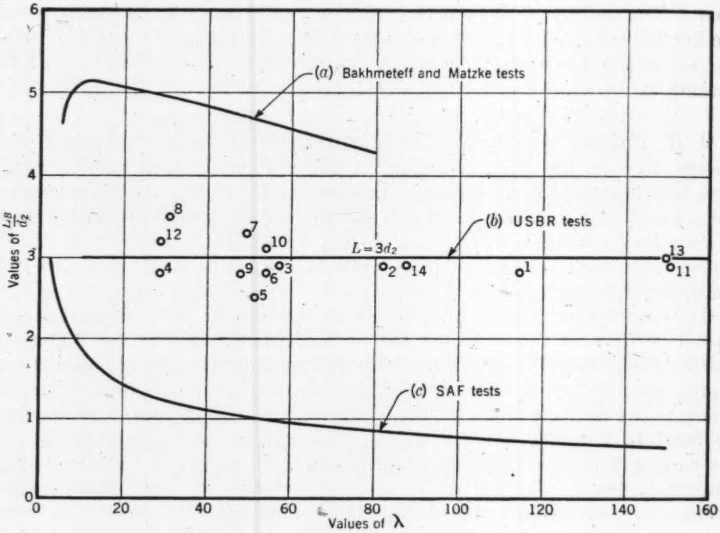

Fig. 37.—Comparison of Stilling Basin Test Results

In Fig. 37, the author's suggested curve for stilling basin length is compared to the design and model data available to the writer, as well as to the curve of B. A. Bakhmeteff, Hon. M. ASCE, and A. E. Matzke, Assoc. M. ASCE, for the length of hydraulic jump (15*d*). The criterion for stilling basin length,

$$L_B = 3\,d_2 \qquad (39)$$

which was developed by the USBR tests, is also shown in Fig. 37. Points 1 to 14, inclusive, are for stilling basins of the flood-control and multiple-purpose dams listed in Table 11. These stilling basins are of the horizontal-apron type with baffle blocks and end sills. All have been model tested for satisfactory operation under maximum design conditions. Those that have been constructed in prototype have operated in a fully satisfactory manner within the ranges of experienced discharge.

Although the definition of the Froude number given by Eq. 1*a* is frequently used in the literature, the more convenient and usual form is

$$\mathbf{F} = \frac{V_1}{\sqrt{g\, d_1}} \qquad (40)$$

The term $\frac{V^2_1}{g\, d_1}$ is generally called the kinetic flow factor, λ. However, because λ is an appropriate dynamic characteristic of the Froude type, it may be used as a parameter in the dimensionless representation of stilling basin length.

The Bakhmeteff and Matzke curve for the length of hydraulic jump is based on the formation of the jump on a horizontal apron without baffle blocks or an end sill. This curve may be used for determining stilling basin lengths for those high dams in which baffle blocks are not used (because of the possible destruction of the blocks by cavitation), and in which unfavorable downstream channel conditions make it desirable to include the entire length of the jump in the stilling basin.

From Fig. 37, it may be concluded that for flood-control and multiple-purpose dams: (1) Baffle blocks and an end sill reduce considerably the required length of a stilling basin; (2) Eq. 39 is a satisfactory criterion for stilling basin length when baffle blocks and an end sill are used; and (3) the SAF stilling basin curve indicates stilling basin lengths dangerously short for the usual case of an erodible downstream channel.

The criterion, Eq. 39, is confirmed by Fig. 6 in which water-surface profiles show that the hydraulic jump is completely contained in a horizontal stilling basin whose length is approximately equal to 3 d_2. For shorter lengths, the crest of the jump occurs beyond the end of the stilling basin. Unless the stilling basin is located in a canyon composed of good rock, maintenance costs to provide protection against violent wave action (which occurs at the crest of the jump and for some distance downstream) may greatly exceed the additional cost of providing a stilling basin of adequate length. Since stilling basins for soil conservation structures are usually located in erodible material, it is questionable whether the short stilling basins given by the SAF curve would provide adequate protection for these structures.

The USBR tests included a test series similar to those made for the SAF stilling basin to determine the optimum size, spacing, and location of chute blocks, baffle blocks, and end sill. In general, the data obtained for the USBR tests are in agreement with the data for the SAF tests. One important difference, however, is the location of the baffle blocks; in the USBR studies it was concluded that the baffle blocks should be located $\frac{2}{3} L_B$ from the upstream end of the stilling basin to minimize cavitation possibilities. Tests on the longer USBR basin did not indicate that locating the baffle blocks $\frac{1}{3} L_B$ from the upstream end of the basin would improve the basin performance, as was the case for the shorter SAF basin.

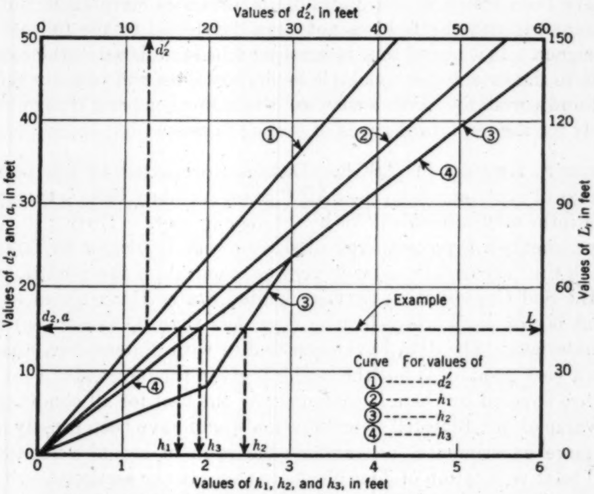
Design curves for stilling basin dimensions, based on the USBR tests, are presented in Fig. 38. In more recent plans chute blocks have not been used when V_1 is in the cavitation range, in which case two rows of baffle blocks are frequently used to obtain the desired energy dissipation.

The 15% reduction in d_2, to obtain d'_2, as given by Eq. 6*a*, was first suggested by the writer on the basis of the USBR tests. Subsequent model tests conducted by the United States Waterways Experiment Station at Vicksburg, Miss., and at the Bonneville (Ore.) and Los Angeles (Calif.) hydraulic laboratories of the Corps of Engineers, United States Army, have confirmed satisfactory stilling action for a 15% reduction in tailwater depth. In recent plans the practice of the Corps of Engineers has been to provide a tailwater depth equal to 0.9 d_2.

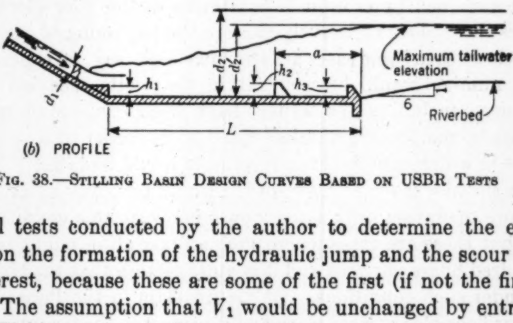
The USBR tests indicated, as did the SAF tests, that d'_2 could be reduced to about 0.75 d_2 before the jump would be swept out of the stilling basin. Thus, a design tailwater depth equal to 0.9 d_2 would provide a reasonable safety factor against excessive negative pressures on baffle blocks, against severe wave action downstream from the stilling basin, and against the jump sweeping out of the stilling basin because of unanticipated lowering of the tailwater.

Eq. 7, for stilling basin freeboard, is somewhat too conservative for flood-control and multiple-purpose dams. Usually, it is considered unnecessary to confine the maximum splash in stilling basins for those dams, because the infrequent occurrence and short duration of maximum discharge would not result in appreciable damage. Freeboard above the maximum tailwater level, equal to from 0.25 d_2 to 0.2 d_2, usually is considered ample protection for the stilling basin and the adjacent structures.

Model tests conducted at the United States Waterways Experiment Station at Vicksburg, Miss., for several large stilling basins showed that quadrant wing walls (located downstream from the end sill) most effectively reduce scour at the end of the stilling basin side walls. However, quadrant wing walls are more costly than perpendicular or 45° angle wing walls. Thus, quadrant wing walls should be used only when it is desirable to provide maximum protection against scour.



(a) DIMENSION CURVES



(b) PROFILE

FIG. 38.—STILLING BASIN DESIGN CURVES BASED ON USBR TESTS

The model tests conducted by the author to determine the effect of air entrainment on the formation of the hydraulic jump and the scour pattern are of special interest, because these are some of the first (if not the first) tests of this nature. The assumption that V_1 would be unchanged by entrained air is questioned. Field tests by the Bureau of Reclamation in 1938 on the Kittitas chute on the Yakima project in Washington indicated that the measured velocity of the water-air mixture was substantially less than the computed theoretical velocity based on Manning's formula. Field measurements on a wasteway at the Rutz Works in Austria, which were published by R. Ehrenberger in 1926 (38) clearly indicated the frictional effect of aeration by rapid increases in depth with sudden increases in chute slope. If air entrainment results in an added friction loss, then V_1 and d_1 at the entrance of large stilling basins would be somewhat smaller and larger, respectively, than theoretical values—thus requiring a smaller d_2-depth for the formation of the hydraulic jump. In that case significant savings might be affected in stilling basin dimensions.

Mr. Blaisdell presents a useful set of design rules for the SAF-type stilling basin. However, hydraulic design engineers should proceed with caution in applying these rules to other types of stilling basins. Many types of stilling basins have been tested in the hydraulic laboratories since 1930, but general design equations and charts have not been developed to the full satisfaction of the designer. It is hoped that interest may be stimulated in the engineering profession to the extent that available model test data will be more thoroughly analyzed and correlated, with a view to establishing general design equations and charts for the important types of stilling basins.

ROBERT F. EWALD,[9] M. ASCE.—Data are presented, in this paper, from a wide range of experiments on the SAF ("Saint Anthony Falls") type of stilling basin in a form very convenient for hydraulic engineers. During the course of these experiments a type of energy dissipator was developed for falling water that has all the "earmarks" of being very economical for the conditions usually met by the Soil Conservation Service, United States Department of Agriculture—that is, for moderate velocities (say, less than 50 ft per sec) on easily eroded materials. The data have been tied in with dimensionless parameters (which is a very good idea) but the reader is given the impression that the type of structure covered by them is economically the best for all conditions.

The value of Mr. Blaisdell's contribution would have been greatly improved by one more experimental parameter—the ratio of actual velocities at the preferred relative location of floor blocks to those in the section d_1. That ratio may set up limitations to the use of the SAF design in certain locations, the limits being governed by erosion or cavitation of the floor blocks. The SAF design places these blocks relatively close to the beginning of the jump in areas where the velocities in some cases are still very high (say, 50 ft per sec) although the Froude number would be well within the limits specified in the paper. Some designers, including the writer, have been confronted with situations where factors in the Froude number were on the order of $v_1 = 125$ ft per sec and $d_1 = 3$—in which case the Froude number would be 172±. The prototype velocities at the blocks for an SAF design would certainly exceed 60 ft per sec. In a structure operating only a few hours per year this condition should not be serious, but there are cases where such an operation might be expected for several hundred hours per year and it is quite certain that the blocks would not stand up under such conditions. At Gatun Dam in the Panama Canal Zone where similar floor blocks were placed with respect to the beginning of the jump, much as proposed in the SAF design, many of the blocks were destroyed within a few years. At Grand Coulee Dam in Washington the upcurved part of the bucket apparently is located at about the same relative position with respect to the jump; and, after less than 10 years of operation, this part of the structure required redesign when it was reconstructed because of the great erosive action.

The writer became interested in the subject of erosion at the toe of high overfall dams early in 1913 and in the fall of that year began a long series of tests on models of a proposed dam on the Little Tennessee River near the mouth of the Cheoah River in North Carolina. This dam was to be nearly 200 ft high and was to provide for possible maximum floods of 160,000 cu ft per sec with a net spillway crest length of about 600 ft. (The dam was actually completed 6 years later.)

---

[9] Pittsburgh, Pa.

The model tests very soon indicated the great significance of the hydraulic jump in the erosion problem and the fact that the design should fundamentally be based on the performance of the jump. As part of this investigation a series of tests was made using staggered baffle piers with a height equal to d_1 at the beginning of the jump, on the theory that these piers would materially reduce the pool depth required to bring the jump to the bucket (34*b*). Although the tests were rather crude, they indicated clearly that the amount of energy absorbed by impact and turbulence at the piers was so small, relative to the absorption inherent in the jump, as to be unimportant, and that the piers were undesirable in view of the difficulties at Gatun Dam which were then being discussed. The tests also indicated that the erosion accompanying the unmodified jump would never be structurally serious because of the highly resistant character of the material on which the dam was to be built and that nature would ultimately form an adequate cushion pool.

At the time the Cheoah Dam tests were made, the literature on the jump available in the United States was limited to a few lines by the late Mansfield Merriman, M. ASCE (39), based on an erroneous derivation of the formula. The derivation by William C. Unwin (40), of course, has been known for some years, but was not likely to be noticed by engineers. The literature on the subject now covers thousands of pages and the subject apparently has not yet been exhausted. Mr. Blaisdell's paper, for example, may lead to modifications of the jump formula to cover the conditions inherent in the SAF design.

FRED W. BLAISDELL,[10] ASSOC. M. ASCE.—The thoughtful and constructively critical comments of the discussers are evidence that the writer's aim of presenting the results of the SAF (Saint Anthony Falls) stilling basin investigation in such a way that each reader could independently evaluate and intelligently discuss the design rules developed therefrom was achieved. The discussions could not have been prepared without the expenditure of considerable time and effort, and the writer wishes to acknowledge this work and to express his sincere appreciation of the contributions of the discussers. They have materially increased the value of the paper to the engineering profession.

Of considerable interest are the energy losses and relationships in the hydraulic jump and stilling basin computed by Mr. Blotcky and summarized in Table 10. The proportion of the energy at Section 1, Fig. 18, that is lost in the hydraulic jump is least at small values of $\mathbf{F}_1$ (15*e*). This may be why the blocks are most effective at low values of $\mathbf{F}_1$, as Mr. Blotcky has noted. However, Col. 9, Table 10, and the results of the original tests as recalled by the writer seem to indicate that the energy loss ascribed to the blocks is far less than is warranted by their importance. For example, in Table 10 the median value of ϵ_b/ϵ_j is 0.11. For this value of ϵ_b/ϵ_j the energy loss due to the blocks alone is only 6% of the energy at Section 1, Fig. 18. Since the reduction in basin length achieved through the use of blocks and sills is in the order of 75%, it may be that the blocks have some function other than the dissipation of energy. However, it is probable that the location of Section 2′, as assumed by Mr. Blotcky, is incorrect. At the end of the SAF basin the depth of flow is increased by the boil and decreased by the end sill. Furthermore, the streamlines have considerable curvature at this point, and, as a result of the surface roller, there may be upstream components of the velocity at this section (see Fig. 1(*b*)). An additional reason why the location of Section 2′, Fig. 18(*b*), is incorrect is the fact that some energy dissipation occurs downstream from the end of the basin. Section 2′ should be selected at some point in the downstream channel. The writer has no data to indicate the depths and velocities at a point where normal flow conditions have been established in the downstream channel. In the absence of this information, Mr. Blotcky's computations summarized in Table 10 are accepted for their relative value.

---

[10] Project Supervisor, U. S. Dept. of Agriculture, SCS, St. Anthony Falls Hydr. Laboratory, Minneapolis, Minn.

These comments regarding Section 2′ also apply to the coefficient of form drag (C_d) computations summarized in Fig. 23. Although the magnitudes of C_d shown in Fig. 23 are probably inaccurate, Mr. Blotcky is to be commended for his most interesting analysis in which he introduces the effect of the floor blocks into the momentum equation for the hydraulic jump.

The use of blocks certainly modifies Eqs. 2, but there is some question as to whether or not their use invalidates it completely, as Mr. Blotcky maintains. In fact, in commenting on Fig. 21 he notes that certain ratios computed for the block jump "are comparable to those in a hydraulic jump * * *."

In view of Eq. 9 and of Mr. Blotcky's pertinent comments, it would seem that the use of d_c, in place of d_2 as used by the writer, is a matter of personal preference. The use of d_c was considered, but this parameter was not adopted because of the facts expressed in Eq. 9 and because its use would require the computation of an additional parameter when designing the SAF basin, without any apparent advantage being gained thereby.

In Fig. 19 Mr. Blotcky has used d_c as a parameter when replotting some of the data presented in Table 2 and Fig. 7. Through the data points he has drawn the curve represented by Eq. 11. The relationship between d_c and d_2 embodied in the hydraulic jump equation makes it difficult to compare mathematically Eq. 11 with Eq. 3. It is, however, possible to express Eq. 11 in terms of d_1. Substituting for q^2 in Eq. 10 its equivalent, $\mathbf{F}_1\, g\, d_1\, d^2{}_1$,

$$d_c = \sqrt[3]{\mathbf{F}_1\, g\, d_1\, d^2{}_1/g} = \sqrt[3]{d^3{}_1\, \mathbf{F}_1} = d_1\, (\mathbf{F}_1)^{0.33} \qquad (41)$$

Substituting Eq. 41 in Eq. 11,

$$\frac{L_B}{d_1\, (\mathbf{F}_1)^{0.33}} = \frac{6.2}{(\mathbf{F}_1)^{0.25}} \qquad (42)$$

or

$$\frac{L_B}{d_1} = 6.2\, (\mathbf{F}_1)^{0.08} \qquad (43)$$

B. A. Bakhmeteff, Hon. M. ASCE, and A. E. Matzke, Assoc. M. ASCE (15*f*), have shown that the relationship L/d_1 between the length of the hydraulic jump, L, and d_1 varies considerably with λ, or $\mathbf{F}_1$ as it is designated by the writer, whereas the ratio L/d_2 is approximately constant. Inasmuch as the action in the SAF stilling basin is considered to be a forced hydraulic jump and the basin length is related to the jump length, the writer prefers the ratio L/d_2.

Mr. Blotcky attempts to compare Eqs. 11 and 3 in Fig. 19. The writer strongly objects to this comparison. The comparison should be between the curve and its pertinent data, which are given for Eq. 3 in Fig. 7 and for Eq. 11 in Fig. 19. The writer has computed L_B by Eqs. 3 and 11 and has tabulated the results in Table 12, using tests selected from Table 6. The values of L_B listed in Table 6 were those used in the tests. These values have been recomputed by inserting in Eq. 3 the observed values of d_1, d_2, and $\mathbf{F}_1$, which differed slightly from values used in the design of the model. It will be noted in every case except two that L_B is shorter when computed by Eq. 11 than when Eq. 3 is used. In some cases the computed basin length is 20% shorter. This difference is great enough to make the use of Eq. 11 inadvisable. Although based on the same data, Eq. 3 has been thoroughly checked by model tests and its use is to be preferred.

On the basis of Fig. 20, the writer agrees with Mr. Blotcky that the form of Eq. 18 is more desirable than that of Eqs. 6. However, most of the data presented in Fig. 11 are not included in Fig. 20. The writer has recomputed the data shown in Fig. 11 and summarized them in Table 13. These data are plotted in Fig. 39, in which the curve shown has the equation:

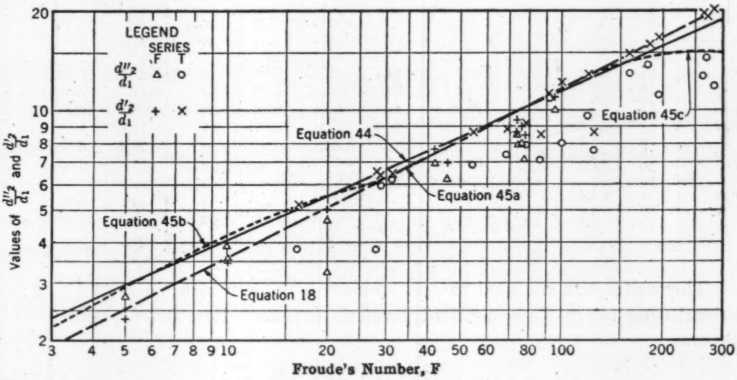


FIG. 39.—DIMENSIONLESS PLOT SHOWING TAILWATER DEPTH AS A FUNCTION OF THE FROUDE NUMBER

$$\frac{d'_2}{d_1} = 1.4\ (\mathbf{F}_1)^{0.45} \qquad (44)$$

Eq. 18 is also shown to permit comparison. The writer considers that Eq. 44, which is based on better data than is Eq. 18, is to be preferred, but that either Eqs. 6 or Eq. 44 will give good results. This contribution by Mr. Blotcky simplifies the design of the SAF stilling basin and is greatly appreciated by the writer. Mr. Blotcky's significant contribution in this instance shows the value of publishing papers in *Proceedings* where they may receive the consulting services of the entire membership of the Society.

The writer has changed the parameters of Eqs. 6 into those of Eq. 44 by substituting for d_2 its equivalent given in Eq. 2*b*. Eqs. 6*a*, 6*b*, and 6*c* then become

$$\frac{d'_2}{d_1} = 0.425\left(-1 + \sqrt{8\,F_1 + 1}\right) \qquad (45a)$$

$$\frac{d'_2}{d_1} = \left(-1 + \sqrt{8\,F_1 + 1}\right)\left(0.55 - \frac{F_1}{240}\right) \qquad (45b)$$

and

$$\frac{d'_2}{d_1} = \left(-1 + \sqrt{8\,F_1 + 1}\right)\left(0.50 - \frac{F_1}{1{,}600}\right) \qquad (45c)$$

respectively. Eqs. 45 have been plotted in Fig. 39 to permit their comparison with Eq. 44.

The writer cannot agree with Mr. Blotcky that the undular type of jump occurs in the block jump simply because d'_2/d_2 is greater than one for small values of F_1. It is the recollection of the writer that the roller associated with the direct jump occurred at all values of $\mathbf{F}_1$ at which tests were made. Because a slope exists at the entrance to the SAF stilling basin, it is believed that increasing d'_2/d_2 is conducive to causing the entering stream to plunge under the tailwater, as it does for the direct jump, rather than to ride at the tailwater surface as it does for the undular jump. In any event, it is difficult to follow Mr. Blotcky's reasoning as to why Eq. 18 is invalid when $\mathbf{F}_1$ is less than 15. The writer feels that the form of Eq. 18 is excellent and represents the complete data at all values of $\mathbf{F}_1$, but that the constants used in Eq. 44 are to be preferred.

Mr. Culp followed closely the model studies leading to the development of the SAF stilling basin design and contributed freely from his experience in the design and construction of soil conservation structures. In matters regarding the feasibility of certain hydraulic features from the viewpoint of the structural designer and construction engineer, his advice was frequently sought, freely given, and invariably followed. It is a pleasure to be able to acknowledge his contribution publicly. Under the direction of Edwin Freyburger, chief of the Soil Conservation Service regional engineering division in Milwaukee, Wis., Mr. Culp designed the first SAF stilling basin before the final report was prepared. Since then he has designed and built several others. It was hoped that he would be able to report on some structures that had been tested by nature at about the design flow. However, since his discussion was written, the Stuart Perry spillway located in Crawford County, Iowa, has received a severe test. Fig. 40 shows a view of this structure taken prior to the storm described in a letter from Mr. Culp, who obtained his information from Floyd Nimmo, construction engineer on the job.

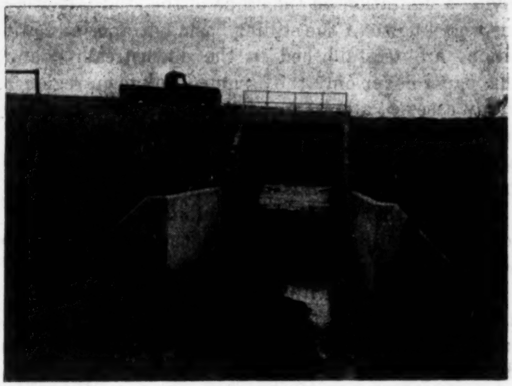

FIG. 40.—STUART PERRY SPILLWAY, CRAWFORD COUNTY, IOWA, PRIOR TO STORM OF JUNE 22, 1947

> "The storm occurred June 22, 1947, between 4:00 p.m. and 6:00 p.m. with most of the rainfall in the first hour. No standard or automatic gauges were in the vicinity, but rough measurements in buckets, etc. indicated a total rainfall of about seven inches. This storm produced a maximum head on the inlet of the spillway of almost four feet, or nearly a foot more than the design head. Hence, even though the inlet was somewhat re-

> stricted by poor placement of the earth fill * * * the flow through the spillway was probably equal to or greater than the design discharge [more than 50% in excess of the design discharge, assuming a 3 ft design head, a 4 ft actual head and unrestricted approach to the inlet]. * * * Mr. Nimmo tells me that the outlet functioned perfectly and that there was very little erosion in the immediate vicinity of the outlet."

Fig. 41 shows views of this structure taken on February 18, 1948. It is apparent that very little scour occurred as a result of the flood of June 22, 1947. The writer has seen three additional outlets which he has every reason to believe have passed heavy flows. These apparently functioned as anticipated, although the downstream channels had not eroded to a stable grade at two of the outlets when the writer saw them in 1945.

Mr. Baumann believes that it would have been helpful to include information regarding the energy gradient between the reservoir and the stilling basin. The SAF stilling basin will be used with drop inlet culverts as well as with overflow spillways. A different value of the coefficient ϕ would have to be determined, not only for each type of structure, but also for each size of structure.[9] To provide a limitation on the scope of the study, it was assumed that flow conditions were known at the stilling basin entrance and at a point where normal conditions are reestablished in the downstream channel; the tests reported in this paper cover only the assumed unknown region between these points. In many cases ϕ, a measure of the lumped-together losses up to the basin entrance, can be computed with sufficient precision from information presently available to the designer. High precision is unnecessary in designing a SAF stilling basin. This comment is no argument for sloppy work, but is rather a recognition of the fact that the magnitude of many of the factors involved can be determined only roughly. The foremost of these factors is probably the rate of runoff on which all subsequent design depends. It is certainly very difficult to determine the rate of runoff with any high degree of precision.

Mr. Baumann's attempt to determine d'_2 from a consideration of the amount of kinetic energy transformed into heat energy is most interesting, but it appears that additional work is required before this method can be used without resort to model studies. However, any attempt to develop an equation from theoretical considerations is always commendable and leads to a better understanding of the problem.

The writer shares most of the views expressed by Mr. Peterka. His comments are a welcome addition to the paper. Nevertheless, the writer cannot agree with Mr. Peterka's comment that the chute blocks and floor blocks of the SAF stilling basin can be dispensed with. It is true that much of the energy dissipation takes place in the channel downstream from the stilling basin. It is also true that the SAF stilling basin throws water upward and away from the structure as does the Fontana Dam (Tennessee Valley) energy dissipator, but the water does not reach a height sufficient to create spray except at the surface under some conditions. The action is such that energy dissipation beyond the basin exit takes place principally near the water surface, as at Fontana Dam, rather than at the bed. However, some energy is dissipated within the SAF basin, in contrast to the Fontana Dam distributor where all energy dissipation takes place beyond the deflector bucket. At high values of **F** a bucket could be used in place of the SAF stilling basin, but at low values of **F** there is insufficient energy available to throw the jet into the air. The writer feels that there is a need for both types of energy dissipator but that the "apron accessories" are required and are economical in the SAF design.

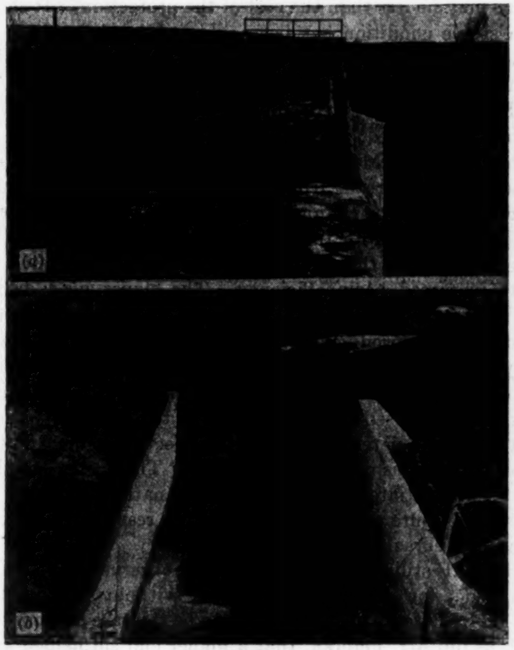

FIG. 41.—STUART PERRY SPILLWAY ON FEBRUARY 18, 1948
(*a*) Upstream View (Compare with Fig. 40)
(*b*) Downstream View; Bank Scour Occurred Before Spillway was Built

Mr. Peterka voices a common objection to blocks and piers, and the writer feels somewhat the same. It is significant, however, that piers are used almost invariably when the problem of energy dissipation is particularly difficult, or when the cost must be kept at a minimum. Such considerations were uppermost in the minds of those engaged in developing the SAF design.

Whether or not special protection from wave action is required in the downstream channel depends to some extent on the frequency with which the design flow is expected and on the duration of such flow. Little wave action was apparent in the models until the discharge approached the design value. At lesser discharges the surface disturbance might be described as "ripples." For soil conservation structures the commonly used design storm has an anticipated 50-yr frequency. For small watersheds the design flow occurs for only a few hours at a time. Under these conditions vegetation is undoubtedly sufficient to protect the banks. The writer shares Mr. Peterka's opinion that for structures subjected to the design flow for long periods, some bank protection from waves will probably be required. Whether it is more expensive to provide bank protection from wave wash for maximum flows or to use a larger basin, as suggested by Mr. Douma, is a problem that the designer of each structure must solve. In many cases the value of the land protected by riprap or other methods may be less than the cost of the protection. It should be noted that, after a stable condition has been achieved in an erodible channel, the normal channel is wider at the basin exit than it is farther downstream. This phenomenon should be taken into consideration if bank protection is used. Otherwise the bank protection would be subject to excessive velocities and might possibly be damaged.

The writer feels that Mr. Peterka need not be concerned about the high surface velocities downstream from the apron. Since the highest velocities are on the center line of the channel and are near the surface, it is not believed that protection is required for this reason alone.

Mr. Peterka suggests that steeper slopes at the basin entrance probably contribute to increased basin efficiency. The slopes used during the SAF tests varied from 1 on 2.6 to 1 on 1.5. In the SAF basin, however, the chute and floor blocks aid in producing a uniform velocity distribution at the basin exit and may offset the poorer results obtained by Mr. Peterka for the Horsetooth Dam outlet works in Colorado when the entering slope was decreased.

The range of slopes used at the entrances to the SAF stilling basin models is too narrow to permit a determination of the effect of changes in the transition profile on the proportions of the chute blocks. The writer can therefore offer no evidence to substantiate or to refute the explanation offered by Mr. Peterka, which he based on "pure conjecture" and on the results of tests on the Enders Dam spillway in Nebraska.

During the SAF stilling basin tests, it was observed that the use of chute blocks permitted a lowering of the tailwater without washing the jump out of the basin. Mr. Peterka also found this to be the case at Enders Dam. The writer found, as did Mr. Peterka, that a higher end sill helped keep the jump in the basin. However, the SAF end sill is subjected to higher velocities than is the Enders Dam sill; its height has a greater effect on the flow; and the end sill could not be raised without greatly increasing the boil height, which would necessitate raising the side walls. All these considerations were kept in mind when it was finally decided that the best solution for the SAF stilling basin was to leave the chute blocks in place and to determine the best end sill height for the assumed form of the stilling basin.

In Fig. 34 Mr. Laushey has attempted to compare d'_2/d_2 for the SAF stilling basin with certain results he obtained. The writer feels that there is only one point of comparison—at the intersection of Eq. 6*b* and Mr. Laushey's curve for $d'_2/d_2 = 0.07$. This intersection indicates only the Froude number (or d_1/d_c) at which the two basins have the same tailwater depth. The limiting curves labeled "SAF; d'_2/d_2 (no factor of safety)" and "limiting curve, rectangular sill" are not based on the same criteria and are therefore not comparable.

The writer does not believe that the height of the end sill in the two types of stilling basin can be compared as Mr. Laushey has done. Fairly high velocities existed at the end sill in the SAF basin, whereas in Mr. Laushey's basin the velocities were, without doubt, comparatively much lower. In the second place, the SAF basin is much shorter. These considerations and others, in addition to the effect of the blocks mentioned by Mr. Laushey, undoubtedly contribute to the differences in the recommended values of d'_2/d_2.

Mr. Laushey's curve for zero end sill height (Fig. 36) gives a basin length at variance with the length of jump determined by Messrs. Bakhmeteff and Matzke. Fig. 36 does, however, give an excellent picture of the basin length reduction that can be achieved through the use of sills, and also clearly shows the further reduction made possible by the block arrangement of the SAF stilling basin.

Mr. Laushey notes that in the SAF stilling basin the tailwater depth had to be increased at values of $\mathbf{F}_1$ less than 30, and states that a similar increase was required for the end sill basin. However, it can be seen in Fig. 34 that for a constant end sill height the relative tailwater depth is increased with increasing values of the Froude number for the end sill basin. Just the opposite is the case for the SAF basin, where Fig. 11 shows that the relative tailwater depth is increased with decreasing values of $\mathbf{F}_1$ when $\mathbf{F}_1$ is less than 30.

The results presented by Mr. Laushey are most interesting and valuable. Rather than deprecate his results, the writer has attempted to show that the proper magnitudes of the parameters are so dependent on the type of basin under consideration that it is not possible to make a valid comparison between many of the common elements making up these two types of basin. In this the writer agrees with Mr. Douma's statement, "* * * hydraulic design engineers should proceed with caution in applying these rules to other types of stilling basins." Mr. Peterka also has expressed somewhat the same thought in his discussion.

Mr. Douma objects to the writer's definition of $\mathbf{F}_1$ and prefers λ. There are three reasons why the writer defined $\mathbf{F}_1$ by Eq. 1*a*: First, he learned it that way; second, it has direct physical significance, because it represents the ratio of the force required to overcome inertia to the force of gravity; and, third, this definition is used (41*a*) in ASCE *Manual of Engineering Practice No. 25*. Many persons use the form preferred by Mr. Douma. However, when writing in an ASCE publication, the writer feels a certain obligation to use the form approved by the Society.

Mr. Douma concludes from Fig. 37 that Eq. 39 is a satisfactory criterion for the stilling basin length when blocks and an end sill are used. The writer agrees with this statement as it applies to the United States Bureau of Reclamation (USBR) tests. He cannot, however, agree that curve (*c*) in Fig. 37 in itself indicates that the SAF stilling basin is too short. In the first place, Mr. Douma presents neither data nor arguments to support his statement. Furthermore, the USBR data cannot alone be used to discredit another stilling basin design based on probably as thorough and exhausting study as was the USBR design. The writer went to great length in his paper to show that the SAF stilling basin gave entirely satisfactory results "for the usual case of an erodible downstream channel," and it can be stated that the SAF stilling basin, like the USBR basin, has given satisfactory service under field conditions.

The writer feels that generalized results of tests made at public expense should be made available to the public. This is one reason why he offered the SAF results for publication; and, for this reason also, it is well that Mr. Douma has presented the design criteria for the USBR stilling basin.

It should be noted that the boil in the SAF basin rises above normal tailwater level (in contrast to larger basins where the velocity at the floor blocks is lower). Therefore, the freeboard normally used by designers should be figured from the top of the boil rather than from the tailwater surface. With this fact in mind, the freeboard proposed by Mr. Douma is in reasonable agreement with that proposed by the writer. Spray will probably go over the top of the SAF basin walls at the design flow, but masses of water, which the writer associates with splash, should not.

Mr. Douma feels that the velocity in open channels with entrained air is less than that of a corresponding nonaerated flow computed by the accepted formulas. He bases his statement on the results obtained by R. Ehrenberger (38) and on field tests made by the Bureau of Reclamation. Offsetting these results are those reported by the late L. Standish Hall, M. ASCE (11), who finds that the velocity increases when air is entrained. The most recent, and undoubtedly the most accurate, series of tests to come to the attention of the writer are those reported by Warren W. DeLapp (42). From a large number of carefully performed experiments in a 1-ft-wide channel having three different roughnesses, Mr. DeLapp shows that, for all practical purposes, normal values of Manning's *n* can be used when computing flows with entrained air. He concludes that the velocities with and without air entrainment will be approximately the same. However, the depth of the flow will increase with air entrainment as a result of the greater volume rate of flow. In view of Mr. DeLapp's results and the conflicting results obtained by others, the writer's assumption of identical velocities without and with air entrainment does not seem unreasonable.

Mr. Ewald has called attention to one feature of the SAF stilling basin on which the experiments are incomplete: No observations were made of the velocities or pressures at the blocks. It is true that the velocities at the floor blocks are high and that cavitation may be expected if they are high enough. Until additional data become available, the designer should proceed with caution whenever he suspects that the velocities at the floor blocks will be such that cavitation can be expected.

After the turbine room tests had been completed, the basin for test T63 was left in place and operated intermittently for purposes of demonstration over a period of 2 years. When the basin was removed, scour was observed on the wood floor in the vicinity of the floor blocks. A view of this scour is shown in Fig. 42. The erosion around the blocks was the only scour noted, its maximum depth being 0.03 in.

Mr. Ewald feels that little energy is absorbed by the floor blocks and bases his opinion on tests performed in 1914 and 1915. He tried blocks only at the beginning and at the end of the hydraulic jump, and in his words (34*b*), "* * * the middle * * * was completely neglected." The best location for the floor blocks is probably somewhere between the ends of the jump. If Mr. Ewald had located the blocks in this region, it is probable that his present opinion would be somewhat revised. Certainly, the reduction in size of the SAF stilling basin could not have been achieved without the use of baffles and sills.

During the analysis of the SAF stilling basin data, it was noted that a significant reduction in basin size could be obtained for a given discharge if **F** could be increased. Because of this discovery, a method of increasing **F** was sought; and, as a result, a study of expanding transitions in high-velocity flows was initiated. This study, which is incomplete in January, 1948, was based on the initial assumption that the velocity would be unchanged along the transition, but that the depth of flow would be decreased. This decrease in depth causes an increase in **F**. The results to date (43) indicate that over-all savings up to 50% in concrete volume and 20% in excavation may be obtained through the use of a transition. This saving cannot ordinarily be accomplished at overflow dams, but it is possible when chutes or culverts are used. The use of a SAF stilling basin in conjunction with a transition may, under optimum conditions, result in a structure only one eighth as large as a comparable hydraulic jump stilling basin. This claim may seem to be fantastic and it may seem impossible to achieve a safe outlet structure of this size. The writer will not attempt to prove his contention here, but suggests that any person interested make the computations himself, and, if he doubts the adequacy of his design, subject it to verification by model tests.

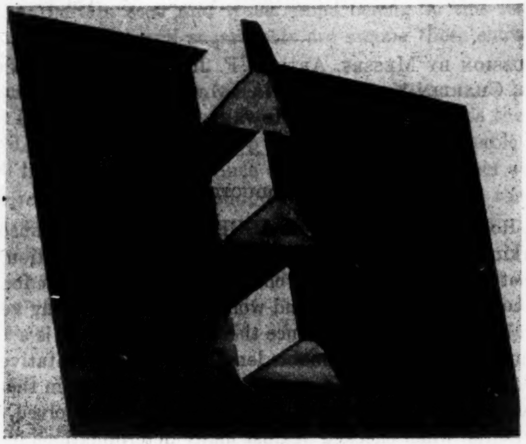

FIG. 42.—SCOUR AROUND FLOOR BLOCKS

The writer may have given the impression, as interpreted by Mr. Ewald, that the SAF stilling basin is economically the best for all conditions. If he has, he wishes emphatically to correct that impression. There are many locations where other types of outlet structure should be used. The writer is confident, however, that the SAF stilling basin can compete with alternate types of outlet which might be used in similar locations.

FORECASTING PRODUCTIVITY OF IRRIGABLE LANDS

BY W. C. MULDROW,[1] ASSOC. M. ASCE

WITH DISCUSSION BY MESSRS. ARTHUR F. JOHNSON, H. W. VAN LOO, WILL H. NOBLE, CHARLES KIRBY FOX, M. R. LEWIS, HARRY F. BLANEY, R. L. PARSHALL, AND HOWARD N. MAGNESS.

INTRODUCTION

In 1941, Robert L. Lowry, Jr., M. ASCE, and Arthur F. Johnson, Assoc. M. ASCE, working with the United States Bureau of Reclamation, produced a heat-unit method of estimating the consumptive use of water for agriculture.[2] The writer considers this a sound and workable method, giving very consistent results from long-term records. Since the only requirement is a United States Weather Bureau record of reasonable length in, or representative of, the area under consideration, the method may be applied anywhere in the western part of the United States. The formula is easily and simply resolved, and the very consistent results, when checked against many determinations by other methods, give an accuracy satisfactory for use in preliminary estimates. As shown by J. L. Burkholder,[3] M. ASCE, in his discussion of the Lowry-Johnson paper, the line produced is the median of a band covering the range of divergence of individual years from the average.

The question of feasibility is always before the engineer on a proposed irrigation project, and feasibility is determined by the ratio between cost and returns. The three indispensable elements of a feasible project are soil, water, and climate. If an irrigable area has fertile soils, a water supply adequate to the production of full crops, and a growing season adapted to the cultivation of a pattern of profitable crops, it probably can afford a project with a relatively high per-acre price. The costs are determined by well-known engineering methods of survey and estimate. For the other side of the equation the irrigation engineer must solve the question: "What will be the returns?"

NOTE.—Published in February, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[3] *Ibid.*, p. 1287

A wide variety of factors affect the crop patterns used in various irrigated communities. Accessibility to markets is an important one. Others are crop pests and diseases, the basic limitations of many crops as to their tolerance of heat and cold, etc. It is generally true that fruit and truck crops, which are most desirable in building up a diet of high nutritional value: (1) Require a long season with abundant heat units to produce high yields; (2) are high-value crops, resulting in the highest per-acre incomes where they can be grown; and (3) are also high-cost crops. Since the production of these crops uses many man-hours of labor, the farm operator is not overjoyed; but this feature is desirable in a national economy where the greatest problem ahead is to provide sufficient work for all. There are also many specialty crops which are sharply limited by their very narrow environmental adaptation. Apples, citrus fruits, peppermint, and certain seed and truck crops belong to this list. Alfalfa, potatoes, the small grains, and sugar beets are among those showing a very wide range of adaptability.

With all these and many other variations in crop patterns, it is submitted that the most important attribute differentiating farm lands is the volume of crops produced. Within the same crop pattern the most valuable and profitable lands will be those able to produce the greatest tonnage per acre. From a broad water-resource planning standpoint, it is also desirable that available water be used where it will do the most good—that is, where an acre-foot of water will produce the greatest amount of crop.

A simple extension of the heat-unit method from consumptive use of water to tonnage of crop produced will provide a method of estimating the productivity of lands on a proposed project. The writer submits Fig. 1 for this purpose.

GRAPH

The original Lowry-Johnson consumptive use curve[4] is shown in Fig. 1 with the consumptive use points of representative localities in the irrigated west superposed. These points range from the Valley of Henry's Fork, Upper Snake River, El. 6500, down by steps to Pasco, Wash., at the junction of the Snake and Columbia rivers, then to the Sacramento Valley and on down to the Imperial Valley in California, near sea level. This range, in available heat units (accumulated day degrees above 32° F), is from 4,300 to 20,000. Alfalfa is grown more universally than any other crop on these irrigated lands. In the Pacific Northwest it occupies from 35% to 60% of the acreage on nearly all projects, and is grown on substantial areas of lands in every locality shown in Fig. 1. The reason, of course, is its ability to gather nitrogen from the air in addition to its forage value. Another crop that is grown throughout this area in considerable amounts is Irish potatoes.

The acre yields used were taken from the 1940 Census,[5] where the statistics are presented by counties. The points shown in Fig. 1 were limited to localities where crops were grown in acreages large enough to give a dependable average.

---

[4] "Consumptive Use of Water for Agriculture," by Robert L. Lowry, Jr., and Arthur F. Johnson, *Transactions*, ASCE, Vol. 107, 1942, p. 1252, Fig. 2.

[5] 1940 Census, Section on Agriculture, Mountain and Pacific States, Vol. 1, Pt. 6.

Two or more counties were usually added together to give coverage for the locality, and the average was taken. Some checking was done through the limited amount of crop census data available to the writer from the records of projects of the United States Bureau of Reclamation. The annual crop census taken by the Bureau on all projects forms the most accurate and detailed body of crop data known to the writer. Some highly interesting and valuable conclusions can be drawn from this thorough analysis. Neither time nor comprehensive data were available to make a detailed and exhaustive study, yet it is felt that the material used is sufficient to place the yield lines shown with a fair degree of accuracy. About 2,000,000 acres of alfalfa are represented by these lines. A new irrigation project, wherever located, may be spotted on this chart by picking its total available heat units from the appropriate Weather Bureau record, and its relative productivity may be read from the yield lines. Also, the relative efficiency in the use of water may be noted from the top curve, "Consumptive Use per Ton of Alfalfa." The values are naturally those for average soils producing alfalfa in each region.

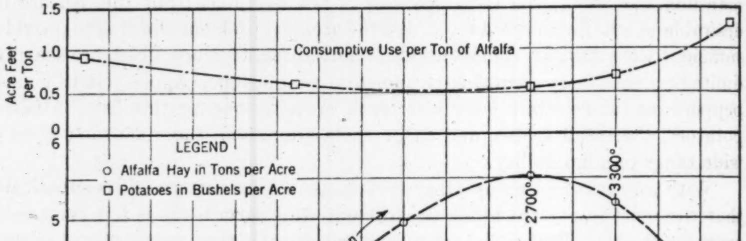

FIG. 1.—CROP YIELDS AS RELATED TO AVAILABLE HEAT UNITS AND CONSUMPTIVE USE OF WATER

It will be noted that, from Henry's Fork down to the Columbia River and Yakima Valley, the heat-unit yield relationship is a straight line, amounting to some 2,400 day degrees per ton. Practically this same value holds good in the Sacramento Valley in California; but, progressing south, into longer and hotter seasons, with more heat units, it appears that the weather becomes too hot for the crop to make effective use of all the heat available. These are questions of plant metabolism, which differs with each species. Thus the yield decreases and the consumption of water per ton increases. The writer was quite surprised by the record in the Imperial Valley in California, where alfalfa grows every month in the year and the farmers harvest eight cuttings; yet the census shows that Imperial County had 114,146 acres of alfalfa in 1939 and that the average yield was 2.99 tons per acre. Other crop yield lines show similar characteristics. The writer traced several, but omitted them from Fig. 1 for simplicity.

It is unfortunate that some common denominator cannot be found, like total digestive nutrients, into which all the crops can be converted for any typical valley pattern; but the problem is not that simple. It is impossible directly to compare the apple orchards on the rolling hillsides of Wenatchee, Wash., with the forage and general crops of a flat and spring-frosty near-by area that may have the same total of heat units. In Yakima Valley, the Parker Heights area might produce the same tonnage of hay, potatoes, and sugar beets as do the bottom lands across the river; but the Heights also produces peaches, cherries, and pears worth several times as much per acre, because they are frost free. There are similar cases in the southwest, where citrus fruits, olives, and avocados occupy limited areas, usually the rolling foothills, while the wide plains below them are devoted to dairy and general farm crops. Imperial Valley does not grow alfalfa to make money, but rather to restore nitrogen and humus to the soils. These elements are later taken out by crops of early-season lettuce, cantaloupes, etc., which sell for many dollars per acre.

Messrs. Lowry and Johnson emphasize that their consumptive-use-of-water curve is not a simple and automatic method of solving the problem but that a full knowledge of all modifying factors is needed to develop good judgment in its use, if the best results are to be obtained. This limitation is even more true with the crop prediction method presented in this paper, although it does offer a quick way to find the relative productivity, quite closely, in terms of ordinary general crop patterns. Also, the upper curve of consumptive use per ton undoubtedly gives a relative measure of efficiency in the use of water for any given crop pattern; but a wide and thorough knowledge of agronomy and of agricultural values in the region under consideration is needed to convert that information into terms of dollars per acre, possible or probable. Irrigation engineers must have practical data to determine the question of project feasibility.

It is recognized that the crop-yield lines are only the median lines of a band, as yields are influenced in some degree by soil fertility, pests, winds, farm methods, etc. Average soil fertility has probably the greatest influence. Klamath Falls, Ore., shows a higher potato yield than Buhl, Idaho, probably because potatoes are grown on newer and richer lands. The richness of the soil solution determines the number of pounds of water a plant must drink to obtain a pound of plant food. Since plant food comes from the breakdown of extremely fine soil particles, the amount of plant food available in any soil, above the clay line, is roughly proportional to the percentage of fines in that soil. Because the alluvial soils of the Columbia River system were formed by degradation, the coarser particles stopping first and the finer particles being carried farther downstream, it is not surprising to find this steady increase in fertility reflected in that part of this curve. In Washington the Walla Walla-Lower Yakima lands have a mean diversion duty of about 4 acre-ft; the Henry's Fork lands average 8 acre-ft; and the Lower Yakima lands consume little more than half as much water to produce a ton of alfalfa as do the Henry's Fork lands. The rise in use per ton in the hotter regions must be ascribed mainly to increased unavoidable ground evaporation which forms part of valley consumptive use. If a proposed project is restricted to high-grade lands, the yields will be greater than those read from Fig. 1, which are drawn from average lands.

SUMMARY

This paper is submitted as a first step toward establishing a set of relationships which clearly exist and which may furnish a worthwhile tool in planning the integrated groups of irrigation and multipurpose projects that will make the best use of land and water resources along the west coast region of the United States. It is hoped that workers in this field will test it by additional data, use their knowledge and experience to correct and refine it, and so make these basic relationships as useful as possible in solving practical problems.

It is not to be expected that this method will serve as an easy substitute for detailed economic studies, in which the agricultural history of near-by and comparable developed areas is used to predict production on the project in question. The method will serve as a check on the validity of the areas selected for comparison and as an indicator of reasonable adjustments where exact parallel conditions cannot be found.

DISCUSSION

Arthur F. Johnson,[6] Assoc. M. ASCE.—An ingenious method of estimating average crop yields from the relation of such yields to available heat in day degrees Fahrenheit using the method for computing available heat presented by Robert L. Lowry, Jr., M. ASCE, and the writer[2] is suggested by the author. The method will be useful for reconnaissance studies where data on crop yields under irrigation are not readily available. It is not sufficiently reliable to serve as a close criterion of project feasibility. As the author wisely states, the method is more limited in estimating productivity than in estimating consumptive use of water due to the greater number of factors contributing to the variability of the results.

The author has confined his treatment to individual crops but has related yields to the average available heat rather than to individual effective heat values for each crop as suggested by C. R. Hedke,[7] M. ASCE. Somewhat more reliable results might be expected by developing separate curves using appropriate temperature bases for each crop.

The yield curves for both alfalfa and potatoes (Fig. 1) are surprisingly well supported by the plotted points representing the areas studied. The marked drop in yield beyond optimum heat conditions is characteristic of most crops. Alfalfa grows continuously where temperatures do not drop below freezing but in the Imperial Valley (California) and in other areas of extremely high sustained summer temperatures its growth is inhibited during the hottest part of the season and it becomes almost dormant. The growing season for potatoes, on the other hand, is comparatively short and it is actually possible to produce two crops in a single year although this would not be an acceptable practice because of the drain on soil fertility and risk of fostering potato diseases. It is presumed that the potato curve in Fig. 1 applies to a single planting so that materially higher total yields might be expected if repeated crops in the same year were included where climatic conditions permit. Nevertheless, as the limit of tolerance to heat is approached, yields may be expected to fall off to a negligible amount.

In Fig. 1, the curve "Consumptive Use per Ton of Alfalfa" was evidently derived by dividing values on the curve "Consumptive Use of Water—Valley Average" by corresponding points on the alfalfa yield curve. This procedure is not proper because the curve of average valley consumptive use represents a composite of consumptive use requirements for crop distributions typical of each heat condition. The percentage of alfalfa is not the same throughout the range of the consumptive use curve but rises from zero in frosty mountain meadows to a maximum and then drops with increasing heat. The percentage of alfalfa is high for the Snake River Valley (Idaho) but is relatively low for the Mesilla Valley (New Mexico) where cotton is "king." Therefore, the derived curve is somewhat lower than would be the case with true values of consumptive use of alfalfa, and the error increases in some degree with increasing heat as alfalfa is a relatively higher consumer of water than the average crop distribution which the Lowry-Johnson curve represents.

[7] "Consumptive Use of Water by Crops," by C. R. Hedke, New Mexico Engr.'s Office, July, 1924 (unpublished).

H. W. Van Loo,[8] Jun. ASCE.—The heat-unit method of estimating the consumptive use of water for agriculture extended to provide a method of estimating the productivity of lands on a proposed project may provide a very satisfactory system of forecasting the returns to any proposed development. However, the relatively low yield of alfalfa in the Imperial Valley (California), about which the late Mr. Muldrow expressed surprise, may not be entirely justifiable.

TABLE 1.—Annual Yield of Alfalfa, in Tons (Total) and Tons per Acre (Unit), for Coachella Valley, California

Year	Acreage	Total yield	Unit yield
1939..........	1,276	5,104	4.0
1940..........	1,400	9,100	6.5
1941..........	1,600	12,000	7.5
1942..........	1,100	5,500	5.0
1943..........	1,310	9,170	7.0
1944..........	1,243	8,079	6.5
1945..........	1,541	7,705	5.0
1946..........	1,741	12,187	7.0
Average.....	...	...	(6.1)

Although the writer does not propose to question the total yield of alfalfa shown for Imperial Valley, there may have been some misinterpretation of conditions. In a region such as Imperial Valley where alfalfa is used on considerable acreage for rejuvenation of the soil, the total yield cannot be divided by the total acreage under cultivation, since the total acreage is not always producing alfalfa during an entire year. A second factor that may have affected the results is that a considerable part of the total acreage is used for pasturing various kinds of livestock. For instance, range cattle may be purchased in Arizona, shipped to Imperial Valley, and fattened on alfalfa. More than likely the acreage used for pasturing has been included in the total acreage since some cutting of alfalfa is usually made, but no correction has been made for the decreased cuttings of alfalfa.

As supporting data for the contention that some error has been made, Table 1 shows the yield of alfalfa for near-by Coachella Valley which is about sixty miles north of Imperial Valley and has nearly identical weather conditions.

The average yield of 6.1 tons of alfalfa per acre for Coachella Valley is about twice as high as the 2.99 tons shown for Imperial Valley. Possibly, the light sandy soils which predominate in Coachella Valley plus the generally well-drained farm lands would account for some of the difference. Whatever the reason for the discrepancy, it is suggested that further examination be made of the yield of crops grown in the warmer sections of the United States.

Will H. Noble,[9] Assoc. M. ASCE.—The law of a heat-productivity relation is set forth admirably in this paper. Perhaps the popular concept that water makes the crop should give way to a concept of heat as the productive agent, with commensurate water an adjunct. The author's demonstrated heat-productivity relation is one of a succession of relations applying to the actual problem of economic feasibility, namely: (1) Water requirement varies with heat, (2) crop production varies with heat, (3) crop value varies with production, hence with heat, and (4) economic feasibility is a function of crop value, hence a function of heat. If procedure toward item (4) is necessarily by way of item (2), the methods of finding the (2) relation should be explored for possible improvement and standardization.

---

[8] Civ. Engr., Coachella, Calif.

[9] State Center, Iowa.

For instance, the heat-productivity relations studied and graphed for the paper appear to be based on the 1940 Census; that is, on 1939 crops, and (presumably)1939 seasonal heat. Since economic feasibility rests on a balance of average annual costs versus average net returns, ratios of average yield to average seasonal heat are required. A compilation of average heat-yield relations for the commonly irrigated crops, with probable deviations from such averages, and a recording of the most favorable heat range for each crop, would be a valuable addition to engineering statistics. It could be based on the United States Weather Bureau value for normal mean monthly temperatures above 32° F, and the annual reports of crop yields and values on United States Bureau of Reclamation projects, as far as they have been published. These crop reports cover existing projects in a block of fifteen states extending eastward from the Pacific coast to include North Dakota, South Dakota, Nebraska, Colorado, New Mexico, and Texas on the east. Deductions from so great a range of data should be of general application in any part of the United States where irrigation may be practiced or proposed. This is true whether the proposal is purely for irrigation or is a multiple-purpose project with irrigation one of a number of interests.

The widely accepted Lowry-Johnson system of heat units, in day degrees of maximum temperatures above 32° F, has quite naturally been used by the author. This system was evolved for solving the heat versus consumptive-use-of-water relation, closely akin to evaporation. For this purpose, use of the maximum daily temperature was found to give a closer correlation than was found with average daily temperature. Unless a similarly superior correlation is found for the heat versus productivity relation by use of the maximum temperatures, it would appear a simpler and more practical procedure to refer directly to the normal mean monthly temperatures of the Weather Bureau's annual summaries, and to arrive directly at the normal seasonal heat in degree months. In this case, the productivity season would naturally terminate with the average date of first killing fall frost.

Since heat determines yield, and yield determines crop value per acre, should there not be a definite heat versus value-per-acre relation? Increased heat means larger crops, or a greater number of crops per season, or higher value crops, all of which mean more dollars per acre, for more heat per acre. Project income is a composite income from a diversity of crops whose seasonal heat ranges include the seasonal heat of the particular project. Must the engineer determine probable yield and price for each crop, then assume some pattern of crop diversity, and so estimate the composite crop value; or does nature itself determine the diversity largely through the available heat? Can a heat versus crop-value graph be drawn that will give the desired preliminary estimate of farm income? The writer's study of Bureau of Reclamation crop statistics for the decade from 1921 to 1930, inclusive (the most stable decade of reclamation history as to commodity prices and construction costs), indicates that such a relation may be definitely charted, with correlations that favorably compare with those for the heat-productivity relation. If so, such a chart or graph should be a logical sequence to the main argument of the paper. For its application, the general price structure would need to be projected forward to the years of construction and operation of the project under consideration; but this must be done whether prices are to be applied item by item, or as a composite per-acre figure.

This discussion is intended to imply acceptance and appreciation of the paper, and a desire to see the idea extended and put into most usable forms. Whatever the form in which it is expressed, the author's well-worded caution against undue reliance on the average ratios found will be applicable. The individual irrigator may not safely assume that his own farm will live up (or down) to the project average income per acre; nor can the irrigation engineer assume that his own project will be an average one. That point he must determine by more particular investigation.

CHARLES KIRBY FOX,[10] M. ASCE.—The question at the end of the second paragraph of this paper—"What will be the returns" [of an irrigation project]? —is timely and shows that engineers are becoming more "cost conscious."

Two aspects of the paper, however, are open to serious discussion, namely: (1) The use of 32° F as a base and (2) the adoption of a range of available heat units in terms of thousands of degree-days above 32° F. Most plants begin growing when the mean temperatures reach from 42° F to 48° F. Since the rate of growth at temperatures lower than 50° F is slow, a mean monthly temperature of 50° F is a logical base. It is an easy base for computation purposes and is readily correlated with data issued by the United States Weather Bureau. The use of thousands of degrees per day above 32° F would complicate computations considerably. Elsewhere the writer has called attention to the advisability of using the 50° F base.[11]

The late Mr. Muldrow is correct in his observation that some plants cease to grow when the weather becomes too warm.

Closely allied to the question of growing temperatures are the following six factors: (*a*) The soils; (*b*) the quantity of water used: (*c*) the character of the water; (*d*) the transportation facilities; (*e*) the value of fluctuating dollar; and (*f*) special conditions and study required by some, often highly profitable, crops.

(*a*) *The Soils.*—The University of California, at Berkeley, has issued a bulletin[12] in which a soil classification is analyzed from a production point of view. The Soil Survey Bureau, United States Department of Agriculture, had reported on fifty-nine California areas of which six areas (more than 2,500,000 acres) were not complete and nine areas (more than 4,750,000 acres) were not computed because of the alkali content of the soil. The University of California bulletin was concerned with the remaining forty-four areas (15,000,000 acres). Its classification, briefly, is as follows:

---

[10] Cons. Engr., Los Angeles, Calif.

[11] Discussion by Charles Kirby Fox of "'A National Reclamation Policy': Report of the Committee of the Irrigation Division," *Transactions*, ASCE, Vol. 95, 1931, p. 1357.

[12] "A Method of Rating California Soils," by Walter F. Weir and R. Earl Storie, *Bulletin No. 599*, College of Agriculture, Univ. of California, Berkeley, Calif.

Class	Percentage of maximum yield
1	> 80
2	60 to 79
3	40 to 59
4	20 to 39
5	10 to 19
6	< 10

The average total producibility of classes 1, 2, and 3 was 70% or, roughly, two thirds. Classes 4, 5, and 6 are not considered suitable agricultural soils for cultivation and irrigation. The East Mesa of Imperial Valley in California is rated on the same basis. The area of California is given as 158,693 sq miles; and, since the foregoing soil survey is supposed to embrace most of the arable land in California, the forty-four soil-class areas have been reduced to a percentage of California area, as shown in Table 2. All these data show that the areas having the best soils are very limited.

TABLE 2.—SUMMARY OF SOIL SURVEY RESULTS (PERCENTAGES)

Class of soil	PRODUCTION BASED ON:		
	Forty-four areas	California	East Mesa
Acres	(14,858,561)	(101,563,520)	(222,025)
1	13.6	1.95	0.2
2	10	1.43	3.6
3	19.3	2.75	26.2
(Total)	(42.9)	(6.13)	(30.0)
4	....	....	12.5
5	....	....	23.2
6	....	....	34.3

(*b*) *The Quantity of Water Used.*—By plotting more than 2,500 determinations of the duty of water (including many multiple tests), it was determined that, if the quantity of water required to produce the maximum yields were known, it could be assumed that two thirds of that water will produce yields of 90%; and one and one-half times that maximum quantity will only produce yields of 66%, or two thirds.

(*c*) *The Character of the Water.*—Alkali or saline waters, depending on relative concentrations, cause a decline in yields. As proof of this fact one has only to examine the thousands of acres of land in old irrigation districts, which were formerly productive but are now waterlogged and saturated with alkali. This is particularly noticeable in the great Central Valley (California) and the Imperial Valley, as well as in the Yuma Project in Arizona. The acreage yields (not dollar) of the Imperial Valley and the Yuma Project were plotted for the period from 1926 to 1940 and showed a decline of approximately one half, in relation to comparable crop yield data for Los Angeles County in California.

(*d*) *The Transportation Facilities.*—In some cases the transportation facilities will limit the yield of commercial crops.

M. R. LEWIS,[13] M. ASCE.—A very interesting method of forecasting the productivity of an area has been presented. However, it is based on climatic conditions; and, because climate is only one of a number of important factors in crop production, it is obvious that any forecast which does not include other factors, particularly soil characteristics, must be subject to wide variation when applied to a single project.

---

[13] With Region 1, U. S. Bureau of Reclamation, Boise, Idaho.

The author suggests that the crop census data secured by the United States Bureau of Reclamation would furnish a basis for a very interesting extension of his study. In the limited time available the writer has attempted to do this for the projects in Region 1 of the Bureau, which is essentially the Columbia River drainage area. Figs. 2(*a*), 2(*b*), and 2(*c*) show the relation between the yield of alfalfa, potatoes, and sugar beets, respectively, to the total heat units on those projects in the region where sufficient acreage of the given crops is grown to make the results significant. In each figure has been indicated, in addition, the comparable data for two Bureau projects outside Region 1. These two projects have been chosen to indicate the wide variation which is found when projects scattered over a wide area are used for this comparison. The yield data are the 5-year averages, 1941 to 1945.

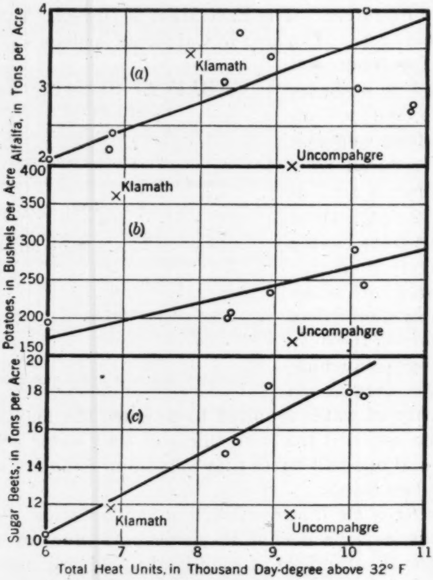

FIG. 2

It will be noted that the sugar beet and potato yields for Region 1 projects conform to a linear relationship. Alfalfa yields do not follow this relationship so closely. As a general proposition, it seems doubtful if any one crop can be used to indicate the productivity over the extremely wide range suggested by the author. It is well known that, in practice, alfalfa in such areas as the Imperial and Salt River valleys grows very little during the extremely hot months. Potatoes have such a short growing season that they can use only a part of the total heat in most sections of the west. It is possible to grow two crops of potatoes, one after the other, in a single season in areas where the total heat units amount to 10,000 day degrees or more. This is not a usual practice and it is therefore impossible to tell what the total production of potatoes might be if the whole of the long growing season were used in the hotter sections; nor do sugar beets require all the growing season in the more southern valleys. It, therefore, appears that no crop is available which could be used to show the productivity over a very wide range—although it seems probable that in the hotter climates sugar cane might be used for this purpose.

Harry F. Blaney,[14] **M. ASCE.**—For many years the writer has been interested in the relationships between temperature, consumptive use of water, and crop yield. The late Mr. Muldrow is to be complimented on his ingenious method of estimating the productivity of lands on a proposed irrigation project, and his paper should encourage further research on the subject. However, the writer does not agree with some of the statements and results presented.

The author states (under the heading, "Graph") that he was

> "* * * quite surprised by the record in the Imperial Valley in California, where alfalfa grows every month in the year and the farmers harvest eight cuttings; yet the census shows that Imperial County had 114,146 acres of alfalfa in 1939 and that the average yield was 2.99 tons per acre."

The writer does not question the census data, but they probably do not reflect the tremendous amounts of green alfalfa produced and fed to livestock shipped into Imperial Valley from other areas. The Imperial County Agricultural Commissioner reports that in 1939 approximately 75,000 head of cattle and 120,000 head of sheep were fattened. Table 3 is taken from records of the annual crop and livestock reports of the Imperial Irrigation District.

TABLE 3.—Head of Livestock Fed in Imperial Valley

Year	Cattle	Sheep	Dairy	Hogs
1942......	84,420	81,080	15,200	42,010
1943......	75,260	81,620	13,050	39.005
1944......	77,200	113,700	12,776	19,817
1945......	116,730	140,593	11,355	18,679

During the winter months livestock are brought into the valley, fed green alfalfa, and are then shipped out to market. The same fields which produce the baled hay also provide the winter pasturage. There is very little permanent pasture in Imperial Valley. In other words, the census data more nearly reveal the amounts of alfalfa harvested and sold, rather than produced; also, the actual yield of alfalfa in the valley is higher than 2.99 tons per acre.

A report on cost of production studies, conducted in 1943 on several representative farms by the Agricultural Extension Service of the University of California and the United States Department of Agriculture, in cooperation with alfalfa growers in Imperial County, states:

---

[14] Senior Irrig. Engr., Div. of Irrig., SCS, Research, U. S. Dept. of Agriculture, Los Angeles, Calif.

"The average yield for all records including that utilized as pasture was 4.64 tons per acre, ranging from 3.5 to 6.21. Average cost per acre was $72.75; income $104.17 and the net profit $31.42."[15]

Mr. Muldrow's statement that "Imperial Valley does not grow alfalfa to make money * * *" may have been true some years ago. However, in recent years the value of Imperial Valley's alfalfa crop was seldom exceeded by that of any other single crop produced in the valley. For example, the Imperial Irrigation District reports that, in 1943, 114,085 acres produced 16,585 carloads of alfalfa valued at $5,970,600; and, in 1945, when the price of alfalfa was good and hay was scarce, 158,713 acres produced 34,343 carloads valued at $11,848,335. Owners are leasing land suitable for growing alfalfa for more than $40.00 per acre per yr.

TABLE 4.—CONSUMPTIVE USE OF WATER BY ALFALFA IN IRRIGATED AREAS

[a] Computed from mean monthly temperatures (t), per cent of daytime hours (p), and consumptive-use coefficient (k); consumptive use $= t\,p\,k$. [b] Month of July excluded for rest period.

As indicated by the author, the "consumptive-use-of-water" curve in Fig. 1 represents average valley crops during the growing season. Studies made by the writer in the Upper Rio Grande Basin in New Mexico[16] and in other areas throughout the west, indicate that consumptive use of water shown at the upper end of this curve is probably more representative of the annual consumptive use by alfalfa. For instance, the annual consumptive use of water by alfalfa in Mesilla Valley in New Mexico[16] has been estimated at 4.0 ft, whereas the average annual valley consumptive use is only 2.8 ft. Alfalfa uses more water than other crops. The consumptive use of water by potatoes should not exceed 2 ft. Table 4 has been prepared to show seasonal consumptive use by alfalfa in various areas of the west. Briefly, the procedure[17] is to correlate existing consumptive use data with monthly temperature, per cent of daytime hours, and growing season. The coefficients so developed for different crops are used to transfer consumptive use data from one section to other areas where only climatological data are available.

[15] "1943 Alfalfa Production Cost and Efficiency Analysis, Imperial County, Calif.," Agri. Extension Service, Univ. of Calif., Berkeley, and U. S. D. A., cooperating with alfalfa growers, Imperial County, Calif. (mimeographed).

[16] "Water Utilization, Upper Rio Grande Basin, Part III," by Harry F. Blaney, P. A. Ewing, O. W. Israelsen, C. Rohwer, and F. C. Scobey, National Resources Committee, Washington, D. C., February, 1938.

[17] "A Method of Estimating Water Requirements in Irrigated Areas from Climatological Data," by Harry F. Blaney and Wayne D. Criddle, SCS, U. S. D. A., June, 1945 (mimeographed).

The curve "Tons per acre, alfalfa hay = 2,400 day degrees per ton" (Fig. 1) is probably incorrect inasmuch as the author did not have all the facts. For instance, the alfalfa yield data are county averages, whereas temperatures may not represent the area where most of the crop is grown. Most of the alfalfa in Los Angeles County is grown in Antelope Valley and other interior valleys, where the temperatures are similar to those for Bakersfield and Riverside, Calif., rather than for those of Los Angeles. The available heat units in Antelope Valley are about the same as in Bakersfield, and are somewhat higher than those in Los Angeles. If the yield of 5.5 tons of alfalfa per acre, shown for Los Angeles, is moved to the left in Fig. 1 to about 16,500 available degree days, and the yield for Imperial Valley is increased from 3.0 to 4.5 tons per alfalfa, the writer believes the resulting curve would more nearly represent field conditions.

The writer agrees with the thoughts expressed in the "Summary." It is a challenge to both engineers and research workers to improve procedure for forecasting the productivity of irrigable lands and the feasibility of proposed irrigation projects.

R. L. PARSHALL,[18] Assoc. M. ASCE.—The production of crops may be said to depend largely on the nature of the soil. However, three other elements are essential, such as moisture, food, and temperature. From the standpoint of forecasting productivity or yield from the land, it is necessary to have in mind the crop to be grown. Some soils, covering rather large areas, are of such a nature as to possess the essential food elements. They are capable of utilizing irrigation water efficiently and economically, and are located geographically so as to give a sufficiently long growing season to permit the various crops to mature. This is, more or less, an ideal condition, and many such areas exist throughout the irrigated west. There are limited areas where food, moisture, and temperature are favorable but where the soil is not suitable for general crops, regardless of how economically adaptable it is to the growing of special crops (such as fruit, trees, or shrubs).

The title of this paper, "Forecasting Productivity of Irrigable Lands" seems to infer that the problem involved is to determine the economic return through agricultural crops to be grown on lands not yet developed. It is quite obvious that, to arrive at an approximation, many factors are to be considered. Since none of these factors are definitely fixed, when they are brought together in the final analysis the conclusion can only be generally stated. The ultimate aim of the idea of productivity is that of approaching maximum yield of crop; and from the standpoint of irrigation it might be inferred that more water means more crop.

Under favorable soil conditions, food and temperature tend to bear out this contention for certain crops, but generally this is not true. Since productivity implies plant growth and development, it is known that the ordinary field crops have no conservation characteristics as far as soil moisture is concerned. As long as moisture is present the physiological development of the plant proceeds and, to promote a profitable yield, water as irrigation must be applied to prevent the growth from suffering a dormant stage or a setback in development. High temperatures augument this condition. The water supply available for application at timely or critical use is vastly more important than would be the factor of temperatures in the evaluation of forecasting productivity of irrigable lands.

HOWARD N. MAGNESS,[19] ESQ.—It is gratifying that the paper by Mr. Muldrow has resulted in such appropriate and beneficial discussion. The writer feels his inability to comment on the discussions and to prepare a closing discussion in the way Mr. Muldrow would have done. Nonetheless, in view of his professional association and fellowship with Mr. Muldrow, the writer welcomes the opportunity to conclude the discussion.

After many years of experience on irrigation planning, management and accomplishments and observations on changes in land use with specialization of crops and increased production, Mr. Muldrow frequently stated that he believed preliminary forecasts of production and basic economic estimates in support of projects were too conservative. The comments of the several discussers indicate a growing desire for more complete economic consideration of returns from proposed improvements. This tendency is rapidly assuming greater importance, especially in the more costly projects involving major engineering developments that affect large segments of land and population, and can result only in a firmer foundation for future planning.

It is realized that the material used by Mr. Muldrow was not as complete as might be desirable. The comments of Messrs. Lewis and Johnson concerning the use of additional crops are pertinent, as are those of Messrs. Blaney and Van Loo, concerning the discrepancy of yields in the Imperial Valley in California. The point raised by Mr. Fox relative to most desirable temperature base is considered reasonable, and comparison of the effect of the two temperature bases mentioned would be desirable.

The suggestion of Mr. Noble that further investigation be made toward evolving a final cash return per acre is especially helpful. It is true that, in general, crops produced in areas of high temperatures have as high a value—or perhaps an even higher value—per pound or other unit of production, as those grown in cooler areas. For this reason, where the temperatures exceed the optimum for the growth of potatoes or alfalfa, they should be replaced by other crops adapted to these temperatures, which possibly have an even higher yield value per acre.

It is realized that the basic paper and the discussions concerning it are too brief to present, fully, even this one feature of irrigation planning—that is, considerations of temperature in relation to crop production. Although vital, temperature is still only one of the factors affecting a project. Mr. Muldrow realized that his paper was only introductory to a complex and very interesting point of investigation. Further study and development of the subject would be most desirable.

CONTINUOUS FRAME ANALYSIS BY ELASTIC SUPPORT ACTION

By J. Charles Rathbun,[1] M. ASCE, and C. W. Cunningham,[2] Assoc. M. ASCE

With Discussion by Messrs. L. J. Mensch, Frederick S. Merritt, I. Oesterblom, Thomas C. Kavanagh, A. Floris, Tao King, Leroy A. Beaufoy, A. A. Eremin, Robert B. B. Moorman, Eduardo Agramonte, Stephen J. Fraenkel and Robert L. Janes, Phil M. Ferguson, Ralph W. Stewart, Maurice Barron, Edwin H. Gaylord, William A. Conwell, Harry A. Garfinkel, and J. Charles Rathbun and C. W. Cunningham.

Synopsis

The purpose of this paper is to present a "classical" or "exact" method of analyzing continuous frames which requires the direct solution of very few, if any, simultaneous equations. The greatest objection to methods of slope deflection, least work, and virtual work is the labor involved in the solution of these equations. There is some parallelism in form with the moment distribution method but the fundamental ideas are entirely different. The repeated cycles are entirely avoided. Reference is made to this parallelism to clarify the derivations and to help in visualizing the several steps in the solution of the problems.

The procedure recommended for the solution of problems requires the calculation of certain quantities which are analogous to the stiffness factors, carry-over factors, and fixed-end moments of moment distribution. Equations are developed for these quantities using a beam with elastic supports. This support condition is a result of the elasticity of the members of the frame adjacent to the supports. The equations have been previously developed using the flexibility of the connections as the elasticity.[3] The method is particularly well adapted to the analysis of frames with flexible connections.

The necessary equations are derived, the general method of procedure is outlined, and then the solution of a progressive series of problems is given in detail or outlined so that it can be followed readily.

Note.—Published in April, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

INTRODUCTION

The method is presented as a series of problems beginning with a simple case and then progressing to more complicated cases as the technique of solution becomes more apparent. A tabular arrangement of required values may be used since the solution follows a fixed pattern.

PART A. DERIVATION OF EQUATIONS

The letter symbols in this paper are defined where they first appear, in the text or by illustration.

The properties of the conjugate beam as presented in standard texts on strength of materials[4,5] are used in the derivations. If the conjugate beam is loaded with the $\frac{M}{E\,I}$-diagram of the given beam, the resulting shear and bending moment at any point are equal, respectively, to the slope and deflection at the corresponding point on the elastic curve of the given beam.

The conjugate beam has the same span length as the given beam. The reactions must be consistent with the $\frac{M}{E\,I}$-loading, and they must also produce shears and moments consistent with the conditions imposed on the given beam. The sign convention will be correct if the following notation is used:

(1) The shear (slope) at any section is positive if the resultant of all forces $\left(\frac{M}{E\,I}\right)$ to the left of the section acts in a positive or upward direction;

(2) The bending moment (deflection) at any section is positive if it causes compression in the upper fibers of the beam;

(3) The $\frac{M}{E\,I}$-diagram has the same sign as the M-diagram and is taken as an upward load if positive; and

(4) The left reaction of the conjugate beam is equal to the slope of the elastic curve at the left support. Similarly, the right reaction is equal to the slope at the right support with its sign changed.

In any continuous frame one or both of the supporting points of a member are elastic by virtue of the flexibility of the other members framing into these points. This elasticity (which is assumed to be the result of flexural deformation only) may be measured by the angular change of a section at the point resulting from a unit moment, assuming that the member under consideration is not acting.

Member RU, Fig. 1(*a*), represents a beam on elastic supports. The elasticity of support U depends on the flexibility of members UV and UY and the elasticity of support R depends on the flexibility of members RS, RP, and PQ. At each of these supports these flexibilities can be combined into one quantity, called the "elastic factor," Z. The method of computing and using this quantity and others required for the analysis will be shown.

1. The Carry-Over Factor and the Elastic Factor for a Prismatic Beam Having a Fixed Support at One End

Fig. 2(*b*) shows the elastic curve of a given beam AB having a span of length L in which point B is a support assumed to be fixed. Beam UY in Fig. 1(*a*) is such a member. The beam is rotated at point A by an applied moment M_{AB} which produces an induced moment M_{BA} at support B. The loaded conjugate beam is shown in Fig. 2(*a*). Since the slope of the given beam AB at point B is zero, the reaction of the conjugate beam B is also zero. For convenience the $\frac{M}{EI}$-diagram of Fig. 2(*a*) has been divided into two triangles (one positive and one negative) by the dotted lines.

(*b*) LOAD AND DEFLECTION DIAGRAM

Fig. 3.—Elastic Support at Both Ends

Taking moments about point A on the conjugate beam: $\frac{M_{AB}}{EI} \times \frac{L}{2} \times \frac{L}{3} - \frac{M_{BA}}{EI} \times \frac{L}{2} \times \frac{2L}{3} = 0$; or

$$M_{BA} = \tfrac{1}{2} M_{AB} \qquad (1)$$

In Eq. 1, the fraction $\frac{1}{2}$ is the well-known "carry-over factor" for a fixed support at point B. The "elastic factor" is found by computing the reaction θ_A of the conjugate beam. Since θ_B is zero, θ_A is equal to the area of the area of the $\frac{M}{EI}$-diagram; or

$$\theta_A = \frac{M_{AB}}{EI} \times \frac{L}{2} - \frac{M_{BA}}{EI} \times \frac{L}{2} \qquad (2a)$$

from which, by Eq. 1,

$$\theta_A = \frac{M_{AB}\,L}{4\,E\,I} \quad \text{(2b)}$$

In Eq. 2b $\frac{L}{4\,E\,I}$ is the "elastic factor" or angular change at point A due to the application of a unit moment. Representing the elastic factor at point A by Z_A, with the far end, B, fixed:

$$Z_A = \frac{L}{4\,E\,I} \quad \text{(3)}$$

If point B is a hinged support, the $\frac{M}{E\,I}$-diagram is a single triangle since M_{BA} is zero, and

$$\theta_A = \frac{M_{AB}\,L}{3\,E\,I} \quad \text{(4)}$$

Since the elastic factor Z_A is equal to $\frac{\theta_A}{M_{AB}}$, it follows:

$$Z_A = \frac{L}{3\,E\,I} \quad \text{(5)}$$

2. THE CARRY-OVER FACTOR AND THE ELASTIC FACTOR FOR A PRISMATIC BEAM HAVING AN ELASTIC SUPPORT AT END B, THE END FARTHEST FROM THE APPLIED MOMENT

Fig. 3(b) shows the elastic curve of a beam AB similar in every respect to that of Fig. 2 except that the slope θ_B at end B is proportional to M_{BA}. From the definition of Z:

$$\theta_B = M_{BA}\,Z_B \quad \text{(6)}$$

Taking moments about end A on the conjugate beam: $-\theta_B\,L - \frac{M_{BA}}{E\,I} \times \frac{L}{2} \times \frac{2\,L}{3} + \frac{M_{AB}}{E\,I} \times \frac{L}{2} \times \frac{L}{3} = 0$. Substituting $M_{BA}\,Z_B$ for θ_B and multiplying by $-\frac{3\,E\,I}{L}$: $3\,E\,I\,M_{BA}\,Z_B + M_{BA}\,L - \frac{M_{AB}\,L}{2} = 0$; $(L + 3\,E\,I\,Z_B)\,M_{BA} = \frac{M_{AB}\,L}{2}$; and

$$M_{BA} = \frac{M_{AB}}{2} \times \frac{L}{L + 3\,E\,I\,Z_B} = \frac{M_{AB}}{2} \times \frac{L}{L_{AB}} \quad \text{(7)}$$

in which $\frac{L}{2\,L_{AB}}$ is the carry-over factor when support B is elastic. The quantity $(L + 3\,E\,I\,Z_B)$ will be called the "elastic length" of the beam with respect to the support B and will be denoted by L_{AB} to simplify the form of the equations involving this expression; thus:

$$L_{AB} = L + 3\,E\,I\,Z_B \quad \text{(8)}$$

The "elastic factor" is obtained by computing the reactions, θ, of the conjugate beam in Fig. 3(a):

$$-\theta_A L + \frac{M_{AB}}{E I} \times \frac{L}{2} \times \frac{2 L}{3} - \frac{M_{BA}}{E I} \times \frac{L}{2} \times \frac{L}{3} = 0 \ldots\ldots\ldots (9a)$$

and

$$\theta_A = \frac{M_{AB} L}{3 E I} - \frac{M_{BA} L}{6 E I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9b)$$

From Eq. 7,

$$\theta_A = \frac{M_{AB} L}{3 E I} - \frac{M_{AB} L^2}{12 E I L_{AB}} \ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

That is,

$$\theta_A = M_{AB} \left(\frac{4 L L_{AB} - L^2}{12 E I L_{AB}} \right) \ldots\ldots\ldots\ldots\ldots\ldots (10b)$$

and

$$Z_A = \frac{\theta_A}{M_{AB}} = \frac{4 L L_{AB} - L^2}{12 E I L_{AB}} = \frac{L}{3 E I} \left[\frac{L_{AB} - \frac{L}{4}}{L_{AB}} \right] \ldots\ldots\ldots (11)$$

Eq. 11 reduces to Eq. 3 when point B is fixed since Z_B is zero and L_{AB} becomes L.

The general use of Eq. 11 will be shown by outlining the procedure for computing the elastic factor for the frame RPQ of Fig. 1(a). The elastic factor Z_{RPQ} depends on the flexibility of the column of PQ which may be obtained from Eq. 3. Therefore, Z_{RPQ} is found by substituting Z_{PQ} from Eq. 3 in Eq. 11. Inasmuch as Z_A in Eq. 11 is a function of Z_B, the latter must be computed first. Thus, one must start with a point such as a fixed or hinged joint whose rigidity is known.

The procedure for computing the elastic factor for part of a frame such as QPRS of Fig. 1(a) will now be given. Fig. 1(b) shows the part QPRS isolated as a free body and subjected to an external positive moment M_R. The thrust and shear have been omitted from the sketch for simplicity. Since the sum of the moments about a joint is zero, the sum of the moments on joint R from RPQ and RS is equal but opposite in sign to the moment M_R. The elastic factor representing the combined flexibility of RPQ and RS is found by noting that each of the aforementioned moments is proportional to the stiffness factor of the member which is equal to the reciprocal of the elastic factor. The moment relation at joint R is

$$M_R = -(M_{RS} + M_{RP}) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Since $\theta = M Z$,

$$\frac{\theta_R}{Z_R} = -\left(-\frac{\theta_R}{Z_{RS}} - \frac{\theta_R}{Z_{RPQ}} \right) \ldots\ldots\ldots\ldots\ldots\ldots (13a)$$

and

$$\frac{1}{Z_R} = \frac{1}{Z_{RS}} + \frac{1}{Z_{RPQ}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13b)$$

in which Z_R is the angular change at joint R when a unit moment is applied to the part QPRS at that joint.

3. End Moments Due to Transverse Loading for a Prismatic Beam on Elastic Supports

Fig. 4(*b*) represents the elastic curve of a beam AB of span length *L*, loaded transversely and having two flexible supports A and B. The moment diagram for the given transverse loads acting on a simple beam of length *L* is shown in Fig. 4(*c*). The moment diagrams due to M_{AB} and M_{BA} are shown in Figs. 4(*d*) and 4(*e*), respectively. The principle of superposition of the simple-beam moment diagrams is used to obtain the moment diagram for the loads and moments acting simultaneously. The resulting curve, divided by EI, is shown in Fig. 4(*a*).

Fig. 4.—Beam on Elastic Supports, Loaded Transversely

Using the $\frac{M}{EI}$-diagram in Fig. 4(*a*) as a load, the reactions, θ_A and θ_B, of the conjugate beam are found by taking moments about supports B and A, respectively. The rotation θ in each equation is then replaced by its corresponding value, MZ, and the equations are solved simultaneously to obtain formulas for the end moments. Taking moments about end B: $-\theta_A L - \frac{M_{AB}}{EI} \times \frac{L}{2} \times \frac{2L}{3} - \frac{M_{BA}}{EI} \times \frac{L}{2} \times \frac{L}{3} + \frac{A}{EI} \times \bar{x}_B = 0$; $3EI\theta_A + M_{AB}L + \frac{M_{BA}L}{2} - \frac{3A\bar{x}_B}{L} = 0$; $3EIM_{AB}Z_A + M_{AB}L + \frac{M_{BA}L}{2} - \frac{3A\bar{x}_B}{L} = 0$; and

$$M_{AB}(L + 3EIZ_A) + \frac{M_{BA}L}{2} = \frac{3A\bar{x}_B}{L} \qquad \text{(14a)}$$

For brevity, let:

$$L + 3EIZ_A = L_{BA} \qquad \text{(14b)}$$

—from which:

$$M_{AB}L_{BA} + \frac{M_{BA}L}{2} = \frac{3A\bar{x}_B}{L} \qquad \text{(15a)}$$

Similarly, by taking moments about point A:

$$M_{BA}\,L_{AB} + \frac{M_{AB}\,L}{2} = \frac{3\,A\,\bar{x}_A}{L} \qquad (15b)$$

The solution of the simultaneous equations (Eqs. 15*a* and 15*b*) is given by Eqs. 16, as follows:

$$M_{AB} = \frac{6\,A}{L}\left(\frac{2\,L_{AB}\,\bar{x}_B - L\,\bar{x}_A}{4\,L_{AB}\,L_{BA} - L^2}\right) \qquad (16a)$$

and

$$M_{BA} = \frac{6\,A}{L}\left(\frac{2\,L_{BA}\,\bar{x}_A - L\,\bar{x}_B}{4\,L_{AB}\,L_{BA} - L^2}\right) \qquad (16b)$$

If one end, such as B, is a hinged support, $M_{BA} = 0$. The numerator and denominator of Eq. 16*a* are then divided by L_{AB} producing

$$M_{AB} = \frac{6\,A}{L}\left[\frac{2\,\bar{x}_B - \dfrac{L\,\bar{x}_A}{L_{AB}}}{4\,L_{BA} - \dfrac{L^2}{L_{AB}}}\right] \qquad (16c)$$

For a hinge, $Z = \infty$; consequently, $L_{AB} = \infty$ by Eq. 8. The last term in both the numerator and the denominator of Eq. 16*c* becomes zero. This equation then reduces to

$$M_{AB} = \frac{3\,A\,\bar{x}_B}{L_{BA}\,L} \qquad (16d)$$

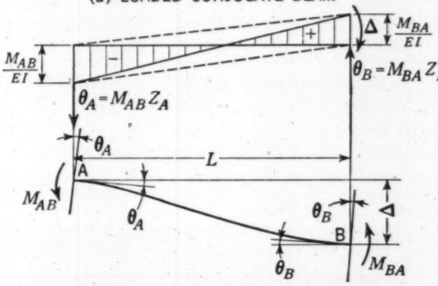
If ends A and B are fixed supports, L_{AB} and L_{BA} of Eqs. 16*a* and 16*b* are replaced by L since Z_A and Z_B are both zero. The resulting equations are the well-known formulas for fixed-end moments in the moment distribution method:

$$M_{AB} = \frac{2\,A}{L^2}\,(2\,\bar{x}_B - \bar{x}_A) \qquad (17a)$$

and

$$M_{BA} = \frac{2\,A}{L^2}\,(2\,\bar{x}_A - \bar{x}_B) \qquad (17b)$$

(*a*) LOADED CONJUGATE BEAM



(*b*) LOAD AND DEFLECTION DIAGRAM

FIG. 5.—UNEQUAL SETTLEMENT OF SUPPORTS

4. END MOMENTS DUE TO THE RELATIVE DISPLACEMENT OF THE ENDS OF A PRISMATIC BEAM ON ELASTIC SUPPORTS

These displacements are perpendicular to the longitudinal axis of the beam. Fig. 5(*b*) shows the elastic curve of a beam AB of span length L when the end B is displaced a distance Δ relative to end A. The induced moments are M_{AB} and M_{BA}. The loaded conjugate beam is shown in Fig. 5(*a*). The displacement of end B, shown as a negative quantity in Fig. 5(*b*), is represented as a negative moment Δ acting on the conjugate beam at support B. Taking moments about end B on the conjugate beam: $-\theta_A L - \frac{M_{AB}}{E I} \times \frac{L}{2} \times \frac{2 L}{3} + \frac{M_{BA}}{E I} \times \frac{L}{2} \times \frac{L}{3} + \Delta = 0$; and

$$M_{AB} L + 3 E I \theta_A - \frac{M_{BA} L}{2} = \frac{3 E I \Delta}{L} \quad \text{(18)}$$

Substituting the value of θ_A and also L_{BA} for $L + 3 E I Z_A$:

$$M_{AB} L_{BA} - \frac{M_{BA} L}{2} = \frac{3 E I \Delta}{L} \quad \text{(19a)}$$

Similarly, taking moments about end A and substituting the corresponding values for θ_B and $L + 3 E I Z_B$ (Eq. 8):

$$M_{BA} L_{AB} - \frac{M_{AB} L}{2} = \frac{3 E I \Delta}{L} \quad \text{(19b)}$$

The solution of the simultaneous equations (Eqs. 19) is given by Eqs. 20, as follows:

$$M_{AB} = \frac{6 E I \Delta}{L} \left(\frac{2 L_{AB} + L}{4 L_{AB} L_{BA} - L^2} \right) = \frac{3 E I \Delta}{2 L} \left[\frac{2 L_{AB} + L}{L_{AB} L_{BA} - \frac{L^2}{4}} \right] \quad \text{(20a)}$$

and

$$M_{BA} = \frac{6 E I \Delta}{L} \left(\frac{2 L_{BA} + L}{4 L_{AB} L_{BA} - L^2} \right) = \frac{3 E I \Delta}{2 L} \left[\frac{2 L_{BA} + L}{L_{AB} L_{BA} - \frac{L^2}{4}} \right] \quad \text{(20b)}$$

If points A and B are fixed supports, L_{AB} and L_{BA} of Eqs. 20 are replaced by L since Z_A and Z_B are both zero. Then these equations reduced to the joint translation equations of moment distribution:

$$M_{AB} = M_{BA} = \frac{6 E I \Delta}{L^2} \quad \text{(21)}$$

5. Flexible Connections

In general, the flexibility of the connections can be taken into consideration by increasing the elastic length of the beams. The "elastic length" of the member used in the computations will then be

$$L' = L + 3 E I Z_J + 3 E I Z_C \quad \text{(22)}$$

in which Z_J refers to the joint and Z_C to the connection. The value of Z_C for the connection must be obtained by experiment or by other methods, as explained elsewhere.[3]

However, Eq. 11 cannot be used for flexible connections because θ_A in this formula is the result of joint rotation only. Therefore, it will be necessary to derive a new expression for the "elastic factor."

Since the rotation at the joint is equal to the rotation of the end of the beam plus the angular change in the connection:

$$\theta_{AJ} = \frac{M_{AB}\,L}{3\,E\,I}\left[\frac{L_{AB} - \dfrac{L}{4}}{L_{AB}}\right] + \theta_{AC} \ldots\ldots\ldots\ldots\ldots (23a)$$

and

$$Z_{AJ} = \frac{\theta_{AJ}}{M_{AB}} = \frac{L}{3EI}\left[\frac{L_{AB} - \dfrac{L}{4}}{L_{AB}}\right] + Z_{AC} = \frac{L}{3EI}\left[\frac{L_{AB} + 3\,E\,I\,\dfrac{L_{AB}}{L}\,Z_{AC} - \dfrac{L}{4}}{L_{AB}}\right]$$

$$= \frac{L\,L_{AB} + 3\,E\,I\,Z_{AC}\,L_{AB} - \dfrac{L^2}{4}}{3\,E\,I\,L_{AB}} = \frac{(L + 3\,E\,I\,Z_{AC})\,L_{AB} - \dfrac{L^2}{4}}{3\,E\,I\,L_{AB}} \ldots (23b)$$

For brevity, let:

$$L + 3\,E\,I\,Z_{AC} = L'_{AC} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

from which

$$Z_{AJ} = \frac{L'_{AC}\,L_{AB} - \dfrac{L^2}{4}}{3\,E\,I\,L_{AB}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

If the connection of AB at end B is flexible—

$$L_{AB} = L + 3\,E\,I\,(Z_B + Z_{BC}) \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

—as stated in Eq. 22.

6. Method of Procedure

If the frame is one in which there is no joint translation (sidesway), the solution of the problem may be divided into six distinct steps. In those cases where the solution involves joint translation, a solution is first obtained assuming that this motion is prevented. Later this assumption is corrected by additional steps.

In the derivation of formulas it was emphasized that the calculation of the elastic factors must begin with a member adjacent to a primary support (a joint whose rigidity is known). However, in some structures (the Vierendeel truss being an example), this is not possible. The computations for the elastic factors cannot be begun where a path can be followed to its starting point. This condition can be avoided temporarily by securing certain joints against rotation. These "fixed joints" can later be released and the effect of their adjustment superimposed on the solution already obtained. In many frames the "fixed joints" are not required.

Step (*a*).—Select a minimum number of "fixed joints," dividing the frame into sections such that in any section one can move on the frame from any point in the section to any other by one, and only one, route.

Step (*b*).—Compute the elastic factors Z_A and Z_B for each member of the frame (see Eqs. 3, 5, or 11). The elastic lengths and the carry-over factors are also computed.

Step (*c*).—Compute the moments at the ends of the members connected to each "fixed joint" when the joint is rotated a unit amount. Distribute the resulting moments throughout the frame.

Step (*d*).—Compute and distribute the end moments of the loaded members by Eqs. 16.

Step (*e*).—The temporary "fixed joints" are eliminated by forming simultaneous equations from the resulting steps (*c*) and (*d*). Solve these equations for the rotation correction factors.

Step (*f*).—Eliminate the fixed condition of the joints by substituting by proportion the results of step (*e*) in step (*c*), and combine the results with those of step (*d*). If there is no joint translation (sidesway), the result of step (*f*) is the final solution of the problem.

7. JOINT TRANSLATION

Each problem contains a definite number of shear requirements that must be satisfied. These result in deformations across the section where they occur. Literal values are assigned to these deformations and an equation of condition is set up for each section. The literal terms of each equation represent the shears across the sections due to the several (unknown) deformations. The solution of the simultaneous equations will give the values of the unknowns. The final moments are found by the principle of superposition, adding the change in the moments due to these deformations to those found by step (*f*). The shear corrections require three additional steps.

Step (*g*).—Translate the joints, successively, along each shear section an equal, arbitrary amount allowing no rotation except that due to the flexibility of the supporting members; and then compute the resulting end moments from Eqs. 20. Distribute these moments in the same manner as those due to a load.

Step (*h*).—Compute the shear on each shear section due to the joint translations of step (*g*). Form equations of condition for the several shear sections noting that these shears are the coefficients of the literal deformations. The solution of these equations gives the amount of deflection necessary to satisfy the shear requirements of the problem.

Step (*i*).—Multiply the moments of step (*g*) by the shear correction factors obtained from the solution of the equations of step (*h*) and add the results to the moments found by step (*f*). The final result is the complete solution of the problem.

The steps in the illustrative problems are lettered to correspond to the foregoing step letters. If a step is not required for a problem, it will be omitted.

A study of Eqs. 3 to 20 will show that E is eliminated from the calculations when the elastic factor from Eq. 3 or Eq. 5 is substituted in the succeeding equations. For convenience in computations involving individual equations, E will be assumed equal to unity. The moment of inertia, I, will be given a proportional value since it is seldom the same for all members of the structure.

In evaluating the formulas, the customary sign convention for moments used in beam analysis has been followed—that is, a moment is positive if it produces compression on the upper fibers of the beam. This notation presents difficulties in frame analysis so, as in moment distribution, the convention used in the problems will be: A positive end moment is one that will tend to turn the end of a member going into a joint in a clockwise direction.

PART B. ILLUSTRATIVE EXAMPLES

EXAMPLE 1 (*a*)

A four-span continuous beam ABCDE (Fig. 6) carries a 4-kip concentrated load at the center of span BC. The left end, A, is fixed and the right end, E, is hinged. The moment of inertia, I, is taken as 15 and is included in the computations for illustrative purposes although the solution is independent of its value. The moments at points A, B, C, and D are the required quantities.

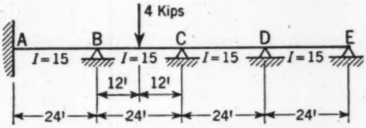


FIG. 6.—FOUR-SPAN CONTINUOUS BEAM WITH ONE CONCENTRATED LOAD

Step (*a*).—Since there are no closed circuits and since the computations for the elastic factors begin with the single members AB and DE, no joints fixed against rotation are needed.

Step (*b*).—To provide a starting point for the computations, assume that points B and C are isolated elastic supports, the elasticity of point B resulting from the flexibility of member BA and that of point C from the flexibility of member CDE. The required elastic factors will be calculated first: For member BA, Eq. 3 gives $Z_{BA} = \frac{24}{4 \times 15} = \frac{1}{2.500}$; and, for member DE, Eq. 5 gives $Z_{DE} = \frac{24}{3 \times 15} = \frac{1}{1.875}$. The elastic factor Z_{CDE} for member CDE is calculated from Eq. 11 which involves the elastic length L_{CD} of member CD; thus (see Eq. 8): $L_{CD} = L + 3\,E\,I\,Z_{DE} = 24 + 3 \times 15 \times \frac{1}{1.875} = 24 + 24 = 48.00$; and (see Eq. 11) $Z_{CDE} = \frac{24}{3 \times 15}\left[\frac{48 - \frac{24}{4}}{48}\right] = \frac{1}{2.143}$.

The elastic lengths, L_{BC} and L_{CB}, needed in step (*d*) are (see Eq. 8): $L_{BC} = L + 3\,E\,I\,Z_{CDE} = 24 + 3 \times 15 \times \frac{1}{2.143} = 45.00$; and $L_{CB} = L + 3\,E\,I\,Z_{BA} = 24 + 3 \times 15 \times \frac{1}{2.500} = 42.00$. The required carry-over factors are: Points B to A (Eq. 1), 0.50; points C to D (Eq. 7) $\frac{24}{2 \times 48} = 0.25$; and points D to E $= 0$ (as is known) because (see Eq. 7) $L_{DE} = \infty$.

The elastic length of member DE is infinite since $Z_E = \infty$ due to the hinge.

Step (*d*).—The maximum ordinate of the moment diagram for the 4-kip concentrated load is $\frac{P\,L}{4} = \frac{4 \times 24}{4} = 24$ ft-kips. Therefore, $A = \frac{1}{2} \times 24 \times 24 = 288$; and $\bar{x}_B = \bar{x}_C = 12$. Then, by Eq. 16*a*,

$$M_{BC} = \frac{6 \times 288}{24}\left(\frac{2 \times 45 \times 12 - 24 \times 12}{4 \times 45 \times 42 - 24 \times 24}\right) = 8.165;$$

and, by Eq. 16*b*,

$$M_{CB} = \frac{6 \times 288}{24}\left(\frac{2 \times 42 \times 12 - 24 \times 12}{4 \times 45 \times 42 - 24 \times 24}\right) = 7.423.$$

Moments M_{BC} and M_{CB} for this problem are tabulated and distributed in Table 1, with the sign notation as mentioned in "Part A: 6. Method of Procedure."

TABLE 1.—MOMENTS AT THE SUPPORTS OF THE CONTINUOUS BEAM ABCDE, FIG. 6

AB	BA	BC	CB	CD	DC	DE	ED
−4.082	−8.165	+8.165	−7.423	+7.423	+1.856	−1.856	0

EXAMPLE 1(*b*)

The same four-span continuous beam as in Example 1(*a*) (Fig. 6) carries a 4-kip load at the center of span BC and a load of 8 kips uniformly distributed over span CD.

Step (*b*).—Compute the following values in addition to those already found in Example 1(*a*): For member CBA, $Z_{CBA} = \frac{24}{3 \times 15}\left[\frac{42 - \frac{24}{4}}{42}\right] = \frac{1}{2.188}$ (see Eq. 11); and L_{DC} (see Eq. 8) $= 24 + 3 \times 15 \times \frac{1}{2.188} = 24 + 20.57 = 44.57$.

The carry-over factor from points C to B is $\frac{24}{2 \times 42} = 0.286$.

Step (*d*).—Find the end moments due to the 8-kip uniform load. The maximum ordinate of the moment-curve diagram (a second degree parabola) is $\frac{W\,L}{8} = \frac{8 \times 24}{8} = 24$ ft-kips. The area under a second degree parabola is equal to two thirds of the area of the circumscribed rectangle. Therefore, $A = \frac{2}{3} \times 24 \times 24 = 384$ and $\bar{x}_C = \bar{x}_D = 12$.

Then, by Eq. 16*a*,

$$M_{CD} = \frac{6 \times 384}{24}\left(\frac{2 \times 48 \times 12 - 24 \times 12}{4 \times 48 \times 44.57 - 24 \times 24}\right) = 10.392;$$

and, by Eq. 16*b*,

$$M_{DC} = \frac{6 \times 384}{24}\left(\frac{2 \times 44.57 \times 12 - 24 \times 12}{4 \times 48 \times 44.57 - 24 \times 24}\right) = 9.402.$$

Moments M_{BC} and M_{CB} from Example 1(*a*), and moments M_{CD} and M_{DC} in this example, are tabulated and distributed in Table 2, the last line of which gives the moments at the several joints, created by the two loads.

TABLE 2.—TABULATION AND DISTRIBUTION OF MOMENTS, EXAMPLE 1(*b*)

Line	Description	AB	BA	BC	CB	CD	DC	DE	ED
1	Moments created by elasticity of supports	....	....	+8.165	− 7.423	+10.392	−9.402	....	....
2	Joint distribution.....	....	−8.165	....	−10.392	+ 7.423	....	+9.402	....
3	Carry-over*..........	−2.598	+2.969	−2.969	....	....	+1.856	−1.856	0
4	Final moments.......	−2.598	−5.196	+5.196	−17.815	+17.815	−7.546	+7.546	0

* For member AB, 5.196 × 0.50 = 2.598; for member BA, 10.392 × 0.286 = 2.969; and, for member DC, 7.423 × 0.25 = 1.856.

EXAMPLE 2

A rigid frame (Fig. 7) carries a 4-kip concentrated load at the center of the beam AC. The moments at points A, B, C, and D are required.

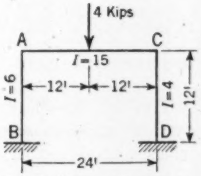

FIG. 7.—RIGID SYMMETRICAL FRAME

Step (*b*).—It will be assumed that points A and C are isolated elastic supports. The elasticity of joint A is a function of the flexibility of member AB and the elasticity of joint C is a function of the flexibility of member CD. Eq. 3 yields for member AB, $Z_{AB} = \frac{12}{4 \times 6} = \frac{1}{2}$; and, for member CD, $Z_{CD} = \frac{12}{4 \times 4} = \frac{3}{4}$. The elastic lengths (Eq. 8) are: $L_{AC} = 24 + 3 \times 15 \times \frac{3}{4} = 24 + 33.75 = 57.75$; and $L_{CA} = 24 + 3 \times 15 \times \frac{1}{2} = 24 + 22.50 = 46.50$.

By Eq. 11: For member ACD—$Z_{ACD} = \frac{24}{3 \times 15}\left[\frac{57.75 - \frac{24}{4}}{57.75}\right] = \frac{1}{2.092}$, and, for member CAB, $Z_{CAB} = \frac{24}{3 \times 15}\left[\frac{46.50 - \frac{24}{4}}{46.50}\right] = \frac{1}{2.153}$.

Step (*g*).—The elastic lengths required in step (*g*) are:

$$L_{AB} = L + 3\,E\,I\,Z_B \quad = 12 + 3 \times 6 \times 0 \quad = 12.00$$

$$L_{BA} = L + 3\,E\,I\,Z_{ACD} = 12 + 3 \times 6 \times \frac{1}{2.092} = 20.60$$

$$L_{CD} = L + 3\,E\,I\,Z_D \quad = 12 + 3 \times 4 \times 0 \quad = 12.00$$

$$L_{DC} = L + 3\,E\,I\,Z_{CAB} = 12 + 3 \times 4 \times \frac{1}{2.153} = 17.56$$

The required carry-over factors are: By Eq. 1—points A to B = 0.50 and points C to D = 0.50; and, by Eq. 7—points A to C = $\frac{24}{2 \times 57.75} = 0.208$ and points C to A = $\frac{24}{2 \times 46.50} = 0.258$.

Step (*d*).—From Example 1(*a*), $A = 288$ and $\bar{x}_A = \bar{x}_C = 12$. Then, by Eqs. 16: $M_{AC} = \frac{6 \times 288}{24}\left(\frac{2 \times 57.75 \times 12 - 24 \times 12}{4 \times 57.75 \times 46.50 - 24 \times 24}\right) = 7.777$; and $M_{CA} = \frac{6 \times 288}{24}\left(\frac{2 \times 46.50 \times 12 - 24 \times 12}{4 \times 57.75 \times 46.50 - 24 \times 24}\right) = 5.865$. These moments are tabulated and distributed in the first line of Table 3(*b*).

Step (*g*).—According to statics the shear equation

$$\frac{M_{AB} + M_{BA} + M_{CD} + M_{DC}}{12}$$

should equal zero; but the actual shear across members AB and CD is

$$\frac{-7.777 - 3.888 + 5.865 + 2.932}{12} = \frac{-2.868}{12};$$

and, therefore, as should be expected, joints A and C must move laterally until the induced moments produce a shear that will counteract the effect of the shear $\frac{-2.868}{12}$. Joint A will be translated a distance Δ, which for convenience is taken as $\frac{12}{E}$, laterally to the right of joint B. However, the direction of the relative movement is entirely arbitrary. In a like manner joint C will be translated the same distance to the right of point D. The induced moments (see Eq. 17) are:

TABLE 3.—TABULATION AND DISTRIBUTION OF MOMENTS, EXAMPLE 2

4	Final moments........................	+2.427	+1.853	−1.853	−1.555	+1.555	+1.778
	(*b*) STEPS (*d*) AND (*i*)						
5	Moments created by the load, assuming that sideway is prevented (step (*d*))....	−3.888	−7.777	+7.777	−5.865	+5.865	+2.932
6	Correction for sidesway (line 4 × 0.376)...	+0.914	+0.698	−0.698	−0.586	+0.586	+0.670
7	Final moments (step (*i*))...............	−2.974	−7.079	+7.079	−6.451	+6.451	+3.602

[a] For members BA and DC, 0.319 × 0.50 = 0.160; for member AC, 1.236 × 0.258 = 0.319; and, for member CA, 1.534 × 0.208 = 0.319.

$$M_{AB} = \frac{6 \times 6 \times 12}{12}\left(\frac{2 \times 12 + 12}{4 \times 12 \times 20.62 - 12 \times 12}\right) = 1.534$$

$$M_{BA} = \frac{6 \times 6 \times 12}{12}\left(\frac{2 \times 20.62 + 12}{4 \times 12 \times 20.62 - 12 \times 12}\right) = 2.267$$

$$M_{CD} = \frac{6 \times 4 \times 12}{12}\left(\frac{2 \times 12 + 12}{4 \times 12 \times 17.60 - 12 \times 12}\right) = 1.236$$

$$M_{DC} = \frac{6 \times 4 \times 12}{12}\left(\frac{2 \times 17.60 + 12}{4 \times 12 \times 17.60 - 12 \times 12}\right) = 1.618$$

These moments are tabulated and distributed in Table 3(*a*). The shear across members AB and CD due to these moments is:

$$\frac{+1.853 + 2.427 + 1.555 + 1.778}{12} = \frac{+7.613}{12}.$$

Step (*h*).—The shear correction factor is: $\frac{2.868}{12} \div \frac{7.613}{12} = \frac{2.868}{7.613} = 0.376.$ The sign of the shear from step (*g*) has been changed to produce reverse balancing moments.

Step (*i*).—Line 7, Table 3(*b*) gives the final moments for the frame including the effect of joint translation.

EXAMPLE 3

A four-span rigid frame is loaded as shown in Fig. 8. The end moments of all members are required.

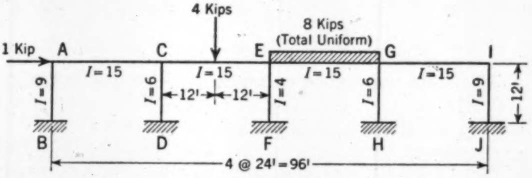

FIG. 8.—FOUR-SPAN RIGID FRAME

Step (*b*).—The necessary elastic lengths and elastic factors are found, first, by progressing from joint I to joint A and then from joint A to joint I. In the computations in Table 4 it will be found convenient to express the elastic factor in its reciprocal form, which is the "stiffness factor." The remaining values are found by symmetry; thus:

TABLE 4.—COMPUTATIONS FOR STEP (*b*), EXAMPLE 3

Member	L	$1/Z$
AB..............	12.00	3.000
CA..............	39.00	2.216
EC..............	34.67	2.267
GE..............	36.50	2.244
IG	34.60	2.268
JI	23.90	....

The following elastic lengths are required for the sidesway calculations and are based on stiffness factors in Table 4: For member DC,

$$L_{DC} = 12 + \frac{3 \times 6}{2.216 + 2.244} = 16.04;$$

for member FE, $L_{FE} = 12 + \dfrac{3 \times 4}{2 \times 2.267} = 14.65$; and, for member HG, $L_{HG} = 16.04$.

The carry-over factors are found by Eq. 7; thus: From point A to point C, $\dfrac{24}{2 \times 34.60} = 0.347$; from point C to point E, $\dfrac{24}{2 \times 36.45} = 0.329$; from point E to point G, $\dfrac{24}{2 \times 34.70} = 0.346$; and, from point G to point I, $\dfrac{24}{2 \times 39.00} = 0.308$. Carry-over factors, from I to G, G to E, E to C, and C to A, are found by symmetry; and the carry-over factors from the column tops to the bases are all 0.500.

Step (*d*).—The values of A, $\bar{x}_A$, and $\bar{x}_B$, for the 4-kip concentrated load and the 8-kip uniform load, are taken from Examples 1(*a*) and 1(*b*). The end moments from each of these loads are computed by Eqs. 16*a* and 16*b*:

$$M_{CE} = \frac{6 \times 288}{24}\left(\frac{2 \times 36.50 \times 12 - 24 \times 12}{4 \times 36.50 \times 34.67 - 24 \times 24}\right) = 9.436$$

$$M_{EC} = \frac{6 \times 288}{24}\left(\frac{2 \times 34.67 \times 12 - 24 \times 12}{4 \times 36.50 \times 34.67 - 24 \times 24}\right) = 8.734$$

$$M_{EG} = \frac{6 \times 384}{24}\left(\frac{2 \times 34.67 \times 12 - 24 \times 12}{4 \times 34.67 \times 36.50 - 24 \times 24}\right) = 11.645$$

$$M_{GE} = \frac{6 \times 384}{24}\left(\frac{2 \times 36.50 \times 12 - 24 \times 12}{4 \times 34.67 \times 36.50 - 24 \times 24}\right) = 12.582$$

To facilitate the distribution of moments, the stiffness factors of the members framing into joints C, E, and G are listed as follows:

Member	Stiffness factor
Joint C—	
CA	2.216
CD	2.000
CE	2.244
Joint E—	
EC	2.267
EF	1.333
EG	2.267
Joint G—	
GE	2.244
GH	2.000
GI	2.216

The end moment from any member is distributed to the other members at the joint in direct proportion to its stiffness. The moments caused by the loads, tabulated in line 6, Table 5(*b*), are distributed first to the right (line 7) and then to the left (line 8) by the proper stiffness and carry-over factors. Since the moments in line 6 are the result of elastic support action, there is no carry-over for $M_{EC} = -8.734$ to joint C or for $M_{EG} = -11.645$ to joint G, the moment $M_{EC} = -8.734$ being distributed to members EF and EG as $+3.234$ and $+5.500$, respectively. The part of $+5.500$ carried over to joint G is $+1.903$. This is combined with -12.582 to produce a net moment $M_{GE} = -10.679$ which is distributed to members GH and GI. Line 9, Table 5(*b*), gives the final moments for this step.

Step (*g*).—If the system is in equilibrium, the sum of the end moments for the columns should equal 1 kip × 12 ft or 12.000 ft-kips. However, the actual sum of these moments listed in line 9, Table 5(*b*), is $+0.157$, showing that an additional $+11.843$ must be furnished. To effect this adjustment the joints A, C, E, G, and I, Fig. 8, will be translated a convenient distance $\Delta = \frac{12}{E}$ laterally to the right. Using Eqs. 20*a* and 20*b*, the induced moments are:

$$M_{AB} = \frac{6 \times 9 \times 12}{12} \times \left(\frac{2 \times 12 + 12}{4 \times 12 \times 23.90 - 12 \times 12} \right) = 1.938$$

$$M_{BA} = \frac{6 \times 9 \times 12}{12} \times \left(\frac{2 \times 23.90 + 12}{4 \times 12 \times 23.90 - 12 \times 12} \right) = 3.219$$

$$M_{CD} = \frac{6 \times 6 \times 12}{12} \times \left(\frac{2 \times 12 + 12}{4 \times 12 \times 16.04 - 12 \times 12} \right) = 2.071$$

$$M_{DC} = \frac{6 \times 6 \times 12}{12} \times \left(\frac{2 \times 16.04 + 12}{4 \times 12 \times 16.04 - 12 \times 12} \right) = 2.536$$

$$M_{EF} = \frac{6 \times 4 \times 12}{12} \times \left(\frac{2 \times 12 + 12}{4 \times 12 \times 14.65 - 12 \times 12} \right) = 1.546$$

$$M_{FE} = \frac{6 \times 4 \times 12}{12} \times \left(\frac{2 \times 14.65 + 12}{4 \times 12 \times 14.65 - 12 \times 12} \right) = 1.773$$

$$M_{GH} = \quad \cdots\cdot \quad = 2.071$$

$$M_{HG} = \quad \cdots\cdot \quad = 2.536$$

$$M_{IJ} = \quad \cdots\cdot \quad = 1.938$$

$$M_{JI} = \quad \cdots\cdot \quad = 3.219$$

These moments are tabulated and distributed in Table 5(*a*). The sum of the end moments for the columns is 25.204.

Step (*h*).—The shear correction factor is: $\frac{11.843}{25.204} = 0.470$.

Step (*i*).—Multiply the moments in line 5, Table 5(*a*), by 0.470 and tabulate the results in line 10, Table 5(*b*). The addition of lines 9 and 10 gives the final moments for the frame including the effect of joint translation.

EXAMPLE 4

A single-panel, open-web (Vierendeel) truss is loaded as shown in Fig. 9. The end moments of all members are required.

TABLE 5.—TABULATION AND DIS-

Line	Description	COLUMNS					JOINT A

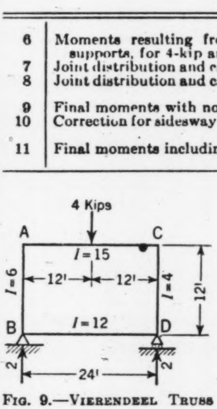

FIG. 9.—VIERENDEEL TRUSS

Step (*a*).—To compute the elastic factors and the elastic lengths for the several members it is necessary to start with a single member having a fixed or hinged joint at one end. The idea of the "fixed joint" is now introduced for the purpose of establishing, temporarily, a joint of known rigidity. Joint B is assumed to be temporarily secured against rotation.

Step (*b*).—Computations for step (*b*) are as shown in Table 6. The elastic and carry-over factors are as follows:

Joint	Computation	Carry-over factor	Joint	Computation	Carry-over factor
A to B	....	0.500	D to B	....	0.500
C to A	$\frac{24}{2 \times 46.50}$	0.258	C to D	$\frac{12}{2 \times 18.00}$	0.333
D to C	$\frac{12}{2 \times 17.57}$	0.341	A to C	$\frac{24}{2 \times 61.50}$	0.195
B to D	$\frac{24}{2 \times 53.85}$	0.223	B to A	$\frac{12}{2 \times 20.66}$	0.290

Step (*c*).—Eq. 11 is used to obtain a general expression for the moments induced in the ends of the members framing into a joint when the joint is rotated a unit amount. If θ_A is equal to unity, Eq. 11 becomes:

$$M_{AB} = \frac{1}{Z_{AB}} \qquad \text{(27)}$$

					(b) Step (d) and Step (i)						
....	....	+9.436	−8.734	....	+11.645	−12.582	....	....	....	....	6
....	....	....	....	+3.234	+5.500	+1.903	+5.066	+5.613	+1.727	−1.727	7
-3.626	−3.273	−2.538	−7.333	−4.312	....	....	....	....	....	....	8
-3.626	−3.273	+6.898	−16.067	−1.078	+17.145	−10.679	+5.066	+5.613	+1.727	−1.727	9
-0.745	+1.171	−0.425	−0.403	+0.806	−0.403	−0.425	+1.171	−0.746	−1.043	+1.043	10
-4.371	−2.102	+6.473	−16.470	−0.272	+16.742	−11.104	+6.237	+4.867	+0.684	−0.684	11

The "fixed joint" B is rotated a unit amount producing the following moments which are assumed positive for convenience: $M_{BA} = 1.755$ and $M_{BD} = 1.688$. The moment M_{BA} (= 1.755) is tabulated and distributed in line 1, Table 7(*a*), assuming that member BD is secured against rotation during the operation; $M_{BD} = 1.688$ is tabulated and distributed in line 2; and line 3 contains the final moments for this step.

The external moment required to rotate joint B a unit amount is found as follows: Let M_B be the external moment. Then $M_B + M_{BA} + M_{BD} = 0$; and $M_B = -(M_{BA} + M_{BD}) = -(1.738 + 1.671) = -3.409$. The quantity M_B is required for the calculation of the rotation correction factor of steps (*e*) and (*g*).

Step (*d*).—From Example 1(*a*), $A = 288$ and $\bar{x}_A = \bar{x}_C = 12$. Then

$$M_{AC} = \frac{6 \times 288}{24}\left(\frac{2 \times 61.50 \times 12 - 24 \times 12}{4 \times 61.50 \times 46.50 - 24 \times 24}\right) = 7.874;$$

and

$$M_{CA} = \frac{6 \times 288}{24}\left(\frac{2 \times 46.50 \times 12 - 24 \times 12}{4 \times 61.50 \times 46.50 - 24 \times 24}\right) = 5.488.$$

Moments M_{AC} and M_{CA} are tabulated and distributed in line 10, Table 7(*c*).

Step (*e*).—The "fixed joint" B is eliminated in the following manner: The external moment required to hold joint B fixed against rotation, as assumed in the computations for step (*d*), is equal but opposite in sign to the sum of the internal moments, M_{BA} and M_{BD} in line 10, Table 7(*c*). This external moment is $-(-3.937 - 0.914) = +4.851$; and, to release the joint, an additional external moment of -4.851 is also applied at joint B. The rotation correction factor is $\dfrac{-4.851}{-3.409} = +1.423$.

Step (*f*).—To find the moments in the members due to the external moment of -4.852 applied at joint B, multiply the moments in line 3, Table 7(*a*), by $+1.423$ and enter the product in line 11, Table 7(*c*). Line 12, Table 7(*c*), gives the final moments if sidesway is prevented.

TABLE 6.—COMPUTATIONS FOR STEP (*b*), EXAMPLE 4

AC.......	L_{AC}	$24 + \frac{3 \times 15}{1.200}$	61.50	Z_{AC}	$\frac{24}{3 \times 15}\left(\frac{61.50 - 6}{61.50}\right)$	$\frac{1}{2.078}$
BA.......	L_{BA}	$12 + \frac{3 \times 6}{2.078}$	20.66	Z_{BA}	$\frac{12}{3 \times 6}\left(\frac{20\ 66 - 3}{20.67}\right)$	$\frac{1}{1.755}$

Step (*g*).—For equilibrium the sum of the end moments for members AB and CD should equal 12×0 or 0 since there are no lateral loads. The actual sum of these moments from line 12, Table 7(*c*), is -1.872, showing that an additional $+1.872$ must be furnished by the lateral movement of joints A and C relative to joints B and D. For the purpose of finding the lateral deformation required for equilibrium, joints A and C are translated a convenient distance $\Delta = 12/E$ laterally to the right. The induced moments are:

$$M_{AB} = \frac{6 \times 6 \times 12}{12}\left(\frac{2 \times 12 + 12}{4 \times 12 \times 20.66 - 12 \times 12}\right) = 1.528$$

$$M_{BA} = \frac{6 \times 6 \times 12}{12}\left(\frac{2 \times 20.66 + 12}{4 \times 12 \times 20.66 - 12 \times 12}\right) = 2.264$$

$$M_{CD} = \frac{6 \times 4 \times 12}{12}\left(\frac{2 \times 18 + 12}{4 \times 18 \times 17.57 - 12 \times 12}\right) = 1.027$$

$$M_{DC} = \frac{6 \times 4 \times 12}{12}\left(\frac{2 \times 17.57 + 12}{4 \times 18 \times 17.57 - 12 \times 12}\right) = 1.009$$

These moments are entered in line 4 and distributed in lines 5 and 6, Table 7(*b*), assuming joint B is fixed against rotation. Line 7 gives the moments before releasing joint B. The releasing moment is + 1.843 or 2.397 − 0.554. The rotation correction factor is $\frac{+\,1.843}{-\,3.409}$ or − 0.541.

TABLE 7.—Tabulation and Distribution of Moments, Example 4

13	Correction for sidesway (line 9 × + 0.333)..............	+0.485	+0.511	−0.511	−0.446	+0.446	+0.430	−0.430	−0.485
14	Final moments...............	−0.979	−6.685	+6.685	−5.893	+5.893	+1.771	−1.771	+0.979

Multiply the moments in line 3, Table 7(*a*), by − 0.541 and enter the product in line 8, Table 7(*b*). Line 9 gives the moments due to the lateral displacement of $12/E$ including the effect of releasing joint B.

Step (*h*).—The sum of the end moments for members AB and CD, from line 9, Table 7(*b*), is + 5.628. The shear correction factor is $\frac{+\,1.872}{+\,5.628} = +\,0.333$.

Step (*i*).—Multiply the moment in line 9, Table 7(*b*), by + 0.333 and tabulate the result in line 13, Table 7(*c*). The addition of lines 12 and 13 gives the final moments for the frame including the effect of joint translation laterally (see line 14, Table 7(*c*)).

EXAMPLE 5

A double-panel, open-web truss is loaded as shown in Fig. 10. The end moments of all members are required.

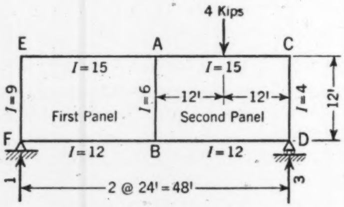

FIG. 10.—DOUBLE-PANEL OPEN-WEB TRUSS

Step (*a*).—Joint B is assumed to be temporarily secured against rotation.

Step (*b*).—In Table 8, the detailed computations are omitted for quantities that have been computed in Example 4. The elastic and carry-over factors are:

Joint	Computation	Carry-over factor	Joint	Computation	Carry-over factor
D to B.....	....	0.500	F to B.....	....	0.500
C to D.....	....	0.333	E to F.....	$\frac{12}{2 \times 25.50}$	0.235

A to B.....	....	0.500	B to A.....	$\frac{12}{2 \times 16.22}$	0.370
E to A.....	$\frac{24}{2 \times 35.04}$	0.343	C to A.....	$\frac{24}{2 \times 34.74}$	0.346
F to E.....	$\frac{12}{2 \times 23.93}$	0.251	D to C.....	$\frac{12}{2 \times 17.29}$	0.347
B to F.....	$\frac{24}{2 \times 37.99}$	0.316	B to D.....	$\frac{24}{2 \times 53.76}$	0.223

Step (*c*).—The "fixed joint" B is rotated a unit amount producing the following moments: $M_{BF} = 1.781$, $M_{BA} = 1.840$, and $M_{BD} = 1.688$. These moments are tabulated and distributed in Table 9(*a*). In line 1, the moment due to the rotation of member BA is distributed as far as members AE and AC. In line 2 the moment due to the rotation of member BF is distributed to member AC where it is combined with that due to the rotation of BA. The resultant moment is then distributed on the remainder of the line. A similar condition exists in line 3 where the distribution is begun with the rotation of member BD. The final moments for this step are given in line 4, Table 9(*a*). The external moment M_B is equal to $-(1.767 + 1.816 + 1.676) = -5.259$.

Step (*d*).—From Example 1(*a*) $A = 288$ and $\bar{x}_A = \bar{x}_C = 12$. Then,

$$M_{AC} = \frac{6 \times 288}{24}\left(\frac{2 \times 61.50 \times 12 - 24 \times 12}{4 \times 61.50 \times 34.74 - 24 \times 24}\right) = 10.733;$$

and

$$M_{CA} = \frac{6 \times 288}{24}\left(\frac{2 \times 34.74 \times 12 - 24 \times 12}{4 \times 61.50 \times 34.74 - 24 \times 24}\right) = 4.980.$$

These moments are tabulated and distributed in line 17, Table 9(*d*).

Step (*e*).—The external moment necessary to release joint B is the sum of the internal moments at point B which are listed in line 17, Table 9(*d*). This releasing moment is -3.573. The rotation correction factor is $\frac{-3.573}{-5.259} = +0.679$.

Step (*f*).—Multiply the moments in line 4, Table 9(*a*), by $+0.679$ to obtain the moments due to -3.573 applied externally at point B and enter the product in line 18, Table 9(*d*). Line 19, Table 9(*d*), gives the final moments if vertical shear deformation is prevented.

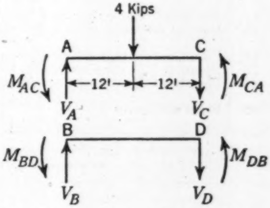

FIG. 11.—FREE-BODY DIAGRAM, SECOND PANEL OF FIG. 10

Step (*g*).—In the first panel of Fig. 10 the sum of the end moments for members EA and FB should equal 1 kip × 24 ft for equilibrium, but the actual sum from line 19, Table 9(*d*), is − 6.428. In the second panel the sum of the end moments for members AC and BD should equal − 1 kip × 24 ft, but the actual sum is + 4.548.

The proof of the statement that the sum of the moments should be − 24 is given as follows: Fig. 11 shows a free-body sketch of members AC and BD. Since they do not enter into the computations, the direct stresses are omitted. In Fig. 11, $V_A = \dfrac{M_{AC} + M_{CA}}{24} + \dfrac{4 \times 12}{24}$; and $V_B = \dfrac{M_{BD} + M_{DB}}{24}$.

[a] Moments resulting from the elasticity of supports. [b] Final moments resulting from translation, assuming joint B fixed against rotation and vertical movement. [c] Correction for the translation of the member indicated.

The sum of the shears $V_A + V_B$ is equal to 1 from the first panel and therefore: $\dfrac{M_{AC} + M_{CA} + M_{BD} + M_{DB}}{24} + 2 = 1$; and $M_{AC} + M_{CA} + M_{BD} + M_{DB} = -1 \times 24$.

that joint B is fixed against rotation. [c] Moments after releasing joint B. [d] Moments created by load, assuming

Since the frame is not in equilibrium vertically, deformation sufficient to satisfy the shear requirements must take place across each panel. To compute these deformations, first translate member EF a convenient distance $\Delta = 24/E$ vertically upward relative to member AB. The induced moments are:

$$M_{EA} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 35.04 + 24}{4 \times 35.04 \times 41.65 - 24 \times 24}\right) = 1.609$$

$$M_{AE} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 41.65 + 24}{4 \times 35.04 \times 41.65 - 24 \times 24}\right) = 1.836$$

$$M_{FB} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 24.00 + 24}{4 \times 24.00 \times 37.99 - 24 \times 24}\right) = 1.688$$

$$M_{BF} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 37.99 + 24}{4 \times 24.00 \times 37.99 - 24 \times 24}\right) = 2.344$$

These moments are entered in line 5 and distributed in lines 6 and 7, Table 9(*b*), assuming joint B fixed against rotation. Line 8 gives the moments before releasing joint B. The releasing amount is + 2.014.

The rotation correction factor is $\frac{+\,2.014}{-\,5.259} = -\,0.383$. Multiply the moments in line 4, Table 9(*a*), by − 0.383 and tabulate the product in line 9, Table 9(*b*). Line 10 yields the moments due to the translation of member EF including the effect of releasing the joint.

Next, to compute the deformations, translate member CD a convenient distance $\Delta = 24/E$ vertically upward relative to member AB. The induced moments are:

$$M_{CA} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 34.74 + 24}{4 \times 34.74 \times 61.50 - 24 \times 24}\right) = 1.056$$

$$M_{AC} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 61.50 + 24}{4 \times 34.74 \times 61.50 - 24 \times 24}\right) = 1.660$$

$$M_{DB} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 24.00 + 24}{4 \times 24.00 \times 53.76 - 24 \times 24}\right) = 1.131$$

$$M_{BD} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 53.76 + 24}{4 \times 24.00 \times 53.76 - 24 \times 24}\right) = 2.066$$

These moments are entered in line 11 and distributed in lines 12 and 13, Table 9(*c*). Line 14 gives the moments before releasing joint B. The releasing moment is − 1.782. The rotation correction factor is − 1.782/− 5.259 = + 0.339. Multiply the moments in line 4, Table 9(*a*), by + 0.339 and list the product, line 15, Table 9(*c*). Line 16 gives the moments due to the translation of member CD including the effect of releasing the joint.

Step (*h*).—Let *X* be the shear correction factor (required deformation across the panel) for the first panel; and let *Y* be the shear correction factor (required deformation across the panel) for the second panel. The sum of the end moments from the tables for the following members is:

Reference	Members EA and FB	Members AC and BD
Line 10, Table 9(*b*)	+ 7.841	− 1.987
Line 16, Table 9(*c*)	+ 1.987	− 6.364
Line 19, Table 9(*d*)	− 6.428	+ 4.547

From the foregoing, the shear equations can be written as follows: For the first panel—

$$7.841\,X + 1.987\,Y - 6.428 = 24.00 \quad \text{(28a)}$$

and, for the second panel—

$$-1.987\,X - 6.364\,Y + 4.547 = -24.00 \quad \text{(28b)}$$

Solving Eqs. 28 simultaneously, $X = 2.980$ and $Y = 3.555$.

Step (*i*).—Multiply the moments in line 10, Table 9(*b*), by + 2.980 and those in line 16, Table 9(*c*), by + 3.555. Tabulate the results in lines 20 and 21, Table 9(*d*). The addition of lines 19, 20, and 21 gives the final moments including the effect of joint translation (see line 22).

Example 6

A four-panel, open-web truss is loaded as shown in Fig. 12. The end moments of all members are required.

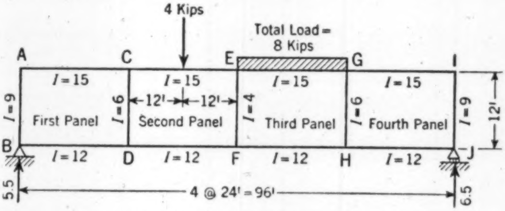

Fig. 12.—Four-Panel Open-Web Truss

Step (*a*).—Joints D and H are assumed to be temporarily secured against rotation.

Step (*b*).—Computations for step (*b*) are arranged in Table 10, the elastic lengths and stiffness factors for JH through DB, HG, and HF being determined by symmetry. The carry-over factors are:

Joint	Computation	Carry-over factor	Joint	Computation	Carry-over factor

Step (*c*).—The "fixed joint" D is rotated a unit amount producing the following moments: $M_{DB} = 1.7813$, $M_{DC} = 1.8445$, and $M_{DF} = 1.8098$. These moments are tabulated and distributed as shown in Table 11 under "(*a*) Unit

Rotation of Joint D." Joint H is assumed fixed against rotation during this operation.

Next the "fixed joint" H is rotated a unit amount producing the following moments: $M_{HJ} = 1.7813$, $M_{HG} = 1.8445$, and $M_{HF} = 1.8098$. From symmetry it is evident that the values given in Table 11 under "(*b*) Unit Rotation of Joint H" are the result of distributing these moments throughout the frame. The final moments for this step are given in line 4, Table 11. To compute the external moments M_D and M_H resulting from a unit rotation of joints D and H proceed as in Table 12.

TABLE 12.—COMPUTATION OF EXTERNAL MOMENTS, STEP (*c*), EXAMPLE 6

Symbol	Joint rotated	Computation	External moment
M_D	D	$-(1.7695 + 1.8290 + 1.8055)$	-5.4040
M_H	D	$-(0.1945 - 0.0105 - 0.0008)$	$+0.2058$
M_D	H	. . . .	$+0.2058$
M_H	H	. . . .	-5.4040

Step (*d*).—The values of A and x for the 4-kip concentrated load and the 8-kip uniform load are taken from Examples 1(*a*) and 1(*b*). Then:

$$M_{CE} = \frac{6 \times 288}{24}\left(\frac{2 \times 36.797 \times 12 - 24 \times 12}{4 \times 36.797 \times 34.738 - 24 \times 24}\right) = 9.444$$

$$M_{EC} = \frac{6 \times 288}{24}\left(\frac{2 \times 34.738 \times 12 - 24 \times 12}{4 \times 36.797 \times 34.738 - 24 \times 24}\right) = 8.660$$

$$M_{EG} = \frac{6 \times 384}{24}\left(\frac{2 \times 34.738 \times 12 - 24 \times 12}{4 \times 34.738 \times 36.797 - 24 \times 24}\right) = 11.547$$

$$M_{GE} = \frac{6 \times 384}{24}\left(\frac{2 \times 36.797 \times 12 - 24 \times 12}{4 \times 34.738 \times 36.797 - 24 \times 24}\right) = 12.592$$

These moments are entered in line 15 and distributed in line 16, Table 13(*c*), assuming that joints D and H are fixed against rotation and that vertical movement of all joints is prevented. Note that -4.105 listed in line 15, Table 13(*c*), under member EF is the proportional part of 11.547 which is distributed to member EF. Line 17 gives the moments before releasing joints D and H.

Step (*e*).—The external moment necessary to release joints D and H is the sum of the internal moments at each of these joints, as listed in line 17, Table 13(*c*); thus: The releasing moment for $D = -0.122 - 1.640 + 0.103 = -1.659$; and the releasing moment for $H = +0.103 + 2.545 + 0.189 = +2.836$. The external moments at each of these joints due to a unit rotation of each joint have been tabulated at the end of step (*c*). Similar to step (*h*), Example 5, let X_L be the rotation correction factor for joint D, or the amount that joint D must rotate to release both joints, assumed fixed during the load computations for step (*d*); and let Y_L be a similar rotation correction factor for joint H.

TABLE 13.—TABULATION AND DISTRIBUTION OF MOMENTS, EXAMPLE 6

Equations can be written: For joint D—

$$-\ 5.404\ X_L + 0.206\ Y_L = -\ 1.659 \qquad (29a)$$

and, for joint H—

$$+\ 0.206\ X_L - 5.404\ Y_L = +\ 2.836 \qquad (29b)$$

Solving simultaneously: $X_L = 0.288$ and $Y_L = -\ 0.514$.

Step (f).—Multiply the moments in line 4, Table 11, by + 0.288 and enter the product in line 18, Table 13(*c*), under the same moment subscripts as those given under "(*a*) Unit Rotation of Joint D" in Table 11. Next multiply the moments in line 4, Table 11, by − 0.514 and enter the result in line 19, Table 13(*c*), under the same moment subscripts as those given under "(*b*) Unit Rotation of Joint H" in Table 11. Line 20, Table 13(*c*), gives the final moments if deformation due to vertical shear is prevented.

Step (g).—To compute the required shear deformations translate member AB a distance $\Delta = 24/E$ vertically upward with respect to CD. The induced

25	+22.388	+16.623	−5.468	−11.155	−16.522	+50.012	−33.490	−43.595	+43.505

moments are:

$$M_{AC} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 34.612 + 24}{4 \times 34.612 \times 41.647 - 24 \times 24}\right) = 1.6156$$

$$M_{CA} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 41.647 + 24}{4 \times 34.612 \times 41.647 - 24 \times 24}\right) = 1.8602$$

$$M_{BD} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 24.000 + 24}{4 \times 24.000 \times 37.992 - 24 \times 24}\right) = 1.6879$$

$$M_{DB} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 37.992 + 24}{4 \times 24.000 \times 37.992 - 24 \times 24}\right) = 2.3440$$

These moments are entered in line 1 and distributed in lines 2 and 3, Table 13(*a*), assuming joints D and H fixed against rotation. Line 4, Table 13(*a*), gives the moments before releasing joints D and H. The releasing line moment for *D* from line 4, Table 13(*a*), is + 2.5341 − 0.4733 − 0.0123 = + 2.0485;

and, similarly, for joint H the releasing moment is $- 0.0123 - 0.0184 - 0.0014 = - 0.0321$.

If X_{T1} and Y_{T1} are the correction factors for joints D and H, respectively, equations can be written: Let X_{T1} equal the rotation correction factor for joint D; and Y_{T1} equal the rotation correction factor for joint H. For joint D—

$$- 5.4040\,X_{T1} + 0.2058\,Y_{T1} = + 2.0485 \qquad (30a)$$

and, for joint H—

$$+ 0.2058\,X_{T1} - 5.4040\,Y_{T1} = - 0.0321 \qquad (30b)$$

Solving Eqs. 30, $X_{T1} = - 0.3794$ and $Y_{T1} = - 0.0085$.

Multiply the moments in line 4, Table 11, by $- 0.3794$ and enter the result in line 5, Table 13(*a*), under the same moment subscripts as those given under "(*a*) Unit Rotation of Joint D," in Table 11. Next multiply the moments in line 4, Table 11, by $- 0.0085$ and tabulate in line 6, Table 13(*a*), under the same moment subscripts as those given under "(*b*) Unit Rotation of Joint H," in Table 11. Line 7, Table 13(*a*), gives the moments due to the translation of AB, including the effect of releasing joints D and H.

Next, CD is translated a distance $\Delta = 24/E$ vertically upward relative to EF. The induced moments are:

$$M_{CE} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 36.797 + 24}{4 \times 36.797 \times 34.738 - 24 \times 24}\right) = 1.9359$$

$$M_{EC} = \frac{6 \times 15 \times 24}{24}\left(\frac{2 \times 34.738 + 24}{4 \times 36.797 \times 34.738 - 24 \times 24}\right) = 1.8543$$

$$M_{DF} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 35.051 + 24}{4 \times 35.051 \times 24.000 - 24 \times 24}\right) = 2.4294$$

$$M_{FD} = \frac{6 \times 12 \times 24}{24}\left(\frac{2 \times 24.000 + 24}{4 \times 35.051 \times 24.000 - 24 \times 24}\right) = 1.8588$$

These moments are written in line 8, and distributed in lines 9 and 10, Table 13(*b*), assuming joints D and H fixed against rotation. Line 11 gives the moments before releasing the joints D and H.

The releasing moment for joint D from line 11, Table 13(*b*), is: $- 0.0352 - 0.4741 + 2.4953 = + 1.9860$; and, similarly, for joint H: $- 0.5047 + 0.0864 + 0.0064 = - 0.4119$. Let X_{T2} and Y_{T2} be the rotation correction factors for joints D and H, respectively. Then equations can be written: For joint D—

$$- 5.4040\,X_{T2} + 0.2058\,Y_{T2} = + 1.9860 \qquad (31a)$$

and, for joint H—

$$+ 0.2058\,X_{T2} - 5.4040\,Y_{T2} = - 0.4119 \qquad (31b)$$

Solving Eqs. 31 simultaneously: $X_{T2} = - 0.3651$ and $Y_{T2} = + 0.0623$.

Multiply the moments in line 4, Table 11, by $- 0.3651$ and tabulate in line 12, Table 13(*b*), under the same moment subscripts as those given under "(*a*) Unit Rotation of Joint D," in Table 11. Next multiply the moments in line 4, Table 11, by + 0.0623 and tabulate in line 13, Table 13(*b*), under the same moment subscripts as those given under "(*b*) Unit Rotation of Joint H," in Table 11. Line 14, Table 13(*b*), gives the moments due to the translation of CD including the effect of releasing joints D and H.

The final moments due to the translation of GH a distance of $\Delta = 24/E$ vertically downward relative to EF are given in line 1, Table 14. These values are obtained from line 14, Table 13(*b*), as a result of the symmetry of the frame.

The final moments due to the translation of IJ a distance $\Delta = 24/E$ relative to GH are given in line 2, Table 14. These values are obtained from Table 13(*a*) as a result of symmetry.

2	IJ.......	−0.9252	−0.3192	+0.1441	+0.1751	+0.0633	−0.0344	−0.0289	−0.0094	+0.0094

TABLE 15.—SUM OF END MOMENTS, STEP (*h*), EXAMPLE 6

Members	Table 13(*a*)	Table 13(*b*)	Table 14	Table 14	Table 13(*c*)	End moments should be:
	Line 7	Line 14	Line 1	Line 2	Line 20	
AC and BD.......	+7.8715	−2.1041	+0.4024	−0.0611	−4.388	+132.000
CE and DF.......	−2.1931	+7.7230	−2.6503	+0.4023	−8.139	+84.000
EG and FH.......	+0.4023	−2.6503	+7.7230	−2.1931	+5.635	−60.000
GI and HJ.......	−0.0611	+0.4024	−2.1941	+7.8715	+6.684	−156.000

Step (*h*).—Let W, X, Y, and Z represent the shear correction factors for the first, second, third, and fourth panels, respectively. Coefficients for the solution are assembled as shown in Table 15 and are used for the construction of shear equations as follows: For the first panel—

$$7.8715\,W - 2.1941\,X + 0.4024\,Y - 0.0611\,Z - 4.388 = +132.000 \quad (32a)$$

for the second panel—

$$-2.1931\,W + 7.7230\,X - 2.6503\,Y + 0.4023\,Z - 8.139 = +84.000 \quad (32b)$$

for the third panel—

$$0.4023\,W - 2.6503\,X + 7.7230\,Y - 2.1931\,Z + 5.635 = -60.000 \quad (32c)$$

and, for the fourth panel—

$$-0.0611\,W + 0.4024\,X - 2.1941\,Y + 7.8715\,Z + 6.684 = -156.000 \quad (32d)$$

Solving Eqs. 28, simultaneously: $W = 22.064$; $X = 15.617$; $Y = -11.224$; and $Z = -24.423$.

Step (*i*).—Multiply the moments in line 7, Table 13(*a*), by $W = 22.064$ and tabulate in line 21, Table 13(*c*). Multiply the moments in line 14, Table 13(*b*), by $X = 15.617$ and tabulate in line 22, Table 13(*c*). Multiply the moments in line 1, Table 14, by $Y = -11.224$ and tabulate in line 23, Table 13(*c*). Multiply the moments in line 2, Table 14, by $Z = -24.423$ and tabulate in line 24, Table 13(*c*). The addition of lines 20 to 24, inclusive, gives the final moments including the effect of joint translation.

EXAMPLE 7

A multiple story transverse bent is loaded as shown in Fig. 13. The end moments of all members are required.

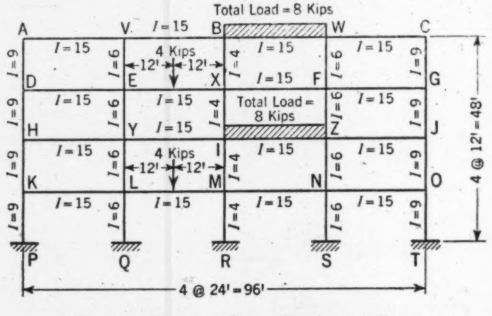

FIG. 13.—MULTIPLE STORY TRANSVERSE BENT

Step (*a*).—Joints V, W, X, Y, and Z are assumed to be secured against rotation temporarily.

Step (*b*).—Compute the stiffness factors, elastic lengths, and carry-over factors.

Step (*c*).—Rotate each of the "fixed joints" a unit amount. Then tabulate and distribute the induced moments for each "fixed joint" in a separate table.

Because of symmetry, only three tables are necessary. Compute the unbalanced moments at each of the "fixed joints" in each table.

Step (*d*).—Compute the end moments for the loaded members. Tabulate and distribute these moments in a fourth table.

Step (*e*).—Compute the releasing moments for each of the "fixed joints" from the table of step (*d*). With unbalanced moments from step (*c*), and these releasing moments, form and solve the five simultaneous equations required for the computation of the rotation correction factors for load.

Step (*f*).—Tabulate the rotation correction moments in the table of step (*d*).

Step (*g*).—Translate each story laterally an amount $\Delta = 12/E$. Tabulate and distribute the induced moments in a separate table for each story. Five simultaneous equations are required for each of the four story tables to correct for the rotation of the five "fixed joints." However, it should be noted that the coefficients of the corresponding unknowns for each set of equations are identical, the only difference being in the constants. Therefore, the four sets of equations may be solved with only slightly more labor than that involved for one set. Tabulate the rotation correction moments in the proper story tables.

Step (*h*).—From the final moments resulting from translation in step (*g*) shear correction equations are formed for the four stories. The solution of these four simultaneous equations gives the required shear correction factors.

Step (*i*).—Tabulate the shear correction moments in the table of step (*d*). The final moments are found by summing up the effect of load, rotation, and translation. Thus, the exact solution of the seventy-two unknown moments is obtained with two sets of simultaneous equations. One set consists of four equations to compensate for sidesway and the other of five equations to correct for the "fixed joints." The latter set will have a column of constants for each load considered.

SUMMARY

A method has been developed for analyzing continuous frames with prismatic members. The extension to members having a variable cross section may be made in a manner similar to that used in previous publications.[6] The method is particularly adapted to the solution of frames such as the Vierendeel truss. The effect of flexible connections which is considered in aircraft analysis is included in the paper.

---

[6] "Lateral Loads and Members of Variable Section," *Bulletin No. 66*, Eng. Experiment Station, Ohio State University, Columbus, Ohio, 1931.

DISCUSSION

L. J. Mensch,[7] M. ASCE.—The method of balancing fixed-end moments—connected with the name of Hardy Cross,[8] M. ASCE,—has had an immense success with teachers and students in the analysis of framed structures. Such members were formerly designed by the conventional moment formulas $\left(\frac{w\,L^2}{10}, \frac{w\,L^2}{12}, \text{and } \frac{PL}{6}\right)$ as first adopted by the Hennebique firm of Paris, France, before the turn of the century, and as since adopted by many building codes, except for the cases of very long spans, for which engineers of mathematical ability used Clapeyron's theorem, or a more or less complicated variation of it.

Professor Cross's method did not require deep studies or high mathematical skill, which explains its immediate success, but, at best, it is only a trial-and-error method requiring considerable time. Shorter methods have been known ever since Saint-Venant demonstrated that distant members have no appreciable effect on the member under investigation. For example, referring to Fig. 8, in the analysis of girder CE, the restraint of members AC, CD, EF, and EG only have to be taken into account.

The authors have shown Clapeyron's so-called exact method with new nomenclature simplified by previous calculation of certain elastic constants. However, even this simplified method requires too much effort for everyday use. Elsewhere[9,10,11,12] the writer has shown that a great deal more time and effort may be saved by the same theorem if Saint-Venant's principle is used. For girder CE in Fig. 8, the primary moments[10] are given by:

$$M_{CE} = \frac{3\,P\,L}{8} \frac{1 + 2\,N_E}{4\,(1 + N_C)\,(1 + N_E) - 1} \quad \text{.............} (33a)$$

$$M_{EC} = \frac{3\,P\,L}{8} \frac{1 + 2\,N_C}{4\,(1 + N_C)\,(1 + N_E) - 1} \quad \text{.............} (33b)$$

when

$$N_E = \frac{3\,K}{\Sigma m\,K_E} \quad \text{......................} (34a)$$

and

$$N_C = \frac{3\,K}{\Sigma m\,K_C} \quad \text{......................} (34b)$$

In these equations m is an elastic factor depending on the restraint of each adjacent member at the far end. When the end is hinged, $m = 3$; when the end is fixed, $m = 4$; when the restraint lies between these two conditions, $m = 3.6$ is a good guess.

[8] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, ASCE, Vol. 96, 1932, p. 1.

[9] *Ibid.*, Vol. 83, 1919–1920, p. 1682.

[10] *Ibid.*, Vol. 102, 1937, p. 1050.

[11] *Ibid.*, p. 897 and p. 438.

[12] *Journal*, ACI, February, 1932, p. 387.

For girders, $K = I/L$; for columns, $K = I/h$. For girder CE, $K = 15/24$; $K'_C = 15/24$; $K''_C = 6/12$; $K'_E = 15/24$; $K''_E = 4/12$;

$$N_C = \frac{3 \times 15/24}{3.6 \times 15/24 + 4 \times 6/12} = 0.442;$$

and

$$N_E = \frac{3 \times 15/24}{3.6 \times 15/24 + 4 \times 4/12} = 0.522.$$

These values, when introduced in Eqs. 33*a* and 33*b* with those for $P = 4{,}000$ and $L = 24$, give $M_{CE} = 9{,}615$ ft-lb and $M_{EC} = 8{,}660$ ft-lb, which agree within 1% with the values given in Table 5. These moments will be modified by the action of the 8,000-lb uniform load on span EG.

The moments in EG are found from the formulas:

$$M_{EG} = \frac{W\,L}{4}\,\frac{1 + 2\,N_G}{4\,(1 + N_E)\,(1 + N_G) - 1} \qquad \ldots\ldots\ldots\ldots (35a)$$

$$M_{GE} = \frac{W\,L}{4}\,\frac{1 + 2\,N_E}{4\,(1 + N_E)\,(1 + N_G) - 1} \qquad \ldots\ldots\ldots\ldots (35b)$$

It is easily found that $N_E = 0.522$ and $N_G = 0.422$, so that

$$M_{EG} = \frac{8{,}000 \times 24}{4}\,\frac{1 + 2 \times 0.422}{4 \times 1.422 \times 1{,}522 - 1} = 11{,}550 \text{ ft-lb}$$

and

$$M_{GE} = \frac{8{,}000 \times 24}{4}\,\frac{1 + 2 \times 0.522}{4 \times 1.422 \times 1.522 - 1} = 12{,}820 \text{ ft-lb},$$

which again closely agree with the tabulated results. Moment M_{EG} must be distributed to EC and EF in relation to stiffness, thus, $M'_{EC}:M'_{EF} = 3.6 \times 15/24 : 4 \times 4/12$, from which $M'_{EC} = 7{,}250$ ft-lb and $M'_{EF} = 4{,}300$ ft-lb. The maximum moment is $M_{EC} = 8{,}660 + 7{,}250 = 15{,}910$ ft-lb, as compared with 16,067 ft-lb given in the table.

The maximum value of M_{EG} is found by a similar distribution of the moment of M_{EC}, and is $M_{EG} = 11{,}550 + 8{,}660 \times 54/86 = 16{,}990$ ft-lb, as compared with 17,145 ft-lb in Table 5.

If the value of $m = 4$ for the columns be replaced by $m = 3.6$, there is a slight modification of the value of the moments, usable for Example 6, Fig. 12.

To show a short cut for analyzing sidesway, Example 2, Fig. 7, is chosen. Then,

$$M_{AC} = \frac{3\,P\,L}{8}\,\frac{1 + 2\,N_C}{4\,(1 + N_A)\,(1 + N_C) - 1} \qquad \ldots\ldots\ldots\ldots (36a)$$

$$M_{CA} = \frac{3\,P\,L}{8}\,\frac{1 + 2\,N_A}{4\,(1 + N_A)\,(1 + N_C) - 1} \qquad \ldots\ldots\ldots\ldots (36b)$$

In this problem $N_C = \dfrac{3 \times 15/24}{4 \times 4/12} = 1.408$ and $N_A = \dfrac{3 \times 15/24}{4 \times 6/12} = 0.938$, so that $M_{AC} = 7{,}720$ ft-lb and $M_{CA} = 5{,}830$ ft-lb when no sidesway is possible. Then the shears acting in the columns will be: In AB $(7{,}720 + 7{,}720/2)/12 = 965$ lb; in CD $(5{,}830 + 5{,}830/2)/12 = 729$ lb. These shears should be equal. They can be made so if an imaginary force of $965 - 729 = 236$ lb be assumed as acting in a horizontal direction (AC) at the top of the column. The problem is to find the proportionate parts to be assigned to each column, and, furthermore, how these shears modify the moments at the top and bottom of the columns.

By figuring a number of multicolumn bents the writer found that the proportionate part taken by column AB closely equals $\frac{K_{AB} + K_{AC}}{K_{AB} + 2\,K_{AC} + K_{CD}}$ $= \frac{6/12 + 15/24}{6/12 + 2 \times 15/24 + 4/12} = 0.54$, and that the shear in AB equals 236 × 0.54 = 127 lb, and, in CD = 238 − 127 = 111 lb. The zero point of moments produced in the fixed-ended columns by these shears is located between 0.4 h and 0.5 h from the column top. In many cases a good average for this distance is 0.45 h. Hence, the moment at the top of column AB is diminished by 127 × 0.45 × 12 = 686 ft-lb, and the moment at the top of column CD is increased by 111 × 0.45 × 12 = 600 ft-lb, which values closely agree with those in Table 3.

As another example for finding the shear, it is proposed to find the proportionate part of the shear for columns CD and AB of Fig. 8. For column CD, it is

$$\frac{K_{CA} + K_{CE} + K_{CD}}{\Sigma K \text{ of columns} + 2\,\Sigma K \text{ of all girders}}$$

$$= \frac{15/24 + 15/24 + 6/12}{2 \times 9/12 + 2 \times 6/12 + 4/12 + 2 \times 4 \times 15/24} = 0.223,$$

and, for column AB, it is $\frac{K_{AC} + K_{AB}}{\Sigma K \text{ of columns} + 2\,\Sigma K \text{ of girders}} = 0.176.$

The authors deserve great credit for having shown clearly the influence of sidesway in their examples. They have, however, side-stepped the issue of the influence of the width of the columns and the depth of the girders on the calculated moments.

Tests to near destruction of properly designed frames have consistently shown reserve strengths from 30% to more than 100% greater than those predicted by the classical "exact" theories. This was partly because the clear spans were smaller than the center-to-center distances, and partly because the plasticity of materials of construction under high stresses and long time loading made the negative moments considerably smaller. This discrepancy has long been known, but the use of the center-to-center distances and the use of a constant modulus of elasticity is still preached; it seems to have become an article of faith.

The writer cannot refrain from emphasizing that the deluge of literature on the analysis of framed structures since World War I has drowned the works of the few true thinking pioneers and the investigators of genius. In addition, this mass of literature has so dazzled students that they have lost their heads in the belief that everything old was wrong and everything new was right, and that a study of these new methods will lead them to an advanced standing in their profession, and to prosperity. The fact is that they are being robbed not only of their time, and their chance of acquiring useful knowledge, but also of their money.

Frederick S. Merritt,[13] Assoc. M. ASCE.—Several papers such as this one have been published in recent years demonstrating the feasibility of one-cycle moment distribution. They are proof that open-minded designers recognize that multicycle distribution has many shortcomings in both theoretical and practical applications. Although it can be proved that, in general, one-cycle distribution is a more powerful tool than multicycle distribution, most of these papers, including this one, do not conclusively show superiority over the multicycle method in solving practical problems. The reasons are quite evident:

---

[13] Asst. Editor, *Engineering News-Record,* New York, N. Y.

Either method can be used to analyze statically indeterminate structures, and the papers on one-cycle distribution published in the past in *Proceedings* have been unable to prove that the method is simpler, quicker, or easier to visualize—because too many extraneous concepts are introduced, requiring much preliminary computation. For example, in this paper "elastic length" is an unnecessary concept, as far as practical problems in general are concerned; results in extra computations when evaluating elastic properties of every span; and increases the number of required formulas, as well as complicating them. Thus, the superiority of one-cycle distribution will not be conclusive until the preliminary computations are reduced to a minimum and then by comparison it is shown that less work is involved than in, say, two cycles of fixed-end distribution.

The first step in streamlining one-cycle moment distribution is to base the method on the fewest necessary and sufficient fundamental terms for evaluating the elastic properties of each span, independent of the rest of the structure. Experience shows that the least number of terms required is three. Although these may be selected in many ways, the best ones are those that yield the simplest and fewest formulas.

A group that satisfies this criterion is $C^F{}_L$, $C^F{}_R$, and K. The first two are the "moment ratios" to left and right, respectively, for fixed ends—the ratio of the moment applied at one end of a beam to the moment carried over or induced at the other end when rotation is completely prevented. The third term is the moment to be applied at one end of the beam, considering it simply supported, to produce a unit rotation at the other end. These terms apply to beams of variable moment of inertia as well as to prismatic sections.

For beams of constant moment of inertia, $C^F{}_L = C^F{}_R = 2$ and $K = 6\,E\,I/L$. Since relative values of K are used in most cases, the coefficient 6 may often be disregarded.

Secondary terms needed to solve specific problems may be evaluated using the fundamental terms. For example, the moment to be applied at the left end of a beam, considering it simply supported, to produce unit rotation there is $K/C^E{}_L$.

The second streamlining step is to evaluate the end restraints due to the rest of the structure in the least number of terms. Instead of using "flexibility" for distribution of moments at a joint, requiring manipulation of reciprocal relationships, as the authors did, it is preferable to use stiffness. The stiffness S of the end of an unloaded span is defined as the moment producing a rotation of unity at the end where it is applied when the other end of the beam is restrained against rotation by other members of the structure.

Simpler formulas result if they are expressed in terms of "moment ratios."[14] The moment ratio C is defined for an unloaded member of a continuous structure as the ratio of the moment introduced at one end of the span to the moment carried over to the other end. Thus, moment ratio is the reciprocal of the authors' carry-over factor.

Equivalent to "combined flexibility," restraint R at the end of an unloaded beam at a joint is the moment applied at that end to produce a unit rotation in all the members at the joint. By definition of continuity, R is equal to the sum of the stiffnesses of the adjacent ends of the other members at the joint. Furthermore, the moment induced in any of these other members bears the same ratio to the applied moment as the stiffness of the member does to the restraint. Consequently, end moments are distributed at a joint in proportion to the stiffnesses of the members.

Stiffness can be expressed in terms of C as follows:

$$S_L = \frac{K}{C^F{}_L - 1/C_R} \qquad \text{(37a)}$$

$$S_R = \frac{K}{C^F{}_R - 1/C_L} \qquad \text{(37b)}$$

For beams of constant moment of inertia,

$$S_L = \frac{K}{2 - 1/C_R}\,; \qquad S_R = \frac{K}{2 - 1/C_L} \qquad \text{(37c)}$$

In turn, moment ratios can be computed in terms of the stiffnesses of adjacent spans:

$$C_L = C^F{}_L + \frac{K}{R_L} \qquad \text{(38a)}$$

$$C_R = C^F{}_R + \frac{K}{R_R} \qquad \text{(38b)}$$

Toward hinged supports, for which $R = 0$, C is infinitely large; toward fixed ends, for which R is infinitely large, $C = C^F$. For beams of constant moment of inertia,

$$C_L = 2 + \frac{K}{R_L}\,; \qquad C_R = 2 + \frac{K}{R_R} \qquad \text{(38c)}$$

A physical interpretation of moment ratios, in addition to the carry-over concept, can be obtained in terms of fixity, defined as the ratio C^F/C, which varies from zero for simple supports to 100% for fixed ends. If θ_P is the rotation of a beam at a hinged support and θ is the rotation when restraint is present, it can be shown that fixity is equal to $1 - \frac{\theta}{\theta_P}$ and, consequently, is a straight-line function of the angular rotation. For example, if a column footing rotates 0.4 as much as it would if it were unrestrained by the soil, the fixity is 1 − 0.4, or 0.6. Also, assuming $C^F = 2$, the moment ratio for the column in the direction of the footing may be taken as 2/0.6, or 3.33. In addition, this concept can be used in the case of flexible connections.

---

[14] "Moment Ratios Simplify Continuity Analysis," by Frederick S. Merritt, *Engineering News-Record*, November 1, 1945, p. 112, and November 15, 1945, p. 102.

Corresponding to Eqs. 16 for prismatic beams, the following formulas apply for end moments in loaded spans of variable moment of inertia (clockwise end moments and rotations being assumed positive):

$$M_L = -\frac{K(C_R\,\phi_L + \phi_R)}{C_R\,C_L - 1} \qquad \text{(39a)}$$

$$M_R = -\frac{K(C_L\,\phi_R + \phi_L)}{C_R\,C_L - 1} \qquad \text{(39b)}$$

in which ϕ represents the simple beam end rotation due to the load on the span. However, it is generally easier to begin distribution with fixed-end moments.

To indicate how this streamlined version works, Example 1(*a*) is recalculated. Referring to Fig. 6 and noting that the relative value of K is unity for all spans:

Step (*a*).—Same as the authors.

Step (*b*).—$S_{BA} = \frac{1}{2 - 1/2} = 0.667$; $C_{CB} = 2 + \frac{1}{0.667} = 3.5$. Similarly, $S_{DB} = \frac{1}{2 - 1/\infty} = 0.5$; $C_{CD} = 2 + \frac{1}{0.5} = 4$; $S_{CD} = \frac{1}{2 - 1/4} = 0.571$; and $C_{BC} = 2 + \frac{1}{0.571} = 3.75$.

Step (*d*).—For a concentrated load at the center of a simply supported span, $\phi = \pm \frac{3\,P\,L}{8\,K}$. Therefore, $M_{BC} = -\frac{3.75 \times 0.375 - 0.375}{3.75 \times 3.5 - 1} \times 4 \times 24 = -8.16$; and $M_{CB} = \frac{3.5 \times 0.375 - 0.375}{3.75 \times 3.5 - 1} \times 4 \times 24 = 7.42$. Then, $M_{AB} = \frac{8.16}{2} = 4.08$ and $M_{DC} = \frac{-7.42}{4} = -1.86$.

Example 4 (Fig. 9) is also solved to illustrate a more general technique.

Step (*a*).—For prismatic beams, the moment ratio can be estimated from

$$C = 2 + \frac{\gamma\,K_1}{\Sigma K} \qquad \text{(40)}$$

in which K_1 is the K-value of the member whose C-value is to be assumed; ΣK is the sum of the K-values of the other members of the joint toward which the ratio is directed; and γ is a constant varying from 1.5 for full restraint to 2.0 for no restraint at the far ends of these other members. Since γ varies between such narrow limits, it has only a very small effect on C.

From Fig. 9, the relative values of K are: $K_{AB} = 6$; $K_{CD} = 4$; $K_{AC} = 7.5$; and $K_{BD} = 6$. Assume $C_{AB} = 2 + \frac{1.75 \times 6}{6} = 3.75$ and $C_{CD} = 2 + \frac{1.75 \times 4}{6} = 3.17$.

Step (*b*).—Through the use of these assumed moment ratios, the distribution constants for the other members may be found. $S_{AB} = \frac{6}{2 - \frac{1}{3.75}} = 3.46$;

$C_{CA} = 2 + \frac{7.5}{3.46} = 4.17; S_{CA} = \frac{7.5}{2 - \frac{1}{4.17}} = 4.26; C_{DC} = 2 + \frac{4}{4.26} = 2.94; S_{DC} = \frac{4}{2 - \frac{1}{2.94}} = 2.41$; $C_{BD} = 2 + \frac{6}{2.41} = 4.49$; and $S_{BD} = \frac{6}{2 - \frac{1}{4.49}} = 3.38$. The corrected $C_{AB} = 2 + \frac{6}{3.38} = 3.77$ and S_{AB} is practically unchanged.

Similarly, $S_{CD} = \frac{4}{2 - \frac{1}{3.17}} = 2.37; C_{AC} = 2 + \frac{7.5}{2.37} = 5.16; S_{AC} = \frac{7.5}{2 - \frac{1}{5.16}} = 4.15$; $C_{BA} = 2 + \frac{6}{4.15} = 3.45$; $S_{BA} = \frac{6}{2 - \frac{1}{3.45}} = 3.51$; $C_{DB} = 2 + \frac{6}{3.51} = 3.71$; and $S_{DB} = \frac{6}{2 - \frac{1}{3.71}} = 3.47$. The corrected $C_{CD} = 2 + \frac{4}{3.47} = 3.15$ and S_{CD} is practically unchanged.

Next, a moment of + 1,000 is applied at each joint separately, and distributed. For example, for a moment of 1,000 at joint A, $M_{AB} = \frac{3.46}{3.46 + 4.15} \times 1{,}000 = 455$; $M_{BA} = \frac{455}{3.77} = 121$; $M_{BD} = -121$; $M_{DB} = -\frac{121}{4.49} = -27$; $M_{DC} = 27; M_{CD} = \frac{27}{2.94} = 9; M_{CA} = -9; M_{AC} = -\frac{9}{4.17} = -2$. Moments thus determined are given in Table 16.

Step (*d*).—From Example 1(*a*), ϕ for the 4-kip load is $\pm \frac{3\,P\,L}{8\,K}$, and the fixed-end moments are numerically equal to $\frac{2 \times 0.375 - 0.375}{4 - 1} \times 4 \times 24 = 12$. These moments are then distributed by multiplying the values in Col. 2, Table 16, by 0.012, and those in Col. 4 by − 0.012. Moments for the 4-kip load with sidesway prevented are shown in Table 17(*a*).

TABLE 16.—INFLUENCE FACTORS FOR MOMENT OF 1,000 APPLIED AT EACH JOINT, EXAMPLE 4

Member (1)	Point of Moment Application Joint A (2)	 Joint B (3)	 Joint C (4)	 Joint D (5)
AC....	546	−139	145	13
AB....	454	139	−145	−13
BA....	112	510	−11	−150
BD....	−112	490	11	150
DB....	6	100	−104	591
DC....	−6	−100	104	409
CD....	−97	−8	357	130
CA....	+97	8	643	−130

Step (*g*).—Under sidesway, joints A and C deflect equal amounts horizontally. Hence, the fixed-end moments in AB and CD caused by a horizontal movement, being proportional to the *K*-values, are in the ratio of 6 to 4. To eliminate the forces that were assumed to prevent sidesway to permit distribution of moments for the 4-kip load, apply fixed-end moments of −1,000 *M* at the top and bottom of CD and of −1,500 *M* at the top and bottom of AB.

Then, using Table 16, distribute the moments and assemble the results as in Table 17(*b*).

Step (*h*).—The shear in AB and CD due to these moments plus the moments previously obtained for the 4-kip load must be zero.

$$+7.19 - 769\,M + 1.48 - 728\,M - 5.44 - 670\,M - 1.32 - 646\,M = 0$$

$$2{,}813\,M = 1.91$$

$$M = 0.00068$$

[a] Distribution of moment applied at the joint designated.

Step (*i*).—Multiplication of the values in line 10, Table 17(*b*), by this value of M gives the sidesway correction for the 4-kip load (line 11, Table 17(*c*)), and the final moments (line 12) are obtained by addition of these corrections to the moments for sidesway prevented (line 4).

I. OESTERBLOM,[15] M. ASCE.—For some years structural frames have been analyzed by the relaxation method so as to avoid the innumerable equations involved in the energy methods, with their attendant confusion and labor. In other words, the classical methods were dead when it came to the matter of analyzing frames. In the face of this trend, the authors have resurrected the classical treatment of frames—with a modification.

The first few pages set up a foundation by borrowing, chiefly from the classics, but also from the modern "relaxationists." A new element, the "elasticity factor," L, is introduced. There follow two pages of real substance and twenty-seven pages of illustrative examples. The first pages can be passed over quickly after they have been recognized as mostly old acquaintances. So also can the last pages, when it is found how simple the problems are; for any method will solve a primitive problem fairly and with little labor.

---

[15] Engr., Carbide and Carbon Chemicals Corp., South Charleston, W. Va.

As to the real substance of the paper, it is claimed that the new method provides very well for "flexible connections," meaning such as have a small but limited rotation; and that it is applicable to Vierendeel type trusses and frames (see heading, "Summary"). In a sense this is true; but the same may be claimed for the relaxation method when used intelligently; seemingly the latter can be adapted more simply and with less labor. The elaborate calculations shown for the easy problems in this paper are thus not at all inviting.

Among the many who have tried to improve upon the relaxation method, or to overcome the discouraging algorithms of the classics in the solution of frames, it has become the custom to illustrate with primitive examples. This is not said in a derogatory sense because such exploration is essential to progress. A few simple problems are in order. In a classroom, no doubt, all the examples had better be primitive, for young minds should not be burdened too heavily; but the larger audience of practicing engineers, will ask of any new method: "Does the method 'work' for an extensive and irregular framework, for short and long spans or columns mixed, for an offset layout, or for an irregular footing plan?" "Will it 'work' with a mixture of all kinds of loads—point loads, spread loads, sway loads, with loads sometimes off and sometimes on?"

With one exception the illustrations are not convincing. Even in the exception the authors offer no solution; they merely present an outline of how the method should be applied. In a practical sense, the exception, Example 7, is not a realistic problem. It does not have the usual complications, but consists of four equal spans in a four-story frame, in which all stories are the same. Loading is confined to two point loads and two spread loads only; no wind is involved. The loads are on the inner spans and are alternating; the point loads are at midspan. The layout is a simple one never found in real life.

Even so, the authors have not presented an answer. Possibly, the elasticity factors L (which should be formulated from all the restraining elements of the frame and not approximated roughly from only those most adjacent) are so complicated that they are entirely beyond human ken, and thus in the same class as the multiple equations in the original classical methods. Perhaps no practical solution is possible; or the answer would be a loose approximation at best. This is thus a challenge to the authors: Can they complete the analysis they have outlined and obtain true answers? If they can they should do so and thus prove that the method has practical value. If they win, their service to the profession is real and they are to be highly honored.

In expressing himself thus forcefully on this subject the writer has had in mind not only the present paper but several others—all erring in the sense that they outline the technique without exploring the underlying philosophy. In a philosophic sense the modern methods are far removed from the classic methods of analyzing elastic frames. Any investigator, pioneering in new ideas as to frames, must therefore anchor his promises to either of the two—

unless he is able to offer an entirely new philosophic approach—for there can be no such thing as a mixture of, or an average between, "energy" and "relaxation" methods; to state the question in more practical terms: Do the current explorers in this field realize the stupendous task they set themselves? The vastly superior relaxation method has its roots in the work of master mathematicians and philosophers, who discovered and developed it under the stress of urgent necessity during World War I; and the development has continued ever since.

When an author therefore makes a claim for a new and better method there must be (and this is a check on his own work) at least one critical and outstanding departure from known and accepted forms. He should analyze and describe this departure and submit a rigorous mathematical proof—either by explicit detail in the text or by tying his thesis by reference to authoritative and readily available sources. If this cannot be done the method is not ready for publication.

A technical paper is a record of constructive thoughts designed for continuing and recurrent study in future time; and it should be sufficiently inclusive to be definitely conclusive both when written and for all time to come. It should be as nearly perfect as possible.

These parenthetical observations, while suggested by this topic, are not aimed exclusively or even primarily at the present paper. They apply to all treatments of statically indeterminate frames, for which claims of complete originality or novelty are advanced.

Thomas C. Kavanagh,[16] Assoc. M. ASCE.—This method of frame analysis is of considerable interest in connection with the calculation of buckling restraints of axially loaded bars in a rigid jointed framework. Methods employing restraint coefficients similar to the authors' "elastic factors" have been employed for this purpose in various forms since the beginning of the twentieth century. All such methods involve solution of the problem of an indeterminate framework wherein the various elastic properties of the members are modified by the presence of axial loads. For the special cases wherein the axial loads are small, their effect may be disregarded as is the custom in ordinary methods of indeterminate analysis.

One of the earliest and most comprehensive uses of restraint coefficients was by H. Zimmermann, who developed the properties of these coefficients (*Spannziffer*) in a long series of publications dating from 1906, summarized in his book[17] on the buckling of frameworks. Eq. 11 is but a slightly different form of the general equation for an axially unloaded bar with rotational end restraints; for on substitution of Eq. 8 it may be rewritten:

$$1 + \frac{L}{3\,E\,I}\left(\frac{1}{Z_B} - \frac{1}{Z_A}\right) - \frac{3}{4}\left(\frac{L}{3\,E\,I}\right)^2 \frac{1}{Z_A}\,\frac{1}{Z_B} = 0 \ldots\ldots\ldots (41)$$

or, by substitution of Mr. Zimmermann's definitions, modified in accordance with the authors' sign convention,

---

[16] Instr. in Civ. Eng., New York Univ., New York, N. Y.

[17] "Knickfestigkeit der Stabverbindungen," by H. Zimmermann, Wilhelm Ernst & Son, Berlin, 1925.

$$m' = -\frac{1}{Z_A}; \qquad m'' = \frac{1}{Z_B} \quad \text{(42)}$$

Eq. 41 takes the basic form,

$$1 + A\,(m' + m'') + \tfrac{3}{4}\,A^2\,m'\,m'' = 0 \quad \text{(43)}$$

in which

$$A = \frac{L}{3\,E\,I} \quad \text{(44)}$$

In the case of the axially loaded member, the coefficients are modified, but the form remains the same, and the equation will be found repeated in most literature pertaining to elastic stability of bars. It is significant to note that Eq. 43 can be rewritten in the form,

$$(A\,m' + 4/3)\,(A\,m'' + 4/3) = (\tfrac{2}{3})^2 \quad \text{(45)}$$

which is an equilateral hyperbola, whose properties and physical interpretation were investigated at length by Mr. Zimmermann. Special cases like Eqs. 3 and 5, or others such as equal end restraints, are readily obtainable from these equations.

In 1935–1936, N. J. Hoff[18,19] developed along different lines the concept of the "relative stiffness factor," defined by:

$$\Omega = \frac{E\,I}{L}\,\frac{\theta}{M} \quad \text{(46)}$$

and used it for both axially loaded or axially unloaded members. The symbols on the right are as defined in the authors' paper.

In 1938, the moment distribution approach was utilized by Eugene E. Lundquist,[20] Assoc. M. ASCE, using the concepts of stiffness (elastic factor) and carry-over factor. That the approach is expressible in terms of Eq. 39 was demonstrated by W. R. Osgood, M. ASCE, in a discussion[21] of the same paper. It might be noted here that since the elastic factor is simply the summation of the stiffnesses of the restraining members, it would seem preferable to retain the widely understood term "stiffness" in place of the new term "elastic factor."

In all the above problems, as related to elastic stability analysis, one is faced with the problem of selecting joints with known or assumed restraints (stiffnesses), after which the remaining joints are resolved in a step-by-step process.

The authors are to be commended upon their clear presentation and the systematic procedure outlined, particularly as related to the problems of flexible connections and joint translation. Although the approach considering joint translation has been solved[22] for axially loaded members, it has never been systematically exploited.

A. Floris,[23] Esq.—Introducing a method of analysis of hyperstatic structures, the authors claim that the theory presented in this paper is classical, or exact, requiring the solution of very few, if any, simultaneous elastic equations. This statement needs a close examination.

Classical methods are those which do not require successive or final corrections. The redundant quantities (that is, forces, moments, displacements, and rotations) of the hyperstatic structure are determined by the aid of an algorism in a systematic and unequivocal manner leading always to simple but troublesome linear simultaneous equations. It follows that the classical methods, although tedious and time consuming, are direct and the results obtained are final.

The authors' analysis, on the other hand, is preeminently a relaxation method. In certain cases, relaxation methods require also the solution of simultaneous equations. It is true, that by introducing the elastic moment area (conjugate beam), the authors side-step the iteration process of the moment-distribution method. Nevertheless, their analysis is an indirect one.

In accordance with the usage of American technical literature, the authors call Mohr's elastic moment-area method, the conjugate beam theory. Mohr in his writings[24, 25] never mentioned it, and it is not known in German technical literature by this name. It belongs, instead, to the elastic weights methods. Furthermore, this terminology is mathematically incorrect; for to be called conjugate there must be two paired quantities equal but differing in sign. The moment and the elastic moment areas are unequal and both of the same sign, positive or negative as the case may be. It is perhaps better to call this method the associate beam theory.

In the moment-distribution method the base system is a beam fixed at both ends. By releasing joints one at a time, the carry-over stiffness factors, fixed-end moments, and final moments are determined. By analogy, the base system of the authors' method is a beam elastically supported at both ends. By releasing the fixed points, after the carry-over and elastic factors have been determined, the moments of the elastic moment area, and, finally, the actual moments are found. As in the relaxation methods, the sidesway produced by unbalanced moments and shears is corrected to satisfy the equilibrium of the structure.

In the moment-distribution method the fixed-end moments can be taken from reference books, and are independent of the elasticity of the structure. The bending moments of the authors' base system (Eqs. 16) depend on the elasticity of the whole structure and cannot be determined in advance.

An attentive reader will search in vain for a proof of the analysis developed in this paper; he must be satisfied with heuristic reasoning. Only comparing them with the solutions reached by other well-known methods can the validity of the results obtained by the authors' method be established.

In Fig. 2 and Fig. 3 the beams and moments are not drawn properly, and the interaction of forces and moments is not clear. Support B is fixed in Fig. 2

[25] "Abhandlungen aus dem Gebiete der Technischen Mechanik," by Otto Mohr, Wilhelm Ernst & Sohn, Berlin, 1914, p. 342.

and elastic in Fig. 3. In both cases, point A is hinged but vertically restrained. This is not mentioned explicitly. In end B of the fixed and elastically supported beams, the moment produced by M_{AB} is a rectangle; the moment area of the vertical reaction at A is a triangle with opposite sign. By superimposing the two moment areas, Figs. 2(*a*) and 3(*a*) are obtained.

In addition, the formulas are presented in a rather unsatisfactory and impractical manner. The general expression (Eq. 10*b*), for instance, can be written in the more convenient form—

$$\theta_A = M_{AB}\left(\frac{L}{3\,E\,I} - \frac{L^2}{12\,E\,I\,L_{AB}}\right) \ldots\ldots\ldots\ldots\ldots (47)$$

—in which the influence of support B is clearly indicated. The first term within the parentheses is the elastic factor at end A when end B can rotate freely, which is the basic case. The second term is the elastic factor that shows the influence of the degree of fixity at end B on the rotation of the beam at support A. If B is fixed, then $Z_B = 0$ and, from Eq. 8, $L_{AB} = L$. Thus the expression within the parentheses becomes equal to Eq. 3. On the other hand, if B is hinged, then $Z_B = \infty$, hence $L_{AB} = \infty$ and the second term within the parentheses vanishes, as it should, to agree with Eq. 4.

In conclusion, the proposed method offers no real advantages over the moment-distribution method, although it can be of some value in cases involving only sidesway. It is more tedious, more complicated, and certainly more difficult to remember and apply than the classical methods. The claim that iteration (cycles of distribution) is avoided and that the method is thus rendered briefer is rather illusory.

TAO KING,[26] M. ASCE.—The "classical" method of analyzing continuous frames, presented in this paper, is at least of theoretical interest. Compared with the Hardy Cross method of moment distribution,[27] the authors claim the advantage of avoiding repeated cycles (but the solution of a "few" simultaneous equations is still required), and express the belief that the method is particularly adapted to the solution of frames such as the Vierendeel truss.

All examples given in the paper can be solved readily by the Cross method of distributing fixed-end moments with the application of proper "correction moments" where required. For practical purposes, only three or four cycles are necessary. If convergency is rather slow, five or six cycles may be required. Another advantage of the Cross method lies in the fact that the angles of joint rotations, $E\,\theta$, and those of bar rotations, $E\,R = \frac{E\,\Delta}{L}$, may easily be calculated from the table of moment distribution. These values, when known, will help one in visualizing the deformed structure under the external loads.

---

[26] Head Prof., Civ. Eng., Peiping Polytechnic College, Peiyang Univ., Peiping, China.

[27] *Transactions*, ASCE, Vol. 96, 1932, p. 1.

The Vierendeel trusses in Examples 4 to 7 have rectangular panels and can be solved best by the Cross method. Example 6 is perhaps the most complicated one given by the authors. The writer has solved it by fixed-end moment distribution, as shown in Table 18.

In Table 18 (*a*), line 1 gives the distributing factors, and line 2 shows the fixed-end moments resulting from the loads applied on the top chords CE and EG, Fig. 12. In lines 3, 6, 9, etc., are given the correction moments to be applied so as to balance the unbalanced moments in the panels, resulting from the external loads or reactions, or from the newly introduced hypothetical moments after each cycle of distribution and carry-over. The balancing moments in each panel are divided between the top and bottom chords in proportion to their stiffness factors. Lines 4, 7, 10, etc., show the distributed moments, and lines 5, 8, 11, etc., give the carried-over moments. Final moments are indicated in line 20, which sums up all the moments in each column. For practical results, one might have stopped at the end of the fourth cycle.

No attempt has been made to balance the shears in the verticals; it can be proved easily that, when the moments around all the joints are balanced and when the proper "correction moments" are applied after each cycle, the final shears in the verticals must necessarily be balanced.

If one wishes to obtain still more "exact" values for the final end moments, Table 18(*b*) may be prepared. The values given in the last horizontal line of Table 18(*b*) agree almost exactly with those in line 25, Table 13. The signs of the moments as used by the writer are exactly opposite to those used by the authors.

The products $E\,\theta$ for each joint and $E\,R$ for each member can be readily computed from Table 18. In Example 6, it is evident that: (1) The $(E\,R)$-value for the top chord in any panel should be the same as that for the bottom chord in the same panel; (2) the $(E\,R)$-value for all the verticals should be the same; and (3) the sum of the $(E\,R)$-values for all the bottom chords should be zero, since the supports B and J are unyielding.

Let $E\,R_1$, $E\,R_2$, $E\,R_3$, and $E\,R_4$ be the angles of bar rotation for top and bottom chords in the first, second, third, and fourth panels (see Fig. 12), and let $E\,R_5$ be the angle of bar rotation for each and every vertical. The tentative values of $E\,R_1$, $E\,R_2$, $E\,R_3$, and $E\,R_4$ are computed as follows:

$$E\,R_{BD} = \frac{\text{sum of correction moments}}{-\,6 \times K_{BD}}$$

$$= \frac{-\,29.333 - 23.371 - 7.987 - 3.229 - 1.315 - 0.541 - 0.379}{-\,6 \times \frac{1}{2}} = +\,22.052.$$

(In the foregoing, the value $-\,0.379$ is the last correction moment, 0.541, multiplied by the ratio $\frac{r}{1-r}$ for member BD.) Similarly, $E\,R_{DF} = +\,15.592$; $E\,R_{FH} = -\,11.257$; and $E\,R_{HJ} = -\,24.422$.

The sum of these ($E\,R$)-values, being equal to + 1.965, is not zero. This discrepancy of + 1.965 must be divided equally among the four panels, since the latter are of equal lengths. In other words, all the verticals must rotate through an angle $E\,R_5$ of − 0.491, which is equal to one fourth of this discrepancy with the sign changed. All the tentative ($E\,R$)-values must be combined with this value of $E\,R_5$ in order to obtain the true values of $E\,R_1$, $E\,R_2$, $E\,R_3$, and $E\,R_4$, thus: + 21.561, + 15.101, − 11.748, and − 24.913, respectively. The ($E\,\theta$)-value for any joint may now be computed from:

Σ	−36.478	+36.478	+38.288	−38.288	−27.304	+49.672	−22.368	−16.609

[a] The lines m_1, m_2, etc., are the algebraic sums of carried-over moments, correction moments, and distributed

$$E\,\theta = \frac{\text{sum of distributed moments at the joint}}{\text{four times the sum of stiffness factors around the joint}} + E\,R_5 \quad (48)$$

Thus, $E\,\theta_B$ is found as follows:

$$
\begin{aligned}
E\,\theta_B = &+ 11.733 + 17.600 + 2.148 + 3.223 + 0.891 + 1.336 + 0.371 \\
&+ 0.556 + 0.155 + 0.232 + 0.065 + 0.097 \\
&+ 0.113/4\,(1/2 + 3/4) - 0.491 = + 7.213
\end{aligned}
$$

[a] The lines m_1, m_2, etc., are the algebraic sums of carried-over moments, correction moments, and distributed moments in cycles 1, 2, etc.; m_7 is obtained by multiplying m_6 by $\frac{r}{1 - r}$, in which $r = \frac{m_6}{m_5}$.

LEROY A. BEAUFOY,[28] ESQ.—The method offered by Professors Rathbun and Cunningham is presented in three divisions in terms of its application to different structural types:

(*a*) Structures in which fixed joints need not be introduced, such as continuous beams on unyielding supports, or single story frames of a type in which only a single sidesway may occur;

(*b*) Vierendeel trusses; and

(*c*) Building frames.

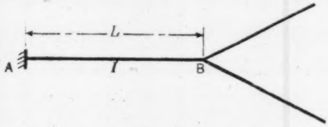

FIG. 14

The writer will direct his discussion at the same three divisions.

In respect of the first, attention is drawn to certain similarities and differences as compared with an earlier paper by Otto Gottschalk.[29] It is easy to show that some of the authors' expressions are, in fact, the same as expressions derived (from a fundamentally different point of view) by Mr. Gottschalk. Thus, consider a beam AB, fixed at end A and connected at joint B to one or more members (Fig. 14). In adapting the Gottschalk symbols to the authors' notation let S_A be the relative stiffness value for end A; S_B be the sum of the relative stiffness values of all members at end A except member BA; $-m$ be the rotation at joint B induced by unit rotation at end A; k be the stiffness ($E\,I/L$) of a member; and c be the carry-over factor from point A to point B. Then, among the expressions derived by Mr. Gottschalk are:

---

[28] Univ. Reader in Civ. Eng., King's College, Univ. of London, London, England.

$$m = \frac{0.5\,k}{S_B + k} \qquad \text{(49a)}$$

$$S_A = (1 - 0.5\,m)\,k \qquad \text{(49b)}$$

and

$$c = \frac{1 - 2\,m}{2 - m} \qquad \text{(49c)}$$

In Eq. 49*a*, writing for *k* its equivalent $\frac{E\,I}{L}$:

$$m = \frac{1}{2\,\frac{S_B\,L}{E\,I} + 2} \qquad \text{(50a)}$$

and substituting this in Eq. 49*c*:

$$c = \frac{1}{2}\left[\frac{L}{L + \frac{3\,E\,I}{4\,S_B}}\right] \qquad \text{(50b)}$$

Transposing to the authors' symbols through their definition for Z_B in Eq. 6, that is,

$$Z_B = \frac{1}{4\,S_B} \qquad \text{(51a)}$$

—and substituting in Eq. 50*b*—

$$c = \frac{1}{2} \times \frac{L}{L + 3\,E\,I\,Z_B} = \frac{1}{2} \times \frac{L}{L_{AB}} \qquad \text{(51b)}$$

which is the same as the corresponding quantity in Eq. 7.

Again, by substituting for *m* from Eq. 50*a*, and writing $E\,I/L$ for *k*, Eq. 49*b* can be rewritten as

$$S_A = \left[\frac{4\,\frac{S_B\,L}{E\,I} + 3}{4\,\frac{S_B\,L}{E\,I} + 4}\right]\frac{E\,I}{L} \qquad \text{(52a)}$$

Substituting $Z_A = \frac{1}{4\,S_A}$ and $Z_B = \frac{1}{4\,S_B}$:

$$Z_A = \frac{L}{3\,E\,I}\left[\frac{(3\,E\,I\,Z_B + L) - \frac{L}{4}}{L + 3\,E\,I\,Z_B}\right] = \frac{L}{3\,E\,I}\left(\frac{L_{AB} - \frac{L}{4}}{L_{AB}}\right) \qquad \text{(52b)}$$

which is the same as Eq. 11.

FIG. 15.—COMPLETE SOLUTION OF EXAMPLE 6 BY MOMENT DISTRIBUTION

However, although the expressions derived by Professors Rathbun and Cunningham are basically the same as those derived by Mr. Gottschalk, the procedure recommended by the authors is quite different. They aim at obtaining a direct solution for a given case of loading, whereas Mr. Gottschalk, by considering the unloaded structure as an elastic body and determining its shape when deformed in a particular manner, obtains influence lines from which stress values for any loading condition can be obtained. Mr. Gottschalk's method, however, can be used for direct stress analysis. The labor involved in the authors' method is no less than that employed in Mr. Gottschalk's method, and the results are tied to a particular loading instead of being readily applied to any loading. In comparing the two methods, therefore, advantage would appear to be with the earlier one.

In fact, taking Example 3 as an instance and comparing the authors' solution with that by the Gottschalk method, there is added labor in the former because of the necessity for calculating the end moments when the ends are elastically supported (what one might call "elastic end moments"); whereas Mr. Gottschalk uses the more easily determined fixed-end moments. Subsequent processes in both methods are comparable and involve approximately the same amount of labor.

The second application, to Vierendeel trusses, is regarded as quite unsatisfactory. As presented, the method involves so many operations that it will not appeal to many engineers who, by using other methods, can much more easily obtain solutions to structures of the types dealt with. Compare the authors' solution to Example 6, which occupied nearly ten pages of the paper, with Fig. 15, which gives, on a single page, the complete solution by moment distribution, using the device of arbitrary joint displacements.[30] It is recognized that the paper sets out specifically to give an "exact" method, but it is submitted that such a method should offer some advantage over existing methods. Whatever the facts may be as regards the claim that the number of simultaneous equations is largely reduced as compared with the classical methods, it remains true to say that many simultaneous equations are left. For instance, Example 6 involves three sets of two simultaneous equations plus one set of four, and it should be noted that for the solution of these equations an ordinary slide rule is inadequate. As the method does not appear to be adapted to the determination of influence lines, separate solutions involving much the same labor would presumably be needed for each case of loading, whenever more than one loading condition has to be investigated. It must also be emphasized that in the case of a Vierendeel truss with non-parallel chords any method utilizing the shearing forces in the panels will encounter special difficulties because the inclined chord mem-

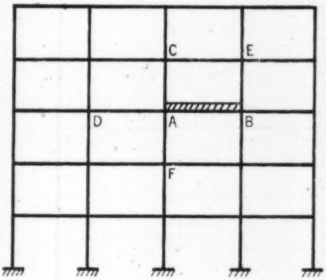

Fig. 16

---

[30] "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, John Wiley & Sons, Inc., New York and London, 1932, p. 228.

bers participate in the resistance to shearing force. It is not considered, therefore, that the authors' claim (that their method is particularly adapted to the solution of Vierendeel trusses) is borne out by the contents of their paper.

The application of the authors' method to building frames may be justified only from the point of view of obtaining an exact solution, for which purpose it has certain merits. Otherwise, it will be found accurate enough in dealing, for example, with the problem in Fig. 16, to start by determining the stiffnesses of the ends AC, AD, and AF, as if all members at points C, D, and F (other than CA, DA, and FA) have their far ends either hinged or fixed. The actual stiffnesses and carry-over factors are determined accordingly, and a solution is readily obtained by the Gottschalk method. It would be easier to assume the far ends to be hinged rather than fixed, since there would then be no unbalanced moments there. The differences between the actual moment and the moments obtained by either of these assumptions will be slight in any case. It may be added that an even quicker solution can be obtained using moment distribution and speeding up the convergence by suitable arbitrary joint displacements.

A final comment relates to a detail in the paper. In Section 7, step (*g*) would be clarified, it is suggested, by adding "the fixed joints must later be released and the moments corrected." In fact the authors do this in Example 6, step (*g*), and mention it again in Example 7, step (*g*). Incidentally, this process alone involves the solution of *a*-groups of *b*-equations each, in which *a* denotes the number of fixed joints and *b* the number of shear displacements.

A. A. EREMIN,[31] Assoc. M. ASCE.—A direct algebraic distribution of moments in continuous frames is shown in this paper by solving the illustrative examples. However, distribution of moments may also be clarified by the graphical construction of moments.

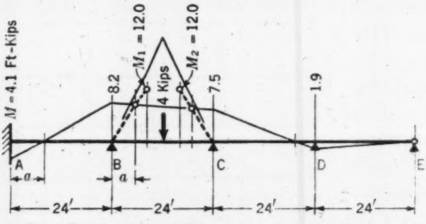

FIG. 17.—GRAPHICAL DETERMINATION OF MOMENTS FOR EXAMPLE 1(*a*)

The moments in Example 1(*a*), determined by the graphics, are shown in Fig. 17. The distance to the inflection point, a, is

$$a = \frac{e\,L}{e + e_0\,Z_A\,\dfrac{I}{L}} \quad \ldots\ldots (53)$$

and the elastic factor is

$$Z_B = \left(e - e_0\,\frac{a}{L - a}\right)\frac{L}{I} \quad \ldots (54)$$

The constants e and e_0 in Eqs. 53 and 54 vary with the shape of the member and may be read from the diagrams prepared by the writer.[32] In a member with a constant section, $e = 0.333$ and $e_0 = 0.167$.

[31] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[32] "Analysis of Continuous Frames by Graphical Distribution of Moments," by A. A. Eremin, Sacramento, Calif., 1943.

The moment closing line in span BC is constructed through the intersection points on the inflection point verticals cut by lines drawn through the central moments M_1 and M_2, as shown in Fig. 17. Similarity of moment distribution shown in Table 1 and that shown by the graphics in Fig. 17 is obvious.

Final moments produced by a combined loading have been computed by the authors by superposition of moments in Tables 2 and 5. The summation operation may be eliminated by application of the "cross lines." The moments determined by the "cross lines" for Example 3 with no sidesway are shown in Fig. 18. Final moments determined by the graphics in Figs. 17 and 18 differ by less than 2% from those computed by the authors.

By applying Eqs. 53 and 54 to the authors' method it may be extended to continuous frames composed of members with varying sections. Application of the "cross lines" and graphical construction of sidesway effect are shown elsewhere.[33,34]

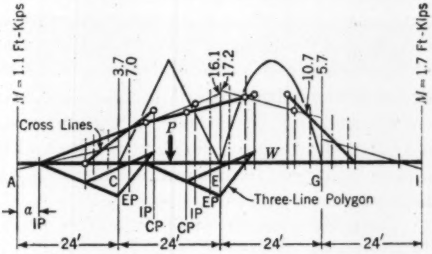

FIG. 18.—GRAPHICAL DETERMINATION OF MOMENTS FOR EXAMPLE 3 WITH NO SIDESWAY

It is still generally believed that the exact computation of moments follows only from algebraic methods. Therefore, it is gratifying that the authors have shown an algebraic method which may be visualized and checked by graphical constructions, not only in the final result but also in successive steps of the computation.

ROBERT B. B. MOORMAN,[35] M. ASCE.—One of the disadvantages in the use of the method of analysis proposed in this paper is the evaluation of $A\bar{x}_A$ and $A\bar{x}_B$ in Eqs. 16 and 17. This may be overcome to a certain degree, for prismatic sections, for uniform loads extending over the span and for concentrated loads by use of the expressions:

$$A\bar{x}_A = \frac{w\,L^4}{24} + \tfrac{1}{6}\,\Sigma P(L - x)(L + x)x$$

$$= \frac{w\,L^4}{24} + \tfrac{1}{6}\,\Sigma P(L^2 - x^2)x \quad (55a)$$

and

$$A\,\bar{x}_B = \frac{w\,L^4}{24} + \tfrac{1}{6}\,\Sigma P(L - x)(2\,L - x)x$$

$$= \frac{w\,L^4}{24} + \tfrac{1}{6}\,\Sigma P(2\,L^2 - 3\,L\,x + x^2)x \quad (55b)$$

The notation is defined in Fig. 19.

[34] *Ibid.*, Vol. 111, 1946, p. 887.

[35] Prof., Civ. Eng., College of Eng., Univ. of Missouri, Columbia, Mo.

It may be of interest to note that methods of analysis along somewhat the same line have been proposed by several others.[36,37,38,39,40]

Eduardo Agramonte,[41] Esq.—The authors have achieved their purpose in presenting a method of direct analysis requiring the solution of few, if any, simultaneous equations; it requires computing stiffness and carry-over factors in order to distribute and to carry over moments. This is more than casual parallelism with other moment-distribution methods and, in fact, warrants the inclusion of the authors' method in the same group.

A single set of basic principles governs slope deflection, iterative and noniterative moment distribution, fixed points, balancing angles, traversing elastic curves, and similar methods. Procedures may vary in many ways, hence the diversity of methods. Some principles and their related operative factors play a prominent part in one group of methods whereas other principles and factors have a greater role in others.

Continuous frame analysis was in need of an expeditious method when Hardy Cross, M. ASCE, presented moment distribution.[8] Universal welcome and adoption are the best proof of its merits; since it is neither unorthodox nor inexact, there is no reason for considering it less classical, precise, or exact than others. Methods of the types presented by T. Y. Lin,[39] Assoc. M. ASCE, J. A. Wise,[42] M. ASCE, and the authors may adequately be grouped as direct, noniterative, or single-cycle moment distribution. Development in this field is in progress; closed frames were a stumbling block, as cyclic computation of stiffnesses, followed by cyclic distribution of moments, appeared inevitable. However, since rapid convergence of values to close degrees of precision was no comfort, the authors' "fixed joint" expedient is a valuable step forward.

Usual moment distribution is simple because prismatic members require only one K-value each, and carry-over factors are known to be 0.5 throughout. For symmetrical members with variable moment of inertia, one stiffness factor and one carry-over factor suffice. Unsymmetrical members require two of each; as a contrast, direct distribution starts with such factors and proceeds to determine two additional stiffnesses, and two more carry-over factors for every member. This amount is quite enough. Auxiliary factors, such as rotation ratios, moment ratios, the authors' "elastic length," and possibly the writer's J-factor (explained hereafter) defeat their purpose.

Direct distribution is especially convenient when dealing with variable moment of inertia. Iterative moment distribution becomes less convergent and its carry-over factors are no longer 0.5. In such cases, direct methods compare to best advantage. For these reasons, the writer feels justified in extending the authors' method to cover nonprismatic members.

Analysis of Individual Members.—If c_{AB} is assumed to be the ordinary carry-over factor from A to B (B fixed), Eq. 1 becomes, for the conditions shown in Fig. 2,

$$M_{BA} = c_{AB}\, M_{AB} \tag{56}$$

Also, if S_{AB} denotes the stiffness of end A when end B is fixed, the flexibility of end A (Eq. 3) will be:

$$Z_{AB(f)} = \frac{1}{S_{AB}} \tag{57}$$

Likewise, if U_{AB} denotes the stiffness of end A when end B is hinged, its value is:

$$U_{AB} = (1 - c_{AB}\, c_{BA})\, S_{AB} \tag{58}$$

Inasmuch as

$$c_{AB}\, S_{AB} = c_{BA}\, S_{BA} \tag{59a}$$

$$c_{AB}\, U_{AB} = c_{BA}\, U_{BA} \tag{59b}$$

Eq. 5 becomes:

$$Z_{AB(h)} = \frac{1}{U_{AB}} \tag{60}$$

Fixed-end moments and c-factors and S-factors for various types of nonprismatic members are available in current literature. As hinged end stiffness factors, U, are decidedly superior to S-factors in direct distribution methods, their appearance in future diagrams or charts for nonprismatic members would be convenient.

The column analogy furnishes the same data for any type of loading and shape. Flexible connections may be treated as incidental to the elastic properties of the member to which they belong, by determining final fixed-end moments and c-factors, U-factors, or S-factors which take the connections into account.

Letting $Z^R{}_A$ and $Z^R{}_B$ be the flexibility of each connection of member AB and $c^{\circ}{}_A$, $c^{\circ}{}_B$, $U^{\circ}{}_A$, $U^{\circ}{}_B$, $\mathrm{FEM}^{\circ}{}_A$, and $\mathrm{FEM}^{\circ}{}_B$, be the factors and fixed-end moments for the member considered deprived of connections, final factors and fixed-end moments become:

$$U_A = \frac{U^{\circ}{}_A}{1 + U^{\circ}{}_A\, Z^R{}_A} \tag{61a}$$

$$c_A = \frac{c^{\circ}{}_A}{1 + U^{\circ}{}_B\, Z^R{}_B} \tag{61b}$$

and

$$\mathrm{FEM}_A = \mathrm{FEM}^{\circ}{}_A - \frac{U_A}{1 - c_A\, c_B}\left(Z^R{}_A\, \mathrm{FEM}^{\circ}{}_A + c_A\, Z^R{}_B\, \mathrm{FEM}^{\circ}{}_B\right) \tag{61c}$$

which are valid for end B by transposition of subindexes.

When one or both ends of a member should be considered infinitely stiff ($I = \infty$) and the central section is prismatic ($I = I_o$) the factors may be computed from Fig. 20, obtained by application of the column analogy.

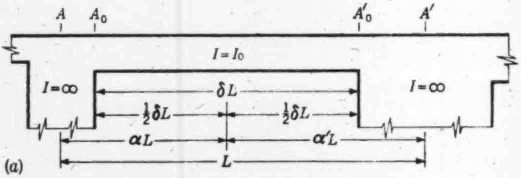
Frame Analysis.—To prevent confusion, the following sign convention is used throughout this discussion:

(*a*) Clockwise rotation is positive.

(*b*) End moments (couples) take the sign of rotation they produce or tend to produce; their sign is opposite to that of the rotations they resist.

(*c*) Bending moments along the span are positive where they produce tension at the under surface of beams or the right side of columns; therefore, when making moment diagrams the sign of all left-end beam moments or bottom-end column moments should be inverted.

(*d*) Shear is positive, where, should transverse shear rupture occur, particles imprisoned between the sliding fracture planes would be made to roll clockwise.



(*b*) STIFFNESS AND CARRY-OVER FACTORS

$$3\,\alpha^2 + \left(\frac{\delta}{2}\right)^2 = m \qquad\qquad m' = 3\,(\alpha')^2 + \left(\frac{\delta}{2}\right)^2$$

$$\frac{m}{\delta^3}\,\frac{4\,E\,I_o}{L} = S \qquad\qquad S' = \frac{m'}{\delta^3}\,\frac{4\,E\,I_o}{L}$$

$$\frac{1}{\delta\,m'}\,\frac{3\,E\,I_o}{L} = U \qquad\qquad U' = \frac{1}{\delta\,m}\,\frac{3\,E\,I_o}{L}$$

$$\frac{3\,\alpha}{m} - 1 = c \qquad\qquad c' = \frac{3\,\alpha'}{m'} - 1$$

$$\text{Check:}\quad \frac{S}{S'} = \frac{U}{U'} = \frac{c'}{c} = \frac{m}{m'}$$

(*c*) FIXED-END MOMENTS FOR UNIFORM LOAD, *w*, ON FULL SPAN

$$(2\,m - \delta^2)\,\frac{w\,L^2}{12} = M_{fAA'} \qquad\qquad M_{fA'A} = (2\,m' - \delta^2)\,\frac{w\,L^2}{12}$$

FIG. 20.—CONSTANTS FOR MEMBERS HAVING INFINITELY STIFF END SECTIONS

In Fig. 21, a positive external moment M_{A-B} acts at end A of member AB causing its positive rotation, θ_A, which is resisted by end B with intensity $M_{AB} = -\,M_{A-B}$. Flexure, thus produced, causes end BA to exert a negative moment M_{BA} at joint B, which in turn induces negative rotation, θ_B. All other members (BC, BD, and BE) react in unison, opposing an aggregate negative moment $M_{B-A} = -\,M_{BA}$. The writer propounds subindexes such as "B–A" as illustrative for moments or factors at joint B, pertaining to all members meeting at this joint except member BA.

If moment M_{A-B}, in Fig. 21, would originate rotation $\theta_A = +1$ radian, it would equal T_{AB}, the stiffness of end A of member AB. The reciprocal of T_{AB} is Z_{AB}; the rotation originated by unit moment $M_{A-B} = +1$—the flexibility of end A. If members AB, BD, and BE are suppressed and an external moment is applied at B to end BC, stiffness T_{BC}, or flexibility Z_{BC} of member BC, would be similarly illustrated.

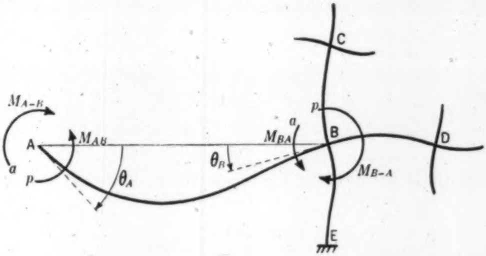


FIG. 21.—EXTERNAL MOMENT APPLIED AT END A OF MEMBER AB

Resistance to rotation at B, provoked by such a moment as M_{BA}, coming from member AB, depends on the aggregate stiffness of ends BC, BD, and BE, which is

$$T_{B-A} = T_{BC} + T_{BD} + T_{BE} = \frac{1}{Z_{B-A}} \qquad (62)$$

which in turn is equivalent to Eq. 13*b*. The total stiffness at B would be:

$$\begin{aligned} T_{B+} &= T_{BA} + T_{BC} + T_{BD} + T_{BE} = T_{B-A} + T_{BA} \\ &= T_{B-C} + T_{BC} = \cdots = T_{B-N} + T_{BN} \qquad (63) \end{aligned}$$

The authors provide no symbol for the carry-over or transmission factor.[43] Let such a factor be g; then $M_{BA} = g_{AB}\,M_{AB}$ in Fig. 21. Elastic lengths, flexibility, and carry-over factors for flexibly connected members are given in the following expressions—respectively, equivalent to Eqs. 24, 22, and 25:

$$L_{2AB} = (1 + Z^R{}_{AB}\,U^o{}_{AB})\,L \qquad (64a)$$

$$L_{3AB} = [1 + (Z^R{}_{BA} + Z_{B-A})\,U^o{}_{BA}]\,L \qquad (64b)$$

and

$$Z_{AB} = \frac{L_{2AB}\,L_{3AB} - c^o{}_{AB}\,c^o{}_{BA}\,L^2}{U^o{}_{AB}\,L_{3AB}\,L} \qquad (64c)$$

Also,

$$g_{AB} = c^o{}_{AB}\,\frac{L}{L_{3AB}} \qquad (65)$$

However, if values of c and U are previously computed to take into account the flexibility of connections, as in Eqs. 61, no further attention is necessary in that respect and Eqs. 66 to Eq. 86 apply directly.

Analysis of the frame may be accomplished by:

$$L_{AB} = (1 + U_{BA}\,Z_{B-A})\,L \qquad (66a)$$

and

$$Z_{AB} = \frac{L_{AB} - c_{AB}\,c_{BA}\,L}{U_{AB}\,L_{AB}} \qquad (66b)$$

---

[43] "Moving Loads on Restrained Beams and Frames," by R. C. Brumfield, *Transactions*, ASCE, Vol. 111, 1946, p. 807.

by following the operative sequence, Eqs. 13*b*, 66*a*, and 66*b*, obtaining *g*-factors independently from:

$$g_{AB} = c_{AB} \frac{L}{L_{AB}} \quad \text{(66c)}$$

Or, by the operative sequence, Eqs. 62, 67*a*, and 67*b*

$$g_{AB} = \frac{c_{AB}\, T_{B-A}}{U_{BA} + T_{B-A}} \quad \text{(67a)}$$

and

$$T_{AB} = \frac{U_{AB}}{1 - c_{BA}\, g_{AB}} \quad \text{(67b)}$$

Or, since products *g T* are as useful as single *g*-factors:

$$g_{AB}\, T_{AB} = \frac{c_{BA}\, U_{BA}\, T_{B-A}}{U_{BA} + (1 - c_{AB}\, c_{BA})\, T_{B-A}} \quad \text{(68a)}$$

and

$$T_{AB} = U_{AB} + c_{BA}\,(g_{AB}\, T_{AB}) \quad \text{(68b)}$$

may be found by the operative sequence, Eqs. 62, 68*a*, and 68*b*.

It may be found less tiresome, however, to avoid the repeated alternative use of expressions so dissimilar as types *a* and *b* of Eqs. 66, 67, or 68 by dealing, in the first place, with stiffnesses,

$$T_{AB} = \frac{(U_{BA} + T_{B-A})\, U_{AB}}{(U_{BA} + T_{B-A}) - c_{AB}\, c_{BA}\, T_{B-A}} \quad \text{(69a)}$$

by using Eqs. 62 and 69*a*, and to compute *g*-factors or (*g T*)-factors afterwards:

$$g_{AB} = \frac{T_{AB} - U_{AB}}{T_{AB}\, c_{BA}} \quad \text{(69b)}$$

or

$$g_{AB}\, T_{AB} = \frac{T_{AB} - U_{AB}}{c_{BA}} \quad \text{(69c)}$$

As a check on *T*-factors, *g*-factors, or (*g T*)-factors computed, obtaining for each member at the same time a new factor, *J*, that is useful for loading and sidesway analyses, these expressions hold true:

$$\frac{g_{AB}\, T_{AB}\, T_{A-B}}{T_{A+}} = J = \frac{g_{BA}\, T_{BA}\, T_{B-A}}{T_{B+}} \quad \text{(70)}$$

If B is fixed, $T_{B-A} = T_{B+} = \infty$, and

$$\frac{g_{AB}\, T_{AB}\, T_{A-B}}{T_{A+}} = J = g_{BA}\, T_{BA} \quad \text{(71)}$$

If B is hinged, $T_{B-A} = g_{AB} = J = 0$, but a check is offered by

$$\frac{c_{AB}\, T_{AB}\, T_{A-B}}{T_{A+}} = g_{BA}\, U_{BA} \quad \text{(72)}$$

Factor *J* is also equivalent to

$$J = \frac{U_{AB}}{c_{BA}} \frac{g_{AB}\, g_{BA}}{1 - g_{AB}\, g_{BA}} = \frac{U_{AB}}{c_{BA}} \frac{L^2}{\dfrac{L_{AB}\, L_{BA}}{c_{AB}\, c_{BA}} - L^2} \quad \text{(73)}$$

Transverse Loading.—Referring to Fig. 4, the moment diagram Fig. 4(*c*) considering the member as simply supported, must first be reduced, dividing its ordinates M by the local values of $E\,I$ along the span. Area A' and the location of the centroid (x_A, x_B) of the resulting diagram must be determined. Then, member AB, as actually connected to the frame, will exert moments M_{AB} at A and M_{BA} at B (opposite to those shown in Fig. 4(*b*) which amount to:

$$M_{AB} = A' \frac{U_{AB}}{c_{BA}} \frac{x_A\,L - \dfrac{x_B}{c_{AB}}\,L_{AB}}{\dfrac{L_{AB}\,L_{BA}}{c_{AB}\,c_{BA}} - L^2} \qquad (74)$$

which is equivalent to Eq. 16*a*. By inverting the subindexes M_{BA} is given. If the J-factor for the span is known,

$$M_{AB} = J \quad A' \left(\frac{x_A}{L} - \frac{x_B}{g_{AB}\,L} \right) \qquad (75a)$$

and

$$M_{BA} = J \quad A' \left(\frac{x_A}{g_{BA}\,L} - \frac{x_B}{L} \right) \qquad (75b)$$

When fixed-end moments are obtainable, no moment diagrams are necessary, since

$$M_{AB} = \frac{\text{FEM}_{AB}}{T_{A+}}\,T_{A-B} - \frac{\text{FEM}_{BA}}{T_{B+}}\,g_{BA}\,T_{BA} \qquad (76)$$

which also is valid for M_{BA} by transposition of the subindexes.

Sidesway.—Eqs. 20 take any of these alternative forms:

$$M_{AB} = \Delta U_{AB} \frac{L_{AB} + c_{AB}\,L}{L_{AB}\,L_{BA} - c_{AB}\,c_{BA}\,L^2} \qquad (77)$$

$$M_{AB} = \frac{\Delta}{L} \frac{1 + g_{AB}}{g_{AB}}\,J \qquad (78)$$

$$M_{AB} = \frac{\Delta}{L} \frac{(T_{AB} + g_{AB}\,T_{AB})\,T_{A-B}}{T_{A+}} \qquad (79)$$

and

$$M_{AB} = \frac{\Delta}{L} \left(\frac{T_{AB}}{g_{AB}\,T_{AB}} + 1 \right) J \qquad (80)$$

Transmission of Moments.—Stiffness T is, by definition, moment capable of provoking unit rotation; moments M_{A-B} and M_{BA} (Fig. 21) provoke rotations θ_A and θ_B, and the moment M_{CB} transmitted to C will provoke rotation θ_C. Hence,

$$\theta_A = \frac{M_{A-B}}{T_{AB}} \qquad (81a)$$

$$\theta_B = \frac{M_{BA}}{T_{B-A}} \qquad (81b)$$

and

$$\theta_C = \frac{M_{CB}}{T_{C-B}} \qquad (81c)$$

and such rotations awake the passive reactions:

$$M_{AB} = -\theta_A T_{AB} \dots\dots (82a)$$

$$M_{B-A} = -\theta_B T_{B-A} \dots\dots (82b)$$

$$M_{BC} = -\theta_B T_{BC} \dots\dots (82c)$$

and

$$M_{BD} = -\theta_B T_{BD} \dots\dots (82d)$$

and so on, for the other moments.

Distribution results from combining Eqs. 81 and Eqs. 82, which give

$$M_{B-A} = -M_{BA} \dots\dots (83a)$$

$$M_{BC} = -\frac{M_{BA}}{T_{B-A}} T_{BC} \dots\dots (83b)$$

and

$$M_{BD} = -\frac{M_{BA}}{T_{B-A}} T_{BD} \dots\dots (83c)$$

Carry-over (active) moments result either from distributed (passive) moments at the far end ($M_{CB} = g_{BC} M_{BC}$) or directly, in a single slide-rule movement, when distributing from active moments outside the far end, thus:

$$M_{CB} = -\frac{M_{BA}}{T_{B-A}} g_{BC} T_{BC} \dots\dots (84a)$$

and

$$M_{DB} = -\frac{M_{BA}}{T_{B-A}} g_{BD} T_{BD} \dots\dots (84b)$$

in which case products $g\,T$ apply throughout instead of single g-factors (see Eqs. 69, 70, 71, 76, 79, and 80). This also allows abbreviated distribution—by computing only active moments for the whole frame first, and passive moments when and where desired.

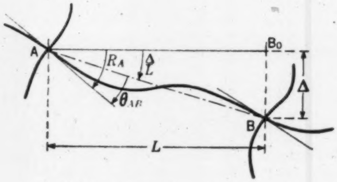

FIG. 22.—ROTATION AT JOINTS

Check on Final Moments.—The tangent at end A of a member AB (Fig. 22) forms an angle θ_{AB} with the straight line joining A and B such that:

$$\theta_{AB} = -\frac{(M_{AB} - \mathrm{FEM}_{AB}) - c_{BA}(M_{BA} - \mathrm{FEM}_{BA})}{U_{AB}} \dots\dots (85)$$

in which the fixed-end moments (FEM) are those due to all transverse loads on the member, and M_{AB} and M_{BA} are the actual moments at each end. This expression holds true with or without relative displacement of the joints. Rotation for any joint, computed separately by applying Eq. 85 to the end of each member framing into the joint, affords the desired check. In the case of displacements or sidesway, the quantity $\frac{\Delta}{L}$ must be noted as the check is in total rotation:

$$\left(\frac{\Delta}{L}\right)_{AB} + \theta_{AB} = R_A = \left(\frac{\Delta}{L}\right)_{AC} + \theta_{AC} \cdots = \left(\frac{\Delta}{L}\right)_{AN} + \theta_{AN} \dots (86)$$

If actual rotations are desired in radians, proper values must be used for E and I; if not, arbitrary values do just as well.

In the practical solution of a problem, ordinary (iterative) distribution requires only one step less than that outlined herein; that is, frame analysis does not apply.

STEPHEN J. FRAENKEL,[44] ESQ., and ROBERT L. JANES,[45] JUN. ASCE.—An interesting new approach to the problem of calculating moments in rigid frames is presented in this paper. At the same time, the presentation of another method for solving stiff-jointed structures raises the basic question as to whether the proposed modifications of the commonly used analytical procedures offer such a significant improvement as to supplant present practices.

The advantage of this method as compared with the classical method of analysis is said to be the elimination of solving simultaneous equations in order to reach a solution. It is possible, however, that the difficulty of solving simultaneous equations has been somewhat exaggerated. In many cases the number of unknowns does not exceed five or six (see Example 3) and, in fact, two or three simultaneous equations will often suffice in a "least work" solution. Although the use of a slope deflection method in the case of a tall building becomes an absurdity, its application in a case of five or six unknowns does not seem unreasonable. It can be assumed, furthermore, that a computing machine is available in engineering offices where structural analyses are executed frequently, and a solution of six simultaneous equations on a machine is a small task. Even where longhand computations are required, the use of a method of successive approximation,[46] makes the solution of such a system of equations a relatively simple and quick matter.

A comparison between various methods of analysis, used in the Examples given by the authors seems an obvious method of judging relative applicability of each. To a small extent, such a comparison may be unfair to the authors, in that the examples chosen were for the purpose of illustrating the method, rather than for illustrating the type of problem most readily solved by it. Even a cursory check of Example 1, however, indicates that it could have been solved with much less effort by the three moment equation, moment distribution, or slope deflection. Example 2 could likewise have been done by the method of least work (requiring two simultaneous equations) or even more simply by a single slope deflection equation.

In view of present methods of analysis it is perhaps more pertinent to compare this method with those based on moment distribution, or with the method of moment distribution itself. It has not been claimed by the authors that this method affords a saving in time over the method of moment distribution, or, for that matter, over any other method, yet unless some advantage can be claimed there seems little practical benefit to be obtained. It is admittedly difficult to judge the relative merit, from a time standpoint, of various methods for accomplishing the same result, principally because the length of time required is intimately connected with the engineer's relative familiarity with the various methods. In spite of this inherent difficulty there appears to be no other satisfactory basis of comparison than a direct application to a particular problem. A comparison has therefore been made using the authors' Example 4 as a basis. The methods used included the authors' method, that of moment distribution,[8] the modification or extension of this method as suggested by J. Wise,[47] and the column analogy.[48] The time required for a solution was considerably greater when using the method presented by the authors than by the use of any other methods. Granting a certain amount of lost motion due to unfamiliarity with the method, it seems doubtful, to say the least, that this time could have been equaled with the authors' method, even if one were thoroughly familiar with it. The discrepancy in time would probably be less in Examples 5, 6, or 7. In other words, it is believed that the procedure, as devised, sacrifices simplicity in simpler problems to applicability, and possibly superiority, when applied to complex frames. It must be remembered that the great majority of engineering calculations for indeterminate frames is relatively elementary and the cases in which the authors' procedure might excel constitute but a small minority of the total amount of work passing through a design office.

---

[44] Res. Engr., Structural Research, Armour Research Foundation, Chicago, Ill.

[45] Supv. of Structural Research, Armour Research Foundation, Chicago, Ill.

[46] "Analysis of Rigid Frames," by A. Amirikian, U. S. Govt. Printing Office, Washington, D. C., 1942.

The suggested procedure would appear, therefore, to be a useful tool only to those who are constantly engaged in the analysis of complex stiff-jointed structures; the average structural engineer who deals with a wide variety of problems would in all likelihood not remember this procedure from one proper application to the next. This discussion is not meant to be a brief for mediocrity but a mere recognition of facts learned in structural design offices.

PHIL M. FERGUSON,[49] M. ASCE.—Although a different vocabulary and a somewhat different language are used in this paper, nevertheless, it seems to resolve itself into a restatement of the method introduced by T. Y. Lin,[39] Assoc. M. ASCE. The fundamental difference apparent between the two papers is the authors' use of an "elastic factor," Z. For the same purpose, Professor Lin uses a "modified stiffness," K_m. (He actually uses relative stiffness, the equivalent of substituting I/L for $4\ E\ I/L$.) If the unmodified K is assumed to represent $4\ E\ I/L$, the authors' Z is simply the reciprocal of K_m, the Lin modified stiffness factor. As a matter of fact, in the actual examples of this paper one finds Z always expressed as 1/2.500, 1/1.875, and so on. In other words, the authors find it convenient to tabulate the "stiffness factor" $1/Z$ instead of Z itself; and $1/Z$ is simply the modified stiffness, K_m, introduced by Professor Lin.

In like fashion, the authors' carry-over factors are identically those "modified carry-over factors" used in the Lin paper. It is true that this paper seems to use different formulas; but the formulas are different only because the authors begin with flexibility instead of its reciprocal, stiffness; also, they define and use a new quantity called "elastic length." Only a few simple algebraic steps are needed to show that the "different" formulas are, in reality, identities. The sequence of calculations for the frame constants also seems to be identical in the two methods.

[47] "A Precise Moment Distribution Method," by J. A. Wise, Univ. of Minnesota, Minneapolis (mimeographed).

[48] "The Column Analogy," by Hardy Cross, *Bulletin No. 215*, Eng. Experiment Station, Univ. of Illinois, Urbana, 1930.

[49] Chairman, Civ. Eng., Univ. of Texas, Austin, Tex.

Likewise, in the handling of load terms, there is but one difference, which is a rather minor one. Professor Lin begins with fixed-end moments and must follow these with a single distribution and carry-over from each unbalanced joint before he obtains the authors' starting moments. The procedures seem to be identical from this point on.

A statement by the authors would be of interest, regarding the relative merits of these two approaches to this same general method—that is, the relative ease with which calculations or solutions can be formulated for more complicated problems. The writer is of the opinion that the basic moment-distribution process (essentially the same as that developed by Hardy Cross,[8] M. ASCE) will henceforth be the chief tool of designers in this field, and that all other methods will be secondary. In this situation he notes some advantages in the Lin approach to this problem. Modified stiffness and carry-over factors are closely related to the basic method in meaning and usage; and Professor Lin develops the factors very simply from it. This makes the development simpler for the student, and easier for the engineer who uses it only occasionally. Furthermore, the Lin formulas are adapted to members of variable section, inasmuch as all published tabulations of stiffness, carry-over factor, and fixed-end moment are directly usable. For variable sections, it would appear that the authors' method requires a return, each time, to the derivations based on the conjugate beam concept.

In the experience of the writer, very little use has been found for the term "flexibility," and it is about to be dropped from his teaching vocabulary. Since flexibility in algebraic terms is the inverse of stiffness, a new symbol and definition does not seem preferable to writing simply $1/K$ or $1/(4\,E\,K)$.

Part B of the authors' paper, with several examples of closed frames, is worthwhile in showing applications of this theory to frames more complicated than those previously covered by such methods. The device of a limited number of joints artifically restrained from rotation in the early stages is ingenious. A statement would be desirable as to whether the direct determination of the frame constants with all joints free to rotate was found to be a longer process, or whether it was ruled out as a method of successive approximation, and therefore not suitable for an "exact" solution. The tabulation forms are interesting and helpful; in fact, the authors are to be congratulated on a paper that is unusually clear and particularly well presented.

As a matter of general procedure, it appears that the multiple-panel Vierendeel truss of Example 6 could be more easily analyzed by the method of successive corrections. If one uses the criterion ratio procedure in such a solution (as was developed for wind stress calculations by L. E. Grinter,[50] M. ASCE, and if one is satisfied with errors as great as 1%, the time required should not be more than one third of that required for Example 6. Since this would not be an exact method, the comparison may not be fair.

Ralph W. Stewart,[51] M. ASCE.—A method is presented in this paper which is efficient in computing the bending moments in complex continuous frames such as Vierendeel trusses, and which is as accurate as the common theory of flexure. This gives the paper considerable value as a reference.

---

[50] "Theory of Modern Steel Structures," by Linton E. Grinter, The Macmillan Co., New York, N. Y., 1936–1937, pp. 168–178.

[51] Bridge Engr., City of Los Angeles, Los Angeles, Calif.

In developing the method by applying certain old theorems of structural mechanics, it appears to the writer that the preliminary work is cumbersome. For example, in order to obtain Eq. 14*a* the authors show five drawings (Figs. 4(*a*) to 4(*e*), inclusive). By simply adding two lines to Fig. 4(*b*) and transferring to it the longitudinal dimensions as shown in Figs. 4(*c*), 4(*d*), and 4(*e*), it is converted into Fig. 23, which shows all the elements of the flexure and makes the other four drawings unnecessary. The authors' procedure for deriving Eq. 14*a* can now be duplicated term by term by referring to Fig. 23 and using its geometrical properties. This reduces the labor involved in the derivation and also eliminates the use of the conjugate beam theorem. Similarly, by adding two lines to each of Figs. 2(*b*), 3(*b*), and 5(*b*), reference to the conjugate beam theory and also the moment-area drawings can be omitted.

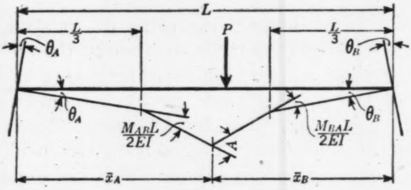

FIG. 23

Beginning with Clapeyron's discovery of the three-moment theorem, various special formulas or constants have been proposed for facilitating the analysis of stresses in continuous structures. These include, among others, the slope deflection equations, the conjugate beam theorem, the carry-over and special stiffness factors used in the end-moment distribution method, and the transmission coefficients. The authors now offer the "elastic length" and the "elastic factor" to add to the list. These special formulas or constants are derivatives obtained by combining part or all the six basic constants of flexure in one form or another.

5	Final moments (without sidesway)..........	....	+0.56	−1.66	−0.53	−2.57	−0.87

Because the propriety of using the adjective "basic" in identifying the constants about to be described has been questioned,[52] it is necessary to explain why this is done. A suitable explanation can be presented by chemical analogy. The most important discovery in chemistry prior to atomic fission was that all molecules could be broken down into components (atoms) which could not at that time be further subdivided. Combinations of atoms became known as "derivatives"; for example, CH_4, C_2H_2, and C_8H_{18} are called hydrocarbon derivatives, and hydrogen and carbon may be considered as their basic components. A similar condition exists in machines, for which the basic components may be listed as shafts, gears, keys, pulleys, belts, and the like.

---

[52] *Transactions*, ASCE, Vol. 108, 1943, p. 1230.

All conditions of flexure may be reduced to an assembly of the following constants, which are designated as basic:[53]

(1) The moment necessary to produce a unit change in the direction of the elastic curve of a beam when applied at the left end, the right end being hinged;

(2) The moment necessary to produce a unit change in the direction of the elastic curve of a beam when applied at the right end, the left end being hinged;

(3) The abscissa of the intersection of the end tangents to the elastic curve of the beam (or the center of gravity of the $\frac{M}{E\,I}$-diagram) for condition (1); and

(4) The corresponding abscissa for condition (2).

These four constants are known as the beam constants. They are interrelated so that, if three are given, the fourth can be computed by Maxwell's theorem of reciprocal deflections (angular). Constants (1) and (2) are the same as the term preceding the parentheses in any slope deflection equation.

The two additional basic constants, known as the load constants, are:

(5) The total curvature in the beam (equal to the area of its $\frac{M}{E\,I}$-diagram), when it is considered as simply supported and subjected to the external loading, which acts on it between the supports; and

(6) The abscissa of the intersection of the end tangents to the elastic curve for condition (5).

−0.09	+0.09	+0.28	+0.25	−0.53	+2.45	−0.91	−1.54	−0.53	+0.25	+0.28	+0.09	−0.09	2
+1.27	−1.27	−4.12	−3.71	+7.93	−1.37	+0.51	+0.86	+0.30	−0.14	−0.16	−0.05	+0.05	3
....	....	....	....	....	−12.00	....	+12.00	....	....	....	....	....	4
+1.12	−1.12	−3.63	−3.27	+7.00	−12.07	−1.08	+13.15	+5.32	+5.06	−10.38	+1.73	−1.73	5

Although constants (1) and (2), which are called the basic stiffnesses, can be further subdivided into force times distance, neither force (which might be axial), nor distance acting alone can produce flexure. The simplest condition which can produce flexure is a combination of force and distance; therefore, constants (1) and (2) have been reduced to the lowest possible terms as far as direct relationship to flexure is concerned.

---

[53] "The Mechanics of Creep for Structural Analysis," by Joseph Marin, *Transactions*, ASCE, Vol. 108, 1943, p. 477.

If a quantic, such as the stiffness value of a member as defined for use in end-moment distribution, contains more than one of these basic constants, it is a derived function and not a basic constant. With these basic constants (Fig. 23) well in mind, a computer does not need to burden his tool kit with extra items like the conjugate beam theorem.

The authors' Example 3 (Fig. 8) is easily solved by the application of only four of these constants, as illustrated by Fig. 24 and Table 19. In Fig. 24 all

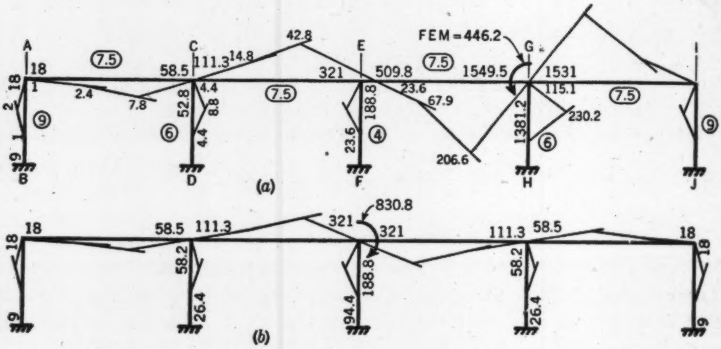

FIG. 24.—MOMENTS FOR EXAMPLE 3

angles of flexure are at the third points of the members. This solution involves a minimum number of slide rule settings and requires no preliminary computation of special constants. It may be assumed that the authors presented problems like Example 3 for the purpose of illustrating the use of the "elastic length" and the "elastic factor," rather than to shorten the solutions by using these special functions.

The authors' solution of Example 3 (Fig. 8), shows that $\frac{2\,I}{L}$ was used for the relative stiffness values of the members (constants (1) and (2) in the list of basic constants of flexure with E omitted). In Fig. 24, a set of values equal to $\frac{12\,I}{L}$ was used in order to avoid fractional values as much as possible. In Fig. 24, the series of angle values will remain identical for any proportional set of stiffness values but the moment values will vary directly as the stiffness values. The authors' "stiffness factors" can therefore be taken from Fig. 24. For example, the authors' stiffness factor at end E of member CE is $\frac{3.21}{6 \times 23.6} = 2.267$, which checks the value in Table 4. If Fig. 24 had been constructed by using $\frac{2\,I}{L}$ values for the relative member stiffnesses, the reduction factor 6 would disappear from this computation and the authors' elastic factors and stiffness factors could be obtained by simply dividing the end slope angles at the activated ends of the members by the moments at these activated ends, and vice versa.

It becomes troublesome to describe flexural analysis procedures with the words "stiffness" or "stiffness factor" meaning any one of the three following separate properties:

(1) Basic stiffness: Used in the slope deflection and traverse methods.
(2) End slope stiffness of a member with the opposite end fixed: Used in end-monent distribution.
(3) End slope stiffness of a member or an assembly of members for whatever remote end conditions exist: Used by the authors of this paper. It is the reciprocal of the "elastic factor."

Figs. 6, 7, and 8 are so easily solved by the use of basic constants that the use of the authors' special devices for such problems seems inadvisable. However, the solution of the Vierendeel truss shown in Fig. 12 is not easy by any method, and for structures of this class the authors' method appears to be useful.

Maurice Barron,[54] M. ASCE.—The authors are to be commended for bringing to the attention of the profession the fact that a method of direct moment distribution is possible, and that it is no longer necessary to use the methods of successive approximation. Unfortunately, the proposed method is elementary when compared to more advanced methods of direct moment distribution.

One such method[55] is that developed by Harris Epstein. Another method,[56] somewhat similar to the Epstein method, has been fully developed by R. C. Brumfield, M. ASCE. It appears that many of the refinements of the Brumfield method could be incorporated into the authors' method. For instance, their concept and use of the artificial fixed joint is evidence of a "stumbling block" that Professor Brumfield has ingeniously eliminated. This problem is encountered in every re-entrant frame. The difficulty arises from the fact that there is no starting point of known restraint. The authors, therefore, fix as many joints as are required and later release these joints, with a further corrective moment distribution. Professor Brumfield has developed a method whereby he can "jump into" any such re-entrant frame and very accurately estimate the transmission coefficient necessary to complete the analysis and, at the same time, check the estimated values. This means that a starting point is available and no corrective distribution is required because of arbitrary fixing of joints. Furthermore, this becomes a very useful tool in analyzing an individual member of a complicated frame without making an elaborate analysis of the surrounding members. The problem of sidesway, or the adjustment for unbalanced shears, is solved by very much the same procedure in both methods.

[54] Chf., Structural Design Div., Clarke, Rapuano and Holleran, Cons. Engrs. and Landscape Architects, New York, N. Y.

[55] "Standards of Design for Concrete," *No. 3Yb*, Bureau of Yards and Docks, U. S. Navy Dept., November 15, 1929, pp. 148-177.

[56] "Moving Loads on Restrained Beams and Frames," by R. C. Brumfield, *Transactions*, ASCE, Vol. 111, 1946, p. 805.

In order to illustrate the relatively weak points of the authors' paper the writer has used the Brumfield method to solve Examples 4 and 5. Additional symbols necessary for adaptation of this method to the authors' examples include:

The flexibility factor, Q, similar to the reciprocal of the ordinary stiffness factor, for uniform prismatic members measured by L/I; the transmission coefficient, C, similar to the ordinary carry-over factor and denoting the ratio of the moment arriving at one end of a member to the moment applied at the opposite end of the same member; the stiffness index, i_s, which is a measure of the resistance a member offers to the rotation of the joint to which it is attached (each member has two stiffness indexes, one for each end); and the restraint index, R, of a member radiating from a joint, a measure of the resistance to rotation offered to that member when it is used to actuate the joint by the other members radiating from the same joint. The relations between these factors are expressed by:

$$i_s = Q\,(2 - C) \qquad \text{(87)}$$

in which the "going away" transmission coefficient is

$$C = \frac{1}{2 + \dfrac{R}{Q}} \qquad \text{(88)}$$

and

$$\frac{1}{R} = \frac{1}{i_{s1}} + \frac{1}{i_{s2}} + \frac{1}{i_{s3}} + \cdots + \frac{1}{i_{sn}} \qquad \text{(89)}$$

In Example 4 (Fig. 9), the authors have arbitrarily chosen joint B as a fixed joint, thereby making the carry-over factors toward joint B of members AB and DB equal to 0.500. The transmission coefficient corresponding to the first of these two carry-over factors can be estimated as follows: $C_{AB} = \dfrac{1}{2 + \dfrac{Q_{BD}\,(2 - 0.25)}{Q_{AB}}} = \dfrac{1}{2 + \dfrac{2\,(2 - 0.25)}{2}} = 0.266.$ The approximate coefficient in the denominator is the average "going away" coefficient of all the restraining members at the joint toward which the desired estimated coefficient is transmitting.

In the computation for the estimated value of C_{AB}, only a rough estimate is required for the value of C_{BD} ($= 0.25$) which appears in the denominator. The value of 0.25 was chosen because the member BD is transmitting toward member DC, which is more flexible than member BD. If these two members were of equal flexibility, the value of 0.3 might be used, whereas if joint D had several restraining members, or one of great rigidity, the value of 0.35 might be used to estimate C_{AB}.

Similarly, C_{BA} is estimated to be: $C_{BA} = \dfrac{1}{2+\dfrac{Q_{AC}\,(2-0.2)}{Q_{BA}}} = \dfrac{1}{2+\dfrac{1.6\,(2-0.2)}{2}}$ $= 0.291$. The value of 0.2, as an approximation of C_{AC}, is used because member AC is transmitting toward the more flexible member CD. If the value 0.25 had been used, C_{BA} would equal 0.294; thus, a 25% change in the estimated coefficient results in only 1% change in the final coefficient, indicating that a crude guess is sufficient for very accurate results. The two estimated coefficients are entered in the tabulated computation of Table 20, and all the transmission coefficients are computed, including the exact values of C_{AB} and C_{BA}. It is interesting to note the agreement between estimated and final coefficients. Also, a comparison of the Brumfield transmission coefficients and the authors' carry-over factors demonstrates that the two are identical at joints twice removed from the fixed joint, showing a rapid convergence to the true value.

FIG. 27.—FRAME CHARACTERISTICS FOR EXAMPLE 5 (FIG. 10)

Distribution of moments in the frame is shown in Fig. 26, in which arrows to the right indicate positive moments (authors' convention), and those to the left indicate negative moments. This sign convention for moments has been used throughout the writer's solution of Examples 4 and 5.

[a] Sideway correction. [b] Vertical sway correction.

FIG. 29.—FINAL MOMENT COMPUTATIONS FOR EXAMPLE 5

The sidesway, or unbalanced shear problem, has also been worked out by the Brumfield method. From Fig. 26(*a*), the total unbalanced moments equal -1.87, which is twelve times the unbalanced shear. The moment corresponding to this unbalanced shear, from Fig. 26(*b*), is $+1{,}879\ M$. Equating these two values, $1{,}879\ M = -1.87$, from which $1{,}000\ M = -0.996$. Application of this factor as a sidesway correction (lines 4 and 9, Fig. 26(*a*)) to the moments for no sidesway (lines 3 and 8) gives the final moments (lines 5 and 10).

In Example 5 (Fig. 10), the authors again use the expedient of fixing joints —in this case joint B. After the preliminary distribution, joint B is released and a corrective distribution is computed. The correction for unbalanced shears in this problem is more complicated than in the previous one, because there is not only a sidesway, but also a vertical sway. The authors' procedure in step (*g*) is to deform the structure a distance, $\Delta = 24/E$, and then to find the induced moments resulting from this distortion. Eight moments are thus required for distribution.

In the Brumfield procedure (Table 21 and Figs. 27, 28, and 29) member AB is translated vertically downward with no rotation of joints. Since the translation for point A of member AE and AC is the same, and the Q-values and L-values are identical, the induced fixed-end moments, M_{EA}, M_{AE}, M_{AC}, and M_{CA}, will be the same. Similarly, the induced fixed-end moments for BD and DB will be the same. Furthermore, the induced fixed-end moments of the top chord members will bear a constant relationship to the fixed-end moments induced in the bottom chord members. The estimated transmission coefficients, shown in Table 20 for members EF and CD, were computed by the same method as used for Example 4. Using the transmission coefficients of Table 20, it is found that: $M_{CA} = -\dfrac{4 \times 24 \times 0.195\ (0.659 \times 3/8)}{1 - 0.0665}$ $= -4.95$ kip-ft; and $M_{AC} = -\dfrac{4 \times 24 \times 0.341\ (0.805 \times 3/8)}{1 - 0.0665} = -10.58$ kip-ft.

Since all horizontal members in this example are the same length (Fig. 10), the induced fixed-end moments will be proportional to the moments of inertia of the respective members, or inversely proportional to the Q-values. Therefore, if 1,000 units of moment ($1{,}000\ M_2$) are distributed at each joint E, A, and C, $800\ M_2$ must be distributed at each joint F, B, and D. These six moments—three at $1{,}000\ M_2$ and three at $800\ M_2$—may be distributed concurrently, and the totals found at all joints. Since the moments at the center are equal and opposite they balance and need not be distributed. In like fashion, joints E, A, and C may be translated horizontally without joint rotation. Again, the induced fixed-end moments without joint rotation will be proportional to the moment of inertia of each vertical member. If 1,000 units of moment ($1{,}000\ M_1$) are distributed at joints E and F, $667\ M_1$ must be distributed at joints A and B, and $444\ M_1$ must be distributed at joints C and D. These six moments—two at $1{,}000\ M_1$, two at $667\ M_1$, and two at $444\ M_1$—may be distributed concurrently, and the moments summed up for each joint.

The final horizontal shears in the vertical members must equal zero, and the vertical shears in the horizontal members must be consistent with the loading. Therefore, it is necessary to write the two simultaneous equations, $+ 2{,}281\ M_1 + 395\ M_2 - 1.90 = 0$; $+ 1{,}307\ M_1 + 2{,}622\ M_2 - 30.43 = 0$. When solved simultaneously, these two equations will yield values of M_1 and M_2 that will balance the shears both vertically and horizontally. By this method $1{,}000\ M_2 = 12.24$ and $1{,}000\ M_1 = -1.28$. Application of the corrections are shown in Fig. 29.

At this point, it should be noted that sidesway results from either a dissymmetry of structure, a dissymmetry of loading, or a combination of both. When vertical sway and horizontal sway can occur, simultaneously, they must be treated simultaneously. The authors have not done so in Examples 5, 6, and 7. The fact that their answers, for Example 5, are so close to the correct ones is due to the unfortunate choice of frame and loading, where dissymmetry of structure is almost balanced by the dissymmetry of loading. The fact that the sum of the authors' moments at the top and bottom of the columns does not quite add up to zero is not due to computational inaccuracies, but to the unbalancing effect of separately correcting for horizontal sway and vertical sway. When a structure has several vertical members to which sidesway may be distributed, the correction will be of little significance, but a fallacy may result, such as in this example, if such structures are used to demonstrate a principle. The question is then raised as to whether the authors' computation of sway is theoretically exact or a practical approximation.

In step (*d*) of Examples 4 and 5, the authors find the end moments of the loaded member by using the moment areas and conjugate beam, which were used in the derivation. The Brumfield method finds these moments directly from the transmission coefficients. Using the authors' carry-over factors and the Brumfield equations, the end moments for Example 4 are found to be: $M_{AC} = -\dfrac{4 \times 24 \times 0.258}{1 - 0.258 \times 0.195}\left(\tfrac{3}{8} - 0.196 \times \tfrac{3}{8}\right) = -7.80$ kip-ft (authors' value 7.874 kip-ft) and $M_{CA} = -\dfrac{4 \times 24 \times 0.195}{0.9495}\left(\tfrac{3}{8} - 0.258 \times \tfrac{3}{8}\right) = -5.48$ kip-ft) (authors' value 5.488 kip-ft). Thus, Professor Brumfield's equation is a more direct solution. In addition, his equations have been extended for uniform loads, triangular loads, and complex loads.

The authors' concept of "elastic length" is interesting but its practical usefulness is questionable. It is evident that the method could have been developed without introducing this new concept.

Many problems confronting the practicing structural engineer are readily solved by the Brumfield method. Some of these problems cannot be solved by any other method, and it is improbable that the authors' method can be extended to be as all-inclusive. If it can be extended, however, it might be useful if the authors would indicate how the extension can be accomplished.

Fig. 30 shows typical examples of some of these problems. In each of the examples shown the moment of inertia may be a variable with little additional work.

Figs. 30(*a*) to 30(*f*) show various types of rectangular and nonrectangular frames. Fig. 30(*g*) shows three curved members with a common point A, and Fig. 30(*h*) shows a frame with both curved and straight members. In Fig. 30(*j*), the intrusion of the column into the ordinary building beam is unimportant, but, in Fig. 30(*k*), the column intrusion is a large part of the beam span and must be considered in the analysis."

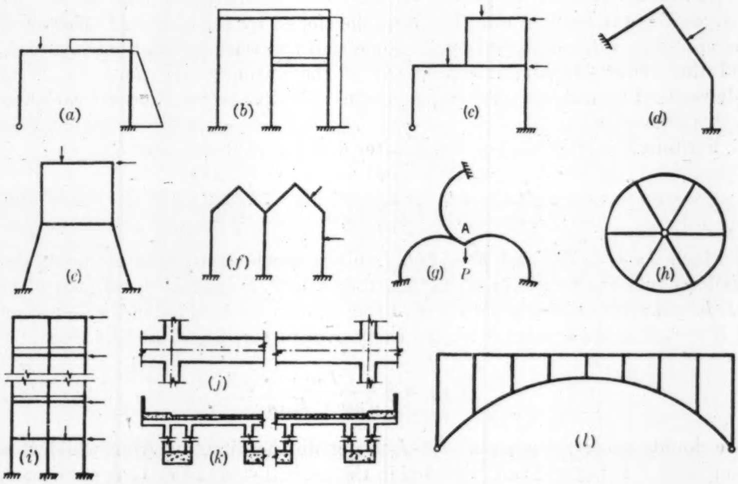

FIG. 30

Fig. 30 (*l*) shows an arch rib with spandrel columns and deck. The analysis of this structure is complicated by the fact that the deck, the spandrel columns, and the ribs will participate in supporting the loads and in resisting temperature stresses. The problem is so complex that, ordinarily, bridge designers will avoid the analysis by judicious use of expansion joints in the deck structure. This procedure obviates the beneficial effects that the rib derives from deck participation.

The Brumfield method uniquely solves the problems presented. It is universal in its application in that it develops transmission coefficients for curved members, as well as for straight members and for members with variable moment of inertia. These transmission coefficients take into account the actual restraints at the ends of the member. If the connection of a member yields and the amount of yielding is known, it may be incorporated into the analysis with little difficulty.

The outstanding feature of all methods of direct moment distribution is that the moments "flow away" from the point of origin in one direction—never returning to that point except in re-entrant frames. The structural "keenness" developed by use of direct methods far exceeds that developed by methods employing successive approximation. This in itself is a strong argument for wide adoption of direct methods such as those proposed by the authors and discussed herein.

Edwin H. Gaylord,[57] Assoc. M. ASCE.—An ingenious method for the analysis of continuous frames has been developed by the authors. However, the procedure is handicapped by the somewhat awkward calculations involved, and the writer suggests modifications of the author's equations which he believes lead to fairly simple computations. Flexible connections are excluded in this discussion.

Forming the reciprocal of Eq. 8, after dividing each term by L:

$$\frac{L}{L_{AB}} = \frac{1}{1 + 3\,E\,I\,Z_B/L} = \frac{J_B}{J_B + K} \qquad (90)$$

in which $J_B = 1/Z_B$, and $K = I/L$. (Since continuous frame moments depend on relative moments of inertia, the ratio I/L may be used instead of $3\,I/L$. If different materials are involved, E must be included in the definition of K.) Using the symbol F for the carry-over factor, Eqs. 7 and 90 give

$$F_{AB} = \tfrac{1}{2}\,\frac{J_{BC}}{J_{BC} + K_{AB}} \qquad (91)$$

The double subscript is used with J to denote the direction from which it is computed. If the division indicated in the parentheses of Eq. 11 is performed, the following equation for J is obtained:

$$J_{AB} = \frac{K_{AB}}{1 - F_{AB}/2} \qquad (92)$$

Once the values of F and J are computed for a given frame, end moments due to transverse loads can be determined rather simply. Consider the moment at point C in span CE, Fig. 8. If the values of x_A and x_B as given by Eqs. 17 are substituted in Eqs. 16a, the following equation is obtained:

$$M_{CE} = \frac{M_{FCE}\,(4\,L_{CE}\,L - L^2) - 2\,M_{FEC}\,(L_{CE}\,L - L^2)}{4\,L_{CE}\,L_{EC} - L^2} \qquad (93a)$$

In Eq. 93a, the subscript F denotes fixed-end moments. The second term in the numerator is negative to conform to the convention which denotes moments as positive when they are clockwise on the joint (or member). The second term is positive for those who prefer the moment sign convention used in strength of materials. Eq. 93*a* can be written:

---

[57] Prof. and Chairman, Dept. of Civ. Eng., Ohio Univ., Athens, Ohio.

$$M_{CE} = 4\,M_{FCE}\,\frac{L - \frac{1}{4}\,\dfrac{L^2}{L_{CE}}}{4\,L_{EC} - \dfrac{L^2}{L_{CE}}} - 2\,M_{FEC}\,\frac{\dfrac{L}{L_{EC}}\,(L_{CE} - L)}{4\,L_{CE} - \dfrac{L^2}{L_{EC}}} \dots\dots (93b)$$

From Eq. 11,

$$L - \frac{1}{4}\,\frac{L^2}{L_{CE}} = \frac{3\,E\,I}{J_{CE}} \dots\dots\dots\dots\dots\dots\dots (93c)$$

From Eq. 93*c*,

$$\frac{L^2}{L_{CE}} = 4\,L - \frac{12\,E\,I}{J_{CE}} \dots\dots\dots\dots\dots\dots\dots (93d)$$

and, therefore,

$$4\,L_{EC} - \frac{L^2}{L_{CE}} = 4\,(L_{EC} - L) + \frac{12\,E\,I}{J_{CE}} \dots\dots\dots\dots (93e)$$

Now, from Eqs. 8 and 13*b*,

$$L_{EC} - L = \frac{3\,E\,I}{J_{CA} + J_{CD}} \dots\dots\dots\dots\dots\dots\dots (93f)$$

Substituting from Eq. 93*f* into Eq. 93*e*

$$4\,L_{EC} - \frac{L^2}{L_{CE}} = 12\,E\,I\left(\frac{1}{J_{CA} + J_{CD}} + \frac{1}{J_{CE}}\right) \dots\dots\dots (93g)$$

The right member of Eq. 93*b* can now be expressed in terms of stiffness factors, by substitution from Eqs. 93*c* and 93*g* into the first term, and, with proper change in notation, by substitution from Eqs. 93*f* and 93*g* into the second term. Finally, observing that $L/L_{EC} = 2\,F_{EC}$, Eq. 93*b* reduces to

$$M_{CE} = M_{FCE}\,\frac{J_{CA} + J_{CD}}{J_{CA} + J_{CD} + J_{CE}} - M_{FEC}\,\frac{F_{EC}\,J_{EC}}{J_{EC} + J_{EF} + J_{EG}} \dots (93h)$$

Denote by the symbol R the ratio of the stiffness factor of any member to the sum of the stiffnesses of all members framing into the joint. Then, for M_{AB}, Eq. 93*h* may be written:

$$M_{AB} = (1 - R_{AB})\,M_{FAB} - F_{BA}\,R_{BA}\,M_{FBA} \dots\dots\dots (94a)$$

or

$$M_{AB} = M_{FAB} - R_{AB}\,M_{FAB} - F_{BA}\,R_{BA}\,M_{FBA} \dots\dots\dots (94b)$$

Eq. 94*a* has the advantage of requiring the addition of only two terms. However, slide rule work is simplified in Eq. 94*b*, since the CI-scale may be used to obtain the second term of the equation for M_{AB}, and the third term of the equation for M_{BA} may then usually be found with either the C-scale or the CF-scale without changing the position of the sliding scale.

TABLE 22.—MODIFIED SOLUTION OF EXAMPLE 1(*a*)

Line	Quantity	 4 Kips 24 Ft 12 Ft 12 Ft 24 Ft 24 Ft A B C D E $I=15$ $I=15$ $I=15$ $I=15$ $K=1$ $K=1$ $K=1$ $K=1$

6	$-F\ R\ M_F$			+1.74	−1.49				
7	M	−4.08	−8.17	+8.17	−7.43	+7.43	+1.86	−1.86	0

Table 22 shows the solution of Example 1(*a*) by Eqs. 91, 92, and 94*a*. Since the I/L-ratios are the same for all members, the value $K = 1$ was chosen for simplicity. The computations start by entering in line 1 the known value $F_{BA} = 0.5$. (In a strict sense, the computations start with the known joint stiffness $J_A = \infty$. Eq. 91 gives $F = 0.5$ when $J \rightarrow \infty$.) With F_{BA} known, the value of J_{BA} is calculated from Eq. 92 and entered in line 2, Table 22. With J_{BA} known, F_{CB} is determined from Eq. 91 and recorded in its proper place. Calculations to the right stop with J_{CB} since the DC-factors are not needed for this example. The known value $F_{DE} = 0$ is recorded next, and computations to the left proceed as outlined, stopping with the factors for span BC. It will be observed that the additions in Eqs. 91 and 92 can be performed mentally, and the equations are easily remembered after using them a few times.

Only two values of R are needed for this example, and they are computed and recorded in line 3, Table 22. The remainder of the calculations is self-explanatory. However, it should be noted that the second term of Eq. 94*a* is a "carry-over" and must be so entered in the table.

The example in Table 23 is given to show the procedure when more than one span is loaded. In this example, Eq. 94*b* is used. It is unnecessary to calculate values of J at the end supports, since $R = 0$ for a fixed-end support and $R = 1$ for a hinged-end support. After the values of R and M_F are determined, $M_{FAB} = 16$ is multiplied by the R-value immediately above, and the negative of the result recorded immediately below in line 5. This product is then multiplied by F_{AB} and the result, -4.29, recorded in line 6 at point B. After lines 5 and 6 have been completed, line 7 is found by adding lines 4, 5, and 6.

The first step in calculating carry-overs to the right is to record at point B of span BC in line 8 the balancing moment for $M_{BA} = -12.86$. The carry-over +3.46 is then recorded at point C. This value added to the moment immediately above gives the balancing monent (+1.74) to be recorded at point C of span CD. The carry-over to point D is then computed, and the process continued until point E is reached. Line 9 is computed similarly, and the final moments in line 10 are determined by adding rows 7, 8, and 9.

[a] Carry-over to the right or left.

The tabular solution can be extended to frames of the type shown in Fig. 8. For sidesway calculations, Eqs. 20 can be expressed in terms of the factors *F*, *J*, and *R*. Consider the leg CD of the frame of Fig. 8. From Eq. 20*a*,

$$M_{CD} = \frac{3\,E\,I\,\Delta}{2\,L}\left[\frac{2}{L_{DC} - \dfrac{L^2}{4\,L_{CD}}} + \frac{L/L_{DC}}{L_{CD} - \dfrac{L^2}{4\,L_{DC}}}\right] \quad \ldots\ldots\ldots (95a)$$

Substituting from Eq. 93*g*, with proper changes in notation, Eq. 95*a* becomes, for M_{AB},

$$M_{AB} = \frac{\Delta}{L}\left[J_{AB}\,(1 - R_{AB}) + F_{BA}\,J_{BA}\,(1 - R_{BA})\right] \quad \ldots\ldots\ldots (95b)$$

The solution of the frame of Fig. 8, with sidesway restrained, is given in Table 24. As in the previous examples in this discussion, relative values of *K* are used. The computation starts with the known values F_{AB}, F_{CD}, F_{EF}, etc., from which the values of J_{AB}, J_{CD}, J_{EF}, etc., are computed by Eq. 92. The values of F_{CA} and J_{CA} are determined next, using the known value of F_{AB}. In calculating F_{EC}, it must be remembered that the stiffness factor *J* in Eq. 91 is given by Eq. 13*b* as the sum of J_{CA} and J_{CD}—that is,

$$F_{EC} = \tfrac{1}{2}\,\frac{J_{CA} + J_{CD}}{J_{CA} + J_{CD} + K_{EC}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (96)$$

Calculations proceed in this manner until the JI-values have been determined. The process must then be repeated, starting with F_{IJ} and working to the left until joint B is reached. Because of the symmetry of the frame in this example, values from point J to the left are the same as those from point B to the right. Finally, values of F and J for joints D, F, and H are determined.

The first step in determining line 8 is the distribution of M_{EC} to members EF and EG in proportion to their stiffness factors (J_E). The carry-over from point E to point G is calculated next and the final moment $M_{GE} = -10.71$ is distributed. Carry-over and distribution are continued until joint J is reached. Carry-over and distribution to the left starts with M_{EG}. Line 8 is omitted for the intermediate columns since the final moments can be determined by equilibrium of joints C, E, and G.

Because of symmetry, only half of the frame is shown in Fig. 31. All distributions in line 4 are completed before starting line 5. The first entry in line 5 is the carry-over to point C from point A. This carry-over is distributed, giving $M_{CE} = +2.85$. The carry-over to point E is based on the sum of the moments +2.85 and −8.33 at point C. The carry-over from point E to point F is recorded in line 6 at point C in span CE. The process continues until joint B is reached. As in Table 24, no distributions are recorded for the intermediate columns. The moment M_{CD} in line 9 is calculated from equilibrium of joint C, and the total distribution, +3.37, is the difference between lines 3 and 9. The carry-over to point D can then be found, and the final moment M_{DC} determined. No explanation of the final steps, lines 10 and 11, Table 24, is necessary.

The writer has found the procedure described especially simple and easily remembered for continuous beams. It can be used very effectively in the construction of influence lines, and the advantage of basing the procedure on fixed-end moments becomes evident in this application. For example, the M_F-values of line 4, and the final moments of line 7, Table 22, can be quickly determined for a sufficient number of positions of load between point B and point C to plot the part BC of the influence lines for moment at point B and point C. Parts BC of the influence lines for M_A and M_D can then be found by multiplying ordinates of the M_B and M_C influence lines by F_{BA} and F_{CD}, respectively. As an alternative procedure, the equations of the influence lines for M_B and M_C may be found. For example:

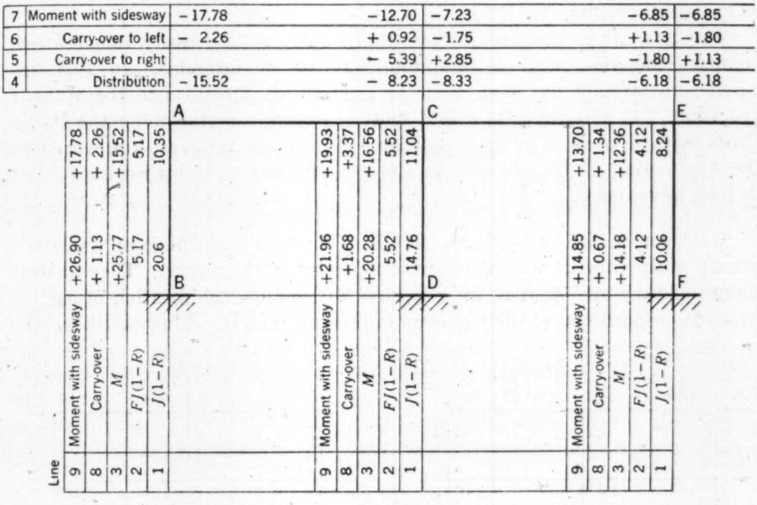

FIG. 31

		A	C	C	E	
7	Moment with sidesway	− 17.78	− 12.70	− 7.23	− 6.85	− 6.85
6	Carry-over to left	− 2.26	+ 0.92	− 1.75	+ 1.13	− 1.80
5	Carry-over to right		− 5.39	+ 2.85	− 1.80	+ 1.13
4	Distribution	− 15.52	− 8.23	− 8.33	− 6.18	− 6.18

Line		A	B	C	D	E	F
9	Moment with sidesway	+17.78	+26.90	+19.93	+21.96	+13.70	+14.85
8	Carry-over	+ 2.26	+ 1.13	+3.37	+1.68	+ 1.34	+ 0.67
3	M	+15.52	+25.77	+16.56	+20.28	+12.36	+14.18
2	$FJ(1-R)$	5.17	5.17	5.52	5.52	4.12	4.12
1	$J(1-R)$	10.35	20.6	11.04	14.76	8.24	10.06

$$M_{FBC} = 24\,k\,(1 - k)^2 \quad \text{.................... (97a)}$$

and

$$M_{FCB} = 24\,k^2\,(1 - k) \quad \text{.................... (97b)}$$

in which $k = x/L$, and x is the abscissa of the unit load position measured from point B. Following the calculations of lines 5, 6, and 7, Table 22, the final moments are

$$M_{BC} = 9.46\,k\,(1 - k)\,(1.36 - k) \quad \text{.............. (98a)}$$

and

$$M_{CB} = 8.45\,k\,(1 - k)\,(0.406 + k) \quad \text{............. (98b)}$$

From Eqs. 98 any desired number of influence line ordinates can be easily calculated. The maximum ordinate of the BC-segment can also be determined readily. Equating to zero the first derivatives with respect to k, it is found that $k = 0.381$ and $k = 0.616$ for maximum values of M_{BC} and M_{CB}, respectively. It should be observed that this also determines maximum ordinates of the BC-segment of the influence lines for M_A and M_D, since these moments are found by multiplying M_B and M_C by the proper carry-over factors, as explained previously.

The practicing engineer prefers (and rightly so) an easily remembered, compact analysis, with a minimum number of formulas. In this discussion an attempt has been made to meet these objections to the authors' procedure. It is quite certain that most engineers will still prefer the Hardy Cross method because of its simplicity. The writer believes, however, that the application of the method to the construction of influence lines offers definite advantages.

William A. Conwell,[58] M. ASCE.—There is something of analytical beauty in the concept which the authors present in this paper. They analyze frames as they are—that is, as structures with joints, the rotation of each of which is proportional to the moments impressed upon it. Many of those who are daily engaged in analysis of continuous frames will appreciate this sophisticated outlook and will, henceforth, be inclined to treat as naive any method which does not treat structures as they actually are.

(*d*) FINAL MOMENTS AND REACTIONS

Fig. 32.—Steps in Solution of Moments and Reactions of Example 5 by Moment Distribution

Although the proposed method of solution involves thought that is closer to the actual condition of the structure than do accepted methods, it also contains formulas which must be remembered to be applied and entails computation which cannot be wholly written on a sketch of the structure. These elements divert the mind of the designer from the structure and are, of course, ones which moment distribution[8] was to eliminate.

---

[58] Gen. Engr., Structural Eng. and Design Dept., Duquesne Light Co., Pittsburgh, Pa.

It is believed that the relative merits of the methods of elastic supports and of moment distribution can best be compared by an application to a particular problem. With the thought of providing such a pointed comparison, the writer has solved Example 5 by moment distribution and gives the results of this analysis in Fig. 32. These values were obtained after an average of seven cycles of moment distribution, which is not a great chore. It was necessary, of course, to solve two equations simultaneously to determine the proportion of the final moments resulting from sidesway and the vertical movement of joints A and B. Aside from this disgression, it was possible to write all computations on a sketch of the frame. Assessment of the relative value of the methods can then be made by comparison of Fig. 32 with seven cycles of moment distribution visualized thereon and Tables 8 and 9 with their supplementary computations.

In the final analysis, the value of the method of elastic supports will be determined in design offices where it will meet competition with other present and proposed methods. One's first impression, however, is that the authors' presentation is one for the expert in continuous frame analysis, rather than for the engineer who meets such design problems only occasionally.

Harry Garfinkel,[59] Esq.—For many years the writer has examined with unabated interest the methods proposed by various investigators for the solution of stresses in continuous frames. All have concentrated on reducing the time element; many have accomplished this purpose remarkably well for the simpler types of frame. In the more complex type of structure, however, the amount of work still required for solution of an actual engineering design leaves much to be desired, both as to method and clarity. Computations for such structures can be quite lengthy and must be reviewed for checking purposes. Complex sign conventions and numerous distributions required for varying loading patterns can cause great annoyance unless the method of analysis is direct and avoids unnecessary artifices for a solution. It is therefore of great importance that any new method should avoid these difficulties as far as possible.

The authors propose a method of analysis of continuous frames that is claimed to be "classical" and "exact." Presumably, these terms are applied because the basic equations of the method originate in classical concepts. The authors' method and steps of operation, however, cannot be termed "exact" in the same sense that such a term is applied to methods, based on least work, slope deflection, or virtual work, which are direct and lead to exact results. Inherent in the authors' method is the artifice of fixing and relaxing one or more joints of the frame. Simultaneous equations are then required to find the releasing moments, which must additionally be distributed to the

FIG. 33.—ARTIFICIAL AND NEUTRALIZING MOMENTS FOR SWAY IN FRAME OF EXAMPLE 6

frame, resulting in little if any saving in time or energy over presently known moment-distribution methods. The authors have attempted the solution of the problem by first calculating approximate values of the frame invariants and then, with the aid of these, distributing moments caused by the loading.

Criticism must be leveled at the manner in which the authors determine these invariants. Introduction of the elastic length concept needlessly complicates the formulas and results in no actual benefit. In re-entrant or completely enclosed frames, such as Vierendeel trusses, the problem of finding the approximate carry-over factors or transmission coefficients by temporarily fixing joints against rotation is unnecessary and entails needless work in distributing moments caused by releasing the joints.

In laying the theoretical basis for their method, the authors have not carried their work through to the logical conclusion of finding all the invariants of the frame. Since these quantities are independent of the manner of loading, they can be determined completely and exactly for any given frame, and it is not necessary to resort to fixing one or more joints against rotation.

The foregoing problem has been completely solved for uniform, nonuniform, and curved members by R. C. Brumfield, M. ASCE, who has shown[56,60] how the complete invariants for a frame, whether re-entrant or not, may be obtained quickly, exactly, and simply, and then with the aid of these, how to distribute in one cycle the moments caused by the loads.

The three major invariants of a continuous frame are:

1. A transmission coefficient (carry-over factor), which is that fraction of the moment arriving at one end of a beam as

---

[60] "Restrained Beams and Rigid Frames," by R. C. Brumfield, 1941 (printed in mimeograph form by The Cooper Union, New York, N. Y.).

a consequence of a unit moment applied at the other end (every member having two transmission coefficients);

2. A moment split, which is that fraction by which moment arriving at a joint through one of the radiating members of the joint is to be multiplied to give the induced moment in the member to which the moment split applies; and

3. A torque split, which is that fraction by which torque applied to a joint is to be multiplied to give the induced torque (or moment) in the member to which it applies.

Once the exact transmission coefficients have been determined, the bending moments at the ends of a loaded member may be found directly in terms of the fixed-end moments and the transmission coefficients.[61]

Comparisons are invidious, and particular problems may be solved more readily by one method than by another. Nevertheless, the writer would like to indicate how simply the invariants, especially those for closed or Vierendeel frames, may be found without arbitrarily fixing any joints, and then with the aid of the three major invariants to complete the solution of moment distribution for Example 6 as a comparison with the authors' method.

The invariants are defined as follows:

$$K = \frac{I}{L} \qquad (99)$$

C_{AB} and C_{BA} are transmission coefficients from A toward B and vice versa; m_{AB} and t_{AB} are the moment split and torque split, respectively, for member AB at joint A; i', the stiffness index, is a measure of the resistance which a member, together with the restraints applied to it at one end, offers to the rotation of

the joint to which it attaches at the opposite end, or

$$i' = \frac{K}{2 - C} \qquad \text{(100)}$$

R', the restraint index, is a measure of the resistance to rotation offered to a member, when it is used to rotate a joint, by the other members radiating from the joint, or

$$R' = i'_1 + i'_2 + i'_3 + \cdots + i'_n \qquad \text{(101)}$$

and R'_T, the restraint index in torsion, is a measure of the resistance to rotation offered to a member by all the members radiating from a joint, or

$$R'_T = i'_0 + i'_1 + i'_2 + i'_3 + \cdots + i'_n \qquad \text{(102)}$$

The primes used in Eqs. 100, 101, and 102 indicate the reciprocals of the values introduced by Professor Brumfield.[56,60] For beams of uniform section, the value of the transmission coefficient is given by

$$C = \frac{1}{2 + \dfrac{K}{R'}} \qquad \text{(103)}$$

for moment split, by

$$m_n = \frac{i'_n}{R'} \qquad \text{(104)}$$

and for torque split, by

$$t_n = \frac{i'_n}{R'_T} \qquad \text{(105)}$$

Calculation of the invariants is a slide rule computation and may be kept in tabular form. For Example 6, the invariants are as shown in Table 25.

For convenience the invariants are also placed on the frame diagram in Fig. 33(a).

If the concept of right and left arrows as shown in Table 26 is used, the chances for errors in sign are obviated. Normal bending moment, indicated by an arrow to the right, is clockwise moment applied to the beam when taken as a free body. Reverse bending moment, indicated by an arrow to the left, is a counterclockwise moment. For a downward load the moment at the right end is normal and at the left end, reverse. The moments are distributed to the frame in accordance with the frame invariants. After going through a joint, the moment changes in character. When going from one end of a beam to the other, moment remains the same in character. If only two members radiate from a joint, the moment split at that joint is unity; if more than two members occur at a joint, the moment splits would, of course, be fractional. In order to determine the transmission coefficients, it is not necessary to assume fixed joints as the authors have done. Much simpler is the method of estimating one of the coefficients and using it to compute another, which, as a result of the rapidly converging nature of Eq. 103, will be correct within one or two thousandths.

It is known that, for an elastically restrained member of uniform section, the transmission coefficient lies between 0 and 0.500, for free ends and fixed ends, respectively. For a series of equal spans having equal moments of inertia, it can be shown[62] that $C = 0.268$. Eq. 103 may be written in the form,

$$C_{AB} = \frac{1}{2 + \frac{K_{AB}}{R'_{AB}}} \qquad \text{(106)}$$

---

[62] "Restrained Beams and Rigid Frames," by R. C. Brumfield, 1941 (printed in mimeograph form by The Cooper Union, New York, N. Y.), p. 9.

and since

$$R'_{AB} = i'_{BD} = \frac{K_{BD}}{2 - C_{BD}} \tag{107}$$

for the two member joint, then

$$C_{AB} = \frac{1}{2 + \dfrac{K_{AB}}{\left(\dfrac{K_{BD}}{2 - C_{BD}}\right)}} \tag{108}$$

which is the form used in estimating C_{AB}. If member BD connects into a stiffer member, the coefficient will be greater than 0.268, and conversely.

Although the Vierendeel truss of Example 6 is symmetrical in form, it is unsymmetrically loaded. To estimate certain of the transmission coefficients (carry-over factors) of a re-entrant frame of this type, an average value must be estimated for $i' = \sum \frac{K_n}{2 - C_n}$ for each of the members radiating from the joint, except the member for which the transmission coefficient is being estimated. For example, to estimate C_{AC} (Fig. 33(*a*)), $C_{CE} > 0.268$, say, 0.300, and $C_{CD} > 0.268$, say, 0.350. Then,

$$C_{AC} = \frac{1}{2 + \dfrac{K}{R'}} = \frac{1}{2 + \dfrac{K_{AC}}{\dfrac{K_{CE}}{2 - C_{CE}} + \dfrac{K_{CD}}{2 - C_{CD}}}} = \frac{1}{2 + \dfrac{0.625}{\dfrac{0.625}{2 - 0.300} + \dfrac{0.500}{2 - 0.350}}}$$

$= 0.341$. If an average value for $2 - C_n$ is assumed, the general formula becomes

$$C_{AC} = \frac{1}{2 + \dfrac{K\,(2 - C_{avg})}{K_1 + K_2 + K_3 + \cdots + K_n}} \tag{109}$$

The value of C_{avg} is not critical. Thus, for $C_{avg} = 0.250$, $C_{AC} = 0.336$; for $C_{avg} = 0.300$, $C_{AC} + 0.340$; and for $C_{avg} = 0.350$, $C_{AC} = 0.343$. An average value of C_n based on a general mental estimate of the coefficients, in this case 0.350, is used. Therefore, $C_{CE} = \dfrac{1}{2 + \dfrac{1.650 \times 0.625}{0.625 + 0.333}} = 0.326.$ Similarly, $C_{BD} = 0.354$ and $C_{DF} = 0.334$. These coefficients give starting points, so that Table 25 becomes routine procedure, advantage being taken of frame symmetry.

The primary bending moments for the given loading without the effects of sway or vertical displacements are obtained from the following equations:[61]

$$M_R = A_R\,[(2\,M_{FR} + M_{FL}) - C_L\,(2\,M_{FL} + M_{FR})] \tag{110a}$$

$$M_L = A_L\,[(2\,M_{FL} + M_{FR}) - C_R\,(2\,M_{FR} + M_{FL})] \tag{110b}$$

$$A_R = \frac{C_R}{1 - C_L\,C_R} \tag{111a}$$

and

$$A_L = \frac{C_L}{1 - C_L C_R} \qquad \text{(111}b\text{)}$$

in which C_R and C_L are the transmission coefficients; M_{FR} and M_{FL} are the fixed-end moments; and M_R and M_L are the restraining moments at the right and left beam ends, respectively.

For span CE: $C_R = 0.326$, $C_L = 0.341$, $A_R = 0.366$, $A_L = 0.384$, $M_{EC} = M_R = 0.366 \times 0.659 \times \frac{3}{8} \times 4 \times 24 = -8.68$ ft-kips, and $M_{CE} = M_L = 0.384 \times 0.674 \times \frac{3}{8} \times 4 \times 24 = -9.32$ ft-kips. For span EG: $C_R = 0.341$, $C_L = 0.326$, $A_R = 0.384$, $A_L = 0.366$, $M_{GE} = M_R = -0.384 \times 0.674 \times \frac{1}{4} \times 8 - 24 = -12.43$ ft-kips, and $M_{EG} = M_L = -0.366 \times 0.659 \times \frac{1}{4} \times 8 \times 24 = -11.58$ ft-kips. These primary moments have been distributed in Table 26, lines 1 and 2, and totaled in line 3. Moments have been distributed through three joints from the joint of origin.

The moments caused by the horizontal sway and vertical displacements must now be determined. Since dissymmetry of loading exists, the frame will tend to lurch sideway. It is allowed to sway laterally and the artificial moments required to rotate the tangents at the column ends parallel to their original direction are shown in Fig. 33(*b*). Neutralizing moments at each joint necessary to balance the artificial moments are apportioned among the radiating members in accordance with the joint torque split obtained from Fig. 33(*a*), or Table 25, and are designated (*n*) in Fig. 33(*b*). In a similar manner, artificial and neutralizing moments are found for vertical displacement as shown in Fig. 33(*c*). The neutralizing moments are distributed to the frame in accordance with the frame invariants given in Table 25 and Fig. 33(*a*). The summations of the distributed neutralizing moments, together with the artificial moments, are given in lines 4 to 8, Table 26. Since there are five unknown moments of translation, five equations must be written and solved simultaneously. The coefficients of M_0 to M_5, forming these equations, are obtained from Table 26 as follows:

For the first equation, the sum of the horizontal shears in the posts AB, CD, EF, GH, and IJ in terms of M_0 to M'_5 is set equal to zero. Designating normal moments as plus and reverse moments as minus,

$$-4{,}156\, M_1 + 1{,}594\, M_2 + 814\, M_3 - 814\, M_4 - 1{,}594\, M_5 - 0.30 = 0 \qquad (112)$$

For the second equation, the internal shear at A and B in members AC and BD is set equal to the left reaction, $R_L = 5.5$ kips, so that

$$+1{,}333\, M_1 - 2{,}104\, M_2 + 604\, M_3 + 81\, M_4 - 15\, M_5 + 4.44 = -5.5 \times 24 \qquad (113)$$

For the third equation, the internal shear to the right of C and D in members CE and DF is set equal to the left reaction. Thus,

$$+745\, M_1 + 608\, M_2 - 2{,}038\, M_3 - 701\, M_4 + 113\, M_5 + 8.03 = (-5.5 + 2)\, 24 \qquad (114)$$

For the fourth equation, the internal shear at I and J in members GI and HJ is set equal to the right reaction, $R_R = 6.5$ kips, giving

$$+ 1{,}333\, M_1 + 15\, M_2 - 81\, M_3 - 604\, M_4 + 2{,}104\, M_5 - 6.71 = 5 \times 24 \ldots (115)$$

The fifth equation is obtained from the vertical displacement diagram (Fig. 33(*c*)). The sum of the deflections of AC and CE must be equal to the sum of the deflections of IG and GE, which can be expressed in terms of M_2 to M_5. Thus,

$$M_2 + M_3 = M_4 + M_5 \ldots\ldots\ldots\ldots\ldots\ldots (116)$$

Solving Eqs. 112 to 116, simultaneously, gives $M_1 = - 0.002423$, $M_2 = + 0.081047$, $M_3 = + 0.057996$, $M_4 = + 0.045476$, and $M_5 = + 0.093567$.

In step (*h*) of Example 6, the authors have set up four equations for vertical shear correction factors. Nowhere, however, does a similar equation or correction factor appear for the horizontal shear or horizontal movement of the top chord. The effects of both horizontal sway and vertical displacement of the joints must be considered as simultaneous actions in determining correction factors, since these factors for vertical and horizontal shear are interrelated. Such correction (for horizontal sway) is not obvious from the authors' calculations in Examples 4, 5, and 6.

The values of M_1 to M_5 found from Eqs. 112 to 116 are multiplied by the respective coefficients in lines 4 to 8, Table 26, to give lines 9 to 13, and are added to the primary moments due to loading in line 3 to give the final moments in line 14. These are to be compared with the authors' values (line 25, Table 13).

In the "Summary," the authors claim their method to be particularly adapted to the solution of Vierendeel trusses. Nevertheless, they have carried the solution of the truss of Example 6 only to the point of finding primary moments corrected for joint translation, despite the fact that a Vierendeel truss of several panels will develop secondary moments due to changes in member lengths caused by the axial stresses. These secondary moments are considerable and cannot be ignored. When the calculations for secondary moments are added to the work required by the authors' method for finding primary moments, it becomes doubtful whether any advantage is to be gained by adopting the proposed system of analysis.

It has been shown elsewhere[63] how the method as used by the writer to find the primary moments has been extended to solve the secondary stresses for this type of truss.

J. Charles Rathbun,[64] M. ASCE, and C. W. Cunningham,[65] Assoc. M. ASCE.—The large number of discussions of the paper is gratifying to the writers, as is also the fact that many discussers have made distinct contributions to the problem of frame analysis. In some of the discussions other methods of solving the same problem are presented by those who prefer them to the one presented in the paper. Although such citations are not pertinent to the subject, they do, in most cases, contribute to the problem of the solution of the rigid frame by calling attention to these methods and are, therefore, of value.

[63] *Transactions*, ASCE, Vol. 111, 1946, p. 848.

[64] Prof., Civ. Eng., College of the City of New York, New York, N. Y.

[65] Associate Prof., Civ. Eng., College of the City of New York, New York, N. Y.

The first paragraph of the "Synopsis" states clearly that the moment-distribution method is entirely distinct from the one presented. The words "classical" and "exact" have been used to show that the method is not one of successive approximations. The writers' use of the word classical is probably a survival of Newton's day, when the method of successive approximations was distinct from the classical methods (the Greek and Roman traditional methods).

An exact method, as used in the paper, is one which derives an exact solution from the data given. A method of successive approximations cannot be exact, in general, although it may be correct or close enough to the exact solution to satisfy the requirements. As an example, π has been computed to more than seven hundred decimal places, but this is not an exact value. Neither classical nor exact is used here in a sense complementary, or otherwise, to any method.

Of the seventeen discussions nine compare this method with the well-known moment-distribution method. These discussions are of little value because they do not apply to the method of the paper or contribute to the subject. Moment distribution is a most valuable method when the answer to a specific problem is desired, but many engineers are willing to consider that it furnishes all that is required for a solution, and they refuse to consider attempts to improve conditions.

Mr. Beaufoy furnishes an example of the trial-and-error solution in Fig. 15, wherein he compares this method with that of the paper. In Fig. 15 there is a self-consistent group of values, but moment EG is in error by 3.67%, or an amount equal to 0.425, and the error in moment GH is equal to 0.698. In his discussion, Mr. Beaufoy does not indicate a way to estimate the amount of these errors. In many problems one may obtain a solution by an approximate method with fewer computations and in less time than by an exact method, but does that constitute a solution to the general problem? The writers think not, and, although they admire this method for practical solutions, they consider it to have no place in a discussion of the paper. This same principle could have been applied in solving for the moments at the fixed joints, since the convergence of the series of trials will usually be very rapid. As this is quite obvious, the writers purposely omitted it from the paper.

The method of Otto Gottschalk is based on unloaded models. It is, therefore, useful only as a check on any analytical solution.

Messrs. Barron and Garfinkel advocate the use of transmission coefficients; this method requires a preliminary assumption for the value of a transmission coefficient. Although the assumed value produces final results that are within the limits of practical accuracy, the method is not exact, and so is not applicable to the writers' method.

Contrary to the statements of Messrs. Barron and Garfinkel, vertical and horizontal sway were treated simultaneously. If there are unbalanced shears in two mutually perpendicular directions, and if these shears are balanced in one direction, those in the other direction are automatically balanced—

provided that all joints are in equilibrium. The following is a proof of this statement as applied to Example 5:

$$M_{BA} + M_{AE} + M_{FB} + M_{BF} = 24 \qquad \text{(117a)}$$

and

$$M_{AC} + M_{CA} + M_{BD} + M_{DB} = -24 \qquad \text{(117b)}$$

Adding Eqs. 117*a* and 117*b*,

$$+ M_{BA} + M_{AE} + M_{FB} + M_{BF} + M_{AC} + M_{CA} + M_{BD} + M_{DB} = 0 \qquad \text{(117c)}$$

Substituting from the equations for joint equilibrium,

$$- M_{EF} - M_{AB} - M_{AC} - M_{FE} - M_{BA} - M_{BD} + M_{AC} - M_{CD} + M_{BD} - M_{DC} = 0 \qquad \text{(117d)}$$

—which reduces to

$$M_{EF} + M_{FE} + M_{AB} + M_{BA} + M_{CD} + M_{DC} = 0 \qquad \text{(117e)}$$

—showing that the sum of the shears in the vertical members is zero, as it should be.

Mr. Barron questions the extension of the method as stated. If the principles outlined are followed, the method can be applied to any type of continuous frame having members of constant or variable moments of inertia. The question of secondary moments in Vierendeel trusses due to change of length of the members caused by the axial stresses, as well as the effect of the width of columns and depths of beams on the analysis, is definitely outside the scope of this paper.

Mr. Oesterblom doubts the adaptability of the method to Example 7—a complicated frame with various types of loading. The authors have solved this problem, obtaining the numerically correct answer, consistent with the assumed data. This work can be duplicated by following the paper and the given examples. The validity of the method and its proof have been brought out fully in the paper. Mr. Oesterblom does not make it clear why he cannot accept it.

Professor King claims an advantage for moment distribution in computing joint and bar rotation. If there is no joint translation, Eq. 9*b* may be used to obtain joint rotation. Eq. 18 may be used to find the joint rotation if there is joint translation, noting that the shear correction factor is equal to $\frac{E\,\Delta}{L}$. Calculations of these quantities by the elastic support method are much simpler and more direct than by the method advocated by Professor King.

Messrs. Fraenkel and Janes (and others) seem to have missed the reason for presenting simple illustrative problems such as the first three. There is no doubt that the first example can be solved more readily by the three-moment theorem; however, the purpose of the examples was to familiarize the reader with the method. There has been criticism of the use of the "conjugate beam" method in deriving some of the formulas. Other accepted methods of deriving these formulas have been used, but it was thought that the conjugate beam method was the best known to the readers.[66]

---

[66] "Elastic Properties of Riveted Connections," by J. Charles Rathbun, *Transactions*, ASCE, Vol. 101, 1936, pp. 550–552.

Mr. Merritt has used the method of moment ratios to solve and check several of the examples of the paper. His expression of "one-cycle distribution" is very apt, and brings out one difference between the moment-distribution method and some newer methods. The preliminary computations should be reduced to a minimum for practical considerations, but, when a new method is being presented, clarity should not be sacrificed for brevity. In the solution of Example 4 Mr. Merritt assumes two moment ratios, which remove his method from the "theoretically exact" category. Both the methods of Mr. Merritt and R. C. Brumfield, M. ASCE, have features that contribute to the ultimate solution of the problem.

Mr. Kavanagh has made a valuable contribution by transforming Eqs. 8 and 11 into one that is well known in the literature of elastic stability of bars, thus indicating the possibility of applying the method to the calculation of buckling restraints in axially loaded members of rigid frames.

Mr. Eremin presents a graphical construction that should be very useful in checking the analytical work for both prismatic and nonprismatic members, and so is an addition to the subject.

Professor Moorman's equations for the statical moment of the moment diagram for prismatic members can be used, not only in this method, but also in any method involving these quantities. The evaluation of x usually presents no difficulty if one sketches the moment curve of the simple beam and then by moments (as in the conjugate beam method) finds its center of gravity.

Mr. Agramonte has developed an interesting but formidable set of equations for nonprismatic members. However, it should be noted that the θ used by Mr. Agramonte is measured from the rotated position of the gravity axis of the member (Fig. 22), whereas the writers measure θ from the position of the unstressed member (Fig. 5 (*b*)).

Professor Ferguson calls attention to the method presented by T. Y. Lin, Assoc. M. ASCE; he then points out the difference between the two papers, noting that the formulas differ, but that one set can be reduced to the other by algebraic transformations. This should be true if both sets of formulas are correct and if they deal with the same ideas. If, as Professor Ferguson thinks, a comparison between the two methods is valuable, it would have been a contribution if he had worked it out in his discussion. He mentions several differences, enough to make it evident that the Lin method is not the same as that of the writers, but that it is valuable.

Professor Gaylord has simplified the writers' equations in a very ingenious manner which ought to appeal to the practicing engineer. Eq. 93*h* is particularly significant since it shows how fixed-end moments are distributed about a joint that is temporarily fixed, and then allowed to assume its natural rotated position.

Mr. Conwell's remark about the analytic beauty in the concept of the method presented is appreciated. Inclusion of the properties of the connections in the analysis is, the writers feel, a must. For work to be of value in practical stress analysis there are usually other considerations besides elasticity of connections that affect the answer even more. For example, a building is stiffened 350%, or thereabouts, by the walls, partitions, and floors. From a strictly practical standpoint there is some question as to the value of any analytical method. However, this does not mean that progress should stop in the development of these methods.

The writers do not agree that the final test is in the designing office, where the designer may not have the time, energy, or desire to learn a new method. It is their experience that those who have taken time to develop skill in its use find that the analysis by elastic support action is as rapid, or more rapid, than the other methods. Its chief value is, however, the presentation of a method which will further the subject of analysis. If advancement were to stop with any of the current methods it would indeed be unfortunate.

Mr. Stewart shows considerable similarity between some of the writers' ideas and the method of traversing the elastic curve; this method is probably more popular than is generally supposed. Combining as it does the advantages of geometry and pictorial representation with the moment-area method, a very efficient system has been devised. Not only is it simple and readily understood, but problems can be solved quickly, and, because of the picture, the action is understood. As previously stated, the writers chose the conjugate beam method of deriving their equations, rather than the one suggested by Mr. Stewart, because they are of the opinion that the older method is more widely known.

Mr. Floris' statement that the writers' method is indirect, that it is primarily a relaxation method, and that conjugate beam is an incorrect name for the Mohr theorem (moment-area method or Greene's theorem) leads the writers to feel that he has deviated widely from the proper scope of discussion. That proof of the formulas and method presented has not been furnished is an unwarranted statement; Eq. 47 is the same as Eq. 10*b* with a slight, unnecessary, algebraic change, which makes it a little difficult to use. Mr. Floris' concluding paragraph is his opinion against that of the writers, whose experience has been to the contrary. Since his discussion shows some misunderstanding of the subject, he should have supported his conclusions so that they could have been of value.

In closing, the authors wish to thank those discussers who have taken the time and trouble to help develop the ideas presented, and to call attention to the writings of others along these lines.

STABILITY OF THIN CYLINDRICAL SHELLS IN TORSION

By R. G. Sturm,[1] M. ASCE

With Discussion by Messrs. S. B. Batdorf and Manuel Stein, Glenn Murphy, L. H. Donnell, R. L. Moore, and R. G. Sturm

Synopsis

Beginning with previously derived general differential equations, this paper leads to the development of a single continuous expression for the critical shearing stress at buckling for all cylindrical shells or tubes whether long, medium, or short. This expression is reduced to a simple equation and a family of curves dependent only on the geometry of the shells and independent of the properties of the materials of which the shell is constructed. The simple equation introduces all factors dependent on the shell material. Comparisons between test results and theoretical values show excellent agreement. Methods for computing the strength of imperfect or incomplete shells are derived and compared with test results. A method of specifying maximum out-of-roundness or local discrepancies for a given percentage of strength is also proposed. A procedure for determining critical shearing stresses in thin-walled pipe lines, tanks, or fuselages is presented.

Introduction

The proper choice of sheet thickness in the design of stressed-skin construction for airplane fuselages, wings, and fuel tanks involves consideration of stability as well as of allowable stresses. Modern trends toward tubular construction for aircraft structures have emphasized the problem of selecting adequate wall thicknesses for very thin-walled tubes or partial tubes. Such members generally tend to buckle at loads far below that required to develop the ultimate strength of the material in tension, compression, or shear. Such buckling frequently results from shearing stresses induced by torque loads or transverse shear. Further interest in the stability of thin-walled tubes has resulted from the use of tubular members for actuating airplane controls. Such

---

[1] Prof., Eng. Mechanics, and Research Prof. of Materials, Purdue Univ., Lafayette, Ind.

members may tend to "snake" and buckle laterally when subjected to torsional loads.

In the transportation of liquids by pipe lines or trucks, one of the major problems is that of selecting the proper wall thickness of the pipe or vessel containing the liquid. Although the side walls of pipe lines or tanks are by no means in simple shear, the resistance to shear buckling may be the controlling factor in the determination of adequate wall thickness. In a number of instances diagonal buckles have occurred near supports on the side of truck tanks thereby indicating the presence of buckling in shear.

In the drilling of oil wells, tubes or rods are used to rotate the drill bits. Because the relative lengths of such members are great, it has been found that a stability problem is encountered in which there is a lateral buckling of the tube or rod as a whole. This type of buckling is different from the local buckling of the walls of thin cylinders or tubes subjected to torsion. A solution to the problem of lateral buckling of a long tube or rod subject to torsion was obtained by A. G. Greenhill[2] in 1883, whereas the first solution of the buckling of the walls of long thin-walled cylinders subjected to torsion, known to the writer, was published by E. Schwerin[3] in 1924.

In 1932 Eugene E. Lundquist,[4] Assoc. M. ASCE, published the results of a great number of tests on thin-walled duralumin cylinders subjected to torsion. His work has been so carefully reported that it provides an excellent basis for comparison between theoretical and experimental results. The following year, 1933, L. H. Donnell[5] published a theoretical solution to the problem of torsion buckling of thin-walled tubes. Mr. Donnell's work is based on a number of simplifications in the general theory of buckling and leads to certain expressions for the critical shearing stress in short and moderately long thin-walled tubes and to other expressions for long tubes. An excellent evaluation of this theory has been presented by S. Timoshenko.[6] Professor Timoshenko recommends that the Donnell theory be used for short tubes but for long tubes he recommends other formulas.

Curves representing the shear buckling strength of thin-walled tubes plotted against the ratio of length to diameter show a sudden break between Mr. Donnell's theory for "short and moderately long tubes" and that of Mr. Schwerin for "long tubes" of only slightly greater length.

Mr. Donnell's experimental results indicate buckling strengths which average only about 75% of his computed values. This discrepancy was excused on the basis of initial departure from perfect circularity of tubes tested.

The confusion resulting from the use of two formulas—one for short tubes and another for long tubes—together with the difficulty encountered in justifying the discrepancies in the values obtained by existing analysis led to the study of the torsion buckling of thin-walled cylinders presented in this paper.

In general this study has for its object a threefold purpose: (I) To derive, on the basis of the theory of elasticity, a general expression for the maximum torque that can be applied to a thin-walled tube without the tube buckling; (II) to compare the theoretical values of critical torque thus obtained with experimental values obtained by other investigators; and (III) to suggest ways of extending these results to practical problems involving shear buckling of thin cylinders.

PART I. DERIVATION OF FORMULAS

Procedure and Assumptions

The general procedure followed in Part I is to derive expressions for the critical torsional shearing stresses in round cylindrical shells of perfectly elastic materials and to treat departures from these conditions as corollaries of the first derivation. The argument used in determining the critical shearing stresses may be stated as follows:

> Consider the cylinder deflected into some shape such that the combined differential equations of continuity and equilibrium, together with the boundary conditions, are satisfied. If the shell is in a state of neutral equilibrium, the external forces necessary to hold the shell in the deflected position will be independent of the magnitude of the deflections as long as they are so small that they do not materially change the general shape of the shell. A slight increase in external force above this value will cause collapse. Therefore, the lowest shearing stress causing neutral equilibrium is considered as the critical shearing stress for the cylinder.

The assumptions involved in the derivation of the general equations may be enumerated as follows: (*a*) The shell is a round cylinder before buckling; (*b*) the shell is of uniform thickness throughout; (*c*) the material in the shell is homogeneous, isotropic, and perfectly elastic; and (*d*) the shell wall is so thin in proportion to the diameter that the curvature will not materially disturb the linear distribution of stress through the thickness of the shell wall—that is, the ordinary flexure formulas may be applied.

System of Coordinates.—The system of cylindrical coordinates used to define and locate any particular element of shell is indicated in Fig. 1. The entire system is based on a reference cylinder the radius of which is the average mean radius of the actual shell, and the longitudinal axis of which coincides with that of the actual shell. The origin of coordinates is taken on the cylinder of reference, at the point of maximum radial displacement of the deflected shell, and midway between the ends of the cylinder.

The y-axis is parallel to the axis of the shell, and lies on the cylinder of reference, positive toward the reader. The s-axis lies on the circumference of a right section of the cylinder of reference, positive in a clockwise direction. The coordinate is $s = r\,\theta$ in which r is the radius of the cylinder of reference, and θ is the angle subtended by s in a right section of the cylinder of reference. The z-axis coincides with the radius of the cylinder of reference, the radial displacement z being measured positive outward.

Notation.—The following letter symbols, adopted for use in the paper and for the guidance of discussers, conform essentially with American Standard Letter Symbols for Mechanics of Solid Bodies (ASA–Z10.3–1942), prepared by a sectional committee of the American Standards Association, with Society participation, and approved by the Association in 1942:

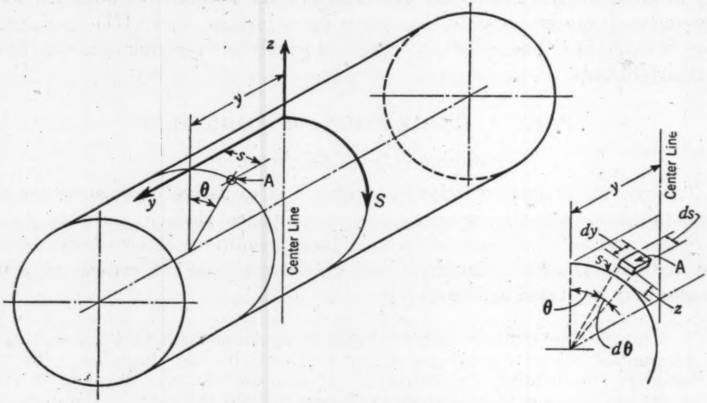

FIG. 1.—SYSTEM OF COORDINATES

a = an aribtrary numerical constant determined from boundary conditions and from the general differential equations; similar definitions apply to constants b, c, d, m, and n;

b = (see a);

c = the distance from the extreme fiber, in the cross section of a beam, to the neutral axis (see Eq. 28); also an arbitrary constant (see a);

D = mean diameter of a cylindrical shell, in inches;

d = (see a);

E = modulus of elasticity of the material in the shell, or in the stiffener, in pounds per square inch;

f = "a function of" (see Eq. 6a); similar definitions apply to functions g, h, j, and ϕ;

G = modulus of elasticity in shear;

g = "a function of" (Eqs. 7); also (see f) "a function of" as in Eq. 14b;

h = (see f);

I = moment of inertia per unit length of shell, in inches^3, $= t^3/12$;

j = (see f);

K = a numerical coefficient dependent on various dimensional ratios:

  K_D = coefficient dependent upon L/D and D/t;

  K_r = coefficient dependent upon r/L and N, introduced by the loading conditions;

L = length of the cylinder, in inches;

M = couple or moment resulting from the distribution of forces or couples on a unit length of the face of the element lying in a plane normal to a given tangent to the shell; units are in inch-pounds per inch and are positive where the force of the couple farthest away from the center of the shell is positive:

- M_s = a bending couple or moment resulting from the distribution of normal forces, in a plane normal to the circumferential (s-axis) tangent;
- M_y = a bending couple or moment resulting from the distribution of normal forces, in a plane normal to the longitudinal (y-axis) tangent;
- M_{sy} = a twisting couple or moment resulting from the distribution of shearing forces, in a plane normal to the circumferential (s-axis) tangent;
- M_{ys} = a twisting couple or moment resulting from the distribution of shearing forces, in a plane normal to the longitudinal (y-axis) tangent;

m = (see a);
N = the number of lobes into which the shell collapses;
n = (see a);
P = normal force, in pounds per linear inch, acting on a unit length of the face of an element:

- P_s = force in a plane normal to the circumferential tangent to the shell;
- P_y = force in a plane normal to the longitudinal tangent to the shell;

Q = a parameter; Q_1 and Q_2 are parameters determined by Eqs. 14 and 15;
Q' = a parameter; Q'_1 and Q'_2 are parameters determined by Eqs. 14 and 15;
q = any integer;
r = mean radius of a cylinder;
S = shearing force on the unit of length of the face of a given element, in pounds per linear inch:

- S_{sy} = force in the y-direction, with the element in a plane normal to the circumferential (s-axis) tangent to the shell;
- S_{sz} = force in the z-direction, with the element in a plane normal to the circumferential (s-axis) tangent to the shell;
- S_{ys} = force in the s-direction, with the element in a plane normal to the longitudinal (y-axis) tangent to the shell;
- S_{yz} = force in the z-direction, with the element in a plane normal to the longitudinal (y-axis) tangent to the shell;

s = an arc length; also axis s in Fig. 1;
t = thickness of shell wall, in inches;
u = longitudinal displacement of a point in the middle surface;
V = total vertical shear on a section, in pounds;
v = circumferential displacement of a point in the middle surface;

W = total weight, or total load uniformly distributed, in pounds (see Fig. 2);
X = a substitution factor (see Eqs. 22);
y = distances along the longitudinal (y-axis) of a tube;
z = radial deflection of a middle surface of a shell; z_o = initial departure from a round cylinder, in inches;
α = angle between the crest of a buckle wave and a longitudinal element of the cylinder (see Fig. 5);
γ = unit detrusion in a tangential plane;
Δ = displacement; a constant (indeterminate in magnitude at the time of collapse) which represents a maximum value of deflection:

Δ' = maximum initial departure from a round cylinder;
Δ_s = circumferential displacement of a point in the middle surface;
Δ_y = longitudinal displacement of a point in the middle surface;

ϵ = unit strain:

ϵ_r = unit strain in a radial direction;
ϵ_s = unit strain in a circumferential direction;
ϵ_y = unit strain in a longitudinal direction;

θ = angular distance;
μ = Poisson's ratio;
τ = tangential shear stress in the wall of the cylinder:

τ' = shear stress denoting combined bending and shear;
τ_c = critical buckling shear stress;

$$\tau_o = K_D \, E \, \frac{t^2}{D^2} \qquad \text{(1)}$$

τ_t = stress that causes local tension equal to the yield point stress;

ϕ = "a function of"; as used in Eq. 8; and
ψ = an infinitesimal angle at the center of curvature of the deflected shell, subtended by the circumferential element of length (see Eq. 4).

Deformed Element of Shell.—The element of shell considered is shown in its deformed state in Fig. 2. If u, v, and z are the displacements in the directions y, s, and z, respectively, of a point in the middle surface of the shell from the undeformed position, then the strains and the detrusion of the middle surface are defined as:

$$\epsilon_y = \frac{\partial u}{\partial y} \;;\quad \epsilon_s = \frac{\partial v}{\partial s} + \frac{v}{r} \;;\quad \gamma_{sy} = \frac{\partial u}{\partial s} + \frac{\partial v}{\partial y} \qquad \text{(2)}$$

By eliminating u and v, the following equation of compatibility[7,8] is obtained:

$$\frac{\partial^2 \epsilon_s}{\partial y^2} + \frac{\partial^2 \epsilon_y}{\partial s^2} - \frac{\partial^2 \gamma_{sy}}{\partial s \, \partial y} - \frac{1}{r} \frac{\partial^2 z}{\partial y^2} = 0 \qquad \text{(3)}$$

Fig. 2.—Free-Body Diagram for an Element of a Thin Shell (All Forces and Couples Are Positive in the Directions Shown—That Is: z Is Positive Outward; y Is Positive Toward the Reader; and s Is Positive Clockwise

Eq. 4 defines an infinitesimal angle at the center of curvature of the deflected shell, subtended by the circumferential element of length.

Internal Forces and Couples.—Fig. 2 shows the forces and couples that hold an element of shell in equilibrium: An external pressure W, in pounds per square inch; two normal forces, P_s and P_y; four shearing forces, S_{sy}, S_{ss}, S_{ys}, and S_{ys}; and four couples, M_s, M_y, M_{sy}, and M_{ys}. These concepts are defined fully in the notation.

ADAPTATION OF GENERAL THEORY OF BUCKLING TO PROBLEM OF TORSION

The derivation of a set of general differential equations governing the behavior of thin-walled cylinders subjected to any type of external load has been presented elsewhere by the writer.[9] The equations were derived from a consideration of the forces acting on a small section of a cylinder subjected to a uniform loading of any kind and of sufficient magnitude to cause the cylinder to be precisely at the point of collapse (see Fig. 1). Since all parts of the shell in Fig. 2 are in equilibrium and since the shell wall is continuous, an interrelation between the forces and deflections is obtainable. The four general differential equations derived from the conditions of equilibrium and continuity applied to the elemental part of the shell[10] are:

$$-\frac{E\,I}{1-\mu^2}\left(\frac{\partial^4 z}{\partial y^4}+\frac{\mu}{r^2}\frac{\partial^2 z}{\partial y^2}+\frac{2}{r^2}\frac{\partial^4 z}{\partial \theta^2\,\partial y^2}+\frac{1}{r^4}\frac{\partial^4 z}{\partial \theta^4}+\frac{1}{r^4}\frac{\partial^2 z}{\partial \theta^2}\right)$$

$$= W + P_s\frac{1}{r}\frac{\partial \psi}{\partial \theta} - P_y\frac{\partial^2 z}{\partial y^2} - S_{ys}\frac{1}{r}\frac{\partial^2 z}{\partial \theta\,\partial y} - S_{sy}\frac{1}{r}\frac{\partial^2 z}{\partial \theta\,\partial y}\ldots\ldots\ldots(5a)$$

$$\frac{1}{r^2}\frac{\partial^2 P_s}{\partial \theta^2}-\frac{\partial^2 P_y}{\partial y^2}-\frac{1+\epsilon_s}{r}\frac{E\,I}{1-\mu^2}\left(\frac{1}{r^4}\frac{\partial^4 z}{\partial \theta^4}+\frac{1}{r^4}\frac{\partial^2 z}{\partial \theta^2}+\frac{2-\mu}{r^2}\frac{\partial^4 z}{\partial \theta^2\,\partial y^2}\right)=0\ldots(5b)$$

$$\frac{\partial^2 P_s}{\partial y^2}+(2+\mu)\frac{\partial^2 P_y}{\partial y^2}+\frac{1}{r^2}\frac{\partial^2 P_y}{\partial \theta^2}-\frac{\mu}{r^2}\frac{\partial^2 P_s}{\partial \theta^2}=\frac{E\,t}{r}\frac{\partial^2 z}{\partial y^2}\ldots\ldots\ldots(5c)$$

and

$$\frac{\partial^2 P_s}{\partial y^2}-\frac{\mu\partial^2 P_y}{\partial y^2}=\frac{E\,t}{r}\left(\frac{\partial^3 v}{\partial y^2\,\partial \theta}+\frac{\partial^2 z}{\partial y^2}\right)\ldots\ldots\ldots\ldots(5d)$$

For the conditions existing in a tube subjected to pure torsion, certain simplifications may be made, as follows:

(1) Since there is no external pressure, $W = 0$ and

$$P_s = 0 + f(y\,s)\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6a)$$

in which $f(y\,s)$ is a function of the coordinates y and s, representing the variation of the circumferential force caused by the radial deflection of the shell. When the deflection is small, $f(y\,s)$ is small, and the quantities $\frac{1}{r}\frac{\partial^2 z}{\partial \theta^2}$, ϵ_s, and $\frac{z}{r}$ which are involved in the definition of $d\psi$ are also very small compared to unity. Consequently, products of $f(y\,s)$ and these terms may be dropped from Eqs. 5a and 5b.

(2) There is no longitudinal force on the cylinder, therefore,

$$P_y = 0 + g(y\,s)\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6b)$$

[9] "A Study of the Collapsing Pressure of Thin-Walled Cylinders," by R. G. Sturm, *Bulletin No. 329*, Univ. of Illinois Eng. Experiment Station, Urbana, Ill., 1941.

[10] *Ibid.*, Section 11, p. 17.

in which $g(y\ s)$ is a function of the coordinates y and s representing the variation in the longitudinal forces caused by the radial deflections of the shell. When the deflection is small, $g(y\ s)$ and the term $\partial^2 z/\partial y^2$ are small. Consequently, the product of $g(y\ s)$ and $\partial^2 z/\partial y^2$ may be dropped from Eq. 5*a*.

(3) Since the tube is circular, the shearing stresses will be constant except for variations caused by radial deflections of the tube and the values S_{ys} and S_{sy} will be constant and equal to $\tau\ t$ (shearing stress times thickness) except for small amounts $j(y\ s)$ and $h(s\ y)$, respectively. Consequently, the variations in S_{ys} and S_{sy} will be very small when the radial deflection, z, is small, and the term $\partial^2 z/\partial\theta\ \partial y$ is also small. The resulting products of the terms $h(s\ y)$ and $j(y\ s)$ and $\dfrac{\partial^2 z}{\partial\theta\ \partial y}$ may be dropped from Eq. 5*a*.

(4) Because of the assumed uniformity of dimensions and material in the cylinder, the average shearing stress is considered constant throughout the length of the cylinder and the displacement v is $\dfrac{S_{ys}}{t\ G}\, y$ except for small variations of $g(y\ s)$. As in previous paragraphs, products of $g(y\ s)$ and z or its derivatives may be considered negligible.

(5) Because the circumferential forces, P_s, are zero except for small variations depending on the radial deflection, the unit strain in the circumferential direction, ϵ_s, can be neglected.

Use of these five simplifications leads to the four general differential equations:

$$\frac{E\ I}{1-\mu}\left[\frac{\partial^4 z}{\partial y^4} + \frac{\mu}{r^2}\frac{\partial^2 z}{\partial y^2} + \frac{2}{r^2}\frac{\partial^4 z}{\partial\theta^2\ \partial y^2} + \frac{1}{r^4}\left(\frac{\partial^4 z}{\partial\theta^4} + \frac{\partial^2 z}{\partial\theta^2}\right)\right] + \frac{1}{r} f(s, y) = \frac{2\ S_{ys}}{r}\frac{\partial^2 z}{\partial\theta\ \partial y} \qquad (7a)$$

$$\frac{\partial^2 f}{r^2\ \partial\theta^2} - \frac{\partial^2 g}{\partial y^2} - \frac{E\ I}{r(1-\mu^2)}\left[\frac{1}{r^4}\left(\frac{\partial^4 z}{\partial\theta^4} - \frac{\partial^2 z}{\partial\theta^2}\right) + \frac{(2-\mu)\ \partial^4 z}{r^2\ \partial\theta^2\ \partial y^2}\right] = 0 \qquad (7b)$$

$$(2+\mu)\frac{\partial^2 g}{\partial y^2} + \frac{\partial^2 g}{r^2\ \partial\theta^2} + \frac{\partial^2 f}{\partial y^2} - \frac{\mu}{r^2}\frac{\partial^2 f}{\partial\theta^2} = \frac{E\ t}{r}\frac{\partial^2 z}{\partial y^2} \qquad (7c)$$

and

$$\frac{\partial^2 f}{\partial y^2} - \mu\frac{\partial^2 g}{\partial y^2} = \frac{E\ t}{r}\left(\frac{\partial^3 v}{\partial y^2\ \partial\theta} + \frac{\partial^2 z}{\partial y^2}\right) \qquad (7d)$$

The problem, as defined, is to find a solution of these simultaneous differential equations which will give the correct type of radial deflection of the cylinder wall and at the same time will fulfil the boundary conditions. The value of torsional shearing forces, $S_{ys} = S_{sy} = \tau\ t$, which will make the magnitude of the deflections indeterminate is the value which will produce neutral equilibrium and hence will be the critical value. The torque producing this stress is the maximum torque that can be applied to the tube without it buckling.

The boundary conditions are simply the conditions of support at the ends of the tube which depend on the fixation of the tube. The first and principal case considered is that of "simply supported ends." In this case the ends of the deflected tube are held so as to retain their original true circularity and, at the same time, to offer no external resistance to a change in slope of a longitudinal tangent.

The particular practical condition of the tube which this case represents is that encountered in an intermediate section of three or more sections of a tube subdivided by bulkheads relatively narrow in the direction of the tube axis.

The mathematical statement of these boundary conditions is as follows: When $y = +\frac{L}{2}$, $z = 0$; and, for all values of θ, $\frac{\partial z}{\partial \theta} = 0$.

The choice of the center of coordinates midway between the ends of the cylinder or tube and at the point of maximum displacement around the shell leads to the boundary condition that $\frac{\partial z}{\partial \theta} = 0$ when $y = 0$ and $\theta = 0$.

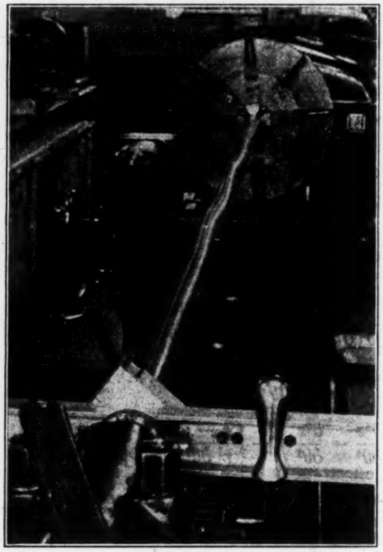

FIG. 3.—THIN-WALLED ALUMINUM ALLOY TUBE ($L/D = 44$ AND $D/t = 138$) AT NEUTRAL EQUILIBRIUM UNDER A TORSIONAL LOAD

Solution of Differential Equations.—The boundary conditions indicate that the solution of the equations is a symmetrical function with respect to both the longitudinal axis, y, and the angular axis, θ. For such high-order differential equations, solutions in the form of the product of two or more simple solutions may be sought. To obtain suggestions as to the correct type of radial deflection of the tube wall in a state of neutral equilibrium, an actual tube (Fig. 3) was twisted until it buckled and then held in its buckled state. The shape of the deflected tube clearly indicates that the general form of the deflected cross section remains essentially the same but that the points of contraflexure tend to spiral around the tube.

The general shape of the deflected tube, as shown in Fig. 3, may be represented by the equation:

$$z = \phi(y) \cos\left(N\theta + \frac{K_r \pi y}{L} \right) \qquad (8)$$

In order that $\phi(y)$ may fulfil the boundary conditions (that is, zero deflection at the end of the tube) and at the same time be symmetrical about the center line of the tube:

$$\phi(y) = \Delta \cos \frac{\pi y}{L} \qquad (9)$$

Thus, it follows that a solution to the differential equations may be expected to be in the form of:

$$z = \Delta \cos\left(N\,\theta + \frac{K_r\,\pi\,y}{L}\right)\cos\frac{\pi\,y}{L} \qquad (10a)$$

This function (Eq. 10*a*) fulfils all the boundary conditions and, by proper evaluation of the constant K_r, will satisfy the differential equations. In order that the state of neutral equilibrium may be reached (that is, in order that the coefficient of the deflection term will vanish), the various derivatives—$\frac{\partial^4 z}{\partial y^4}$, $\frac{\partial^4 z}{\partial \theta^4}$, $\frac{\partial^4 z}{\partial \theta^2\,\partial y^2}$, $\frac{\partial^2 z}{\partial y^2}$, $\frac{\partial^2 z}{\partial \theta^2}$, and $\frac{\partial^2 z}{\partial \theta\,\partial y}$—must all have the same general functions.

Eq. 10*a* may be expanded for the purpose of determining the values of the derivatives; thus:

$$z = \Delta\left[\cos(N\,\theta)\cos\frac{K_r\,\pi\,y}{L}\cos\frac{\pi\,y}{L} - \sin(N\,\theta)\sin\frac{K_r\,\pi\,y}{L}\cos\frac{\pi\,y}{L}\right] \qquad (10b)$$

By substituting the following quantities—

$$m = (K_r + 1)\,\frac{\pi}{L} \qquad (11a)$$

and

$$n = (K_r - 1)\,\frac{\pi}{L} \qquad (11b)$$

—it is possible to rearrange the terms in Eq. 10*a* to give:

$$z = z_1 + z_2 \qquad (12)$$

in which

$$z_1 = \frac{\Delta}{2}\left[\cos(N\,\theta)\cos(m\,y) - \sin(N\,\theta)\sin(m\,y)\right] \qquad (13a)$$

and

$$z_2 = \frac{\Delta}{2}\left[\cos(N\,\theta)\cos(n\,y) - \sin(N\,\theta)\sin(n\,y)\right] \qquad (13b)$$

When these values for z_1 and z_2 are substituted into Eq. 7*a* (which contains the value of shear, $S_{ys} = S_{sy} = \tau\,t$), it is found that they will each yield a value of τ. The function, f, may be defined in terms of K_r from Eqs. 7*b*, 7*c*, 11*a*, and 11*b*, so that the value of τ that will produce neutral equilibrium is dependent only on the constant K_r. Since there can be only one value of shearing stress which will produce neutral equilibrium, the value of τ obtained from the use of z_1 must be the same as the value of τ obtained from the use of z_2. It is possible to solve for the value of K_r that will give the same value of τ from both z_1 and z_2. This value of τ is the computed critical buckling shear stress and is designated as τ_c.

DETERMINATION OF PARAMETERS

To determine the constant parameter, K_r, it is necessary to determine the function f, but, to determine f from Eqs. 7*b* and 7*c*, it is necessary to eliminate the function, g. From Eqs. 7*b* and 7*c*, it may be noted that the functions, f and g, must have the following forms:

$$f = Q_1 z_1 + Q_2 z_2 = f_1 + f_2 \dots \tag{14a}$$

and

$$g = Q'_1 z_1 + Q'_2 z_2 = g_1 + g_2 \dots \tag{14b}$$

or

$$f_1 = Q_1 z_1 ; f_2 = Q_2 z_2 \dots \tag{15a}$$

and

$$g_1 = Q'_1 z_1 ; g_2 = Q'_2 z_2 \dots \tag{15b}$$

Since the functions, f and g, must satisfy the differential Eqs. 7*b* and 7*c*, for all values of y and θ, the parts involving z_1 and z_2 must satisfy these equations separately. The substitution of these values and the values of z_1 and z_2 from Eq. 13*b* into Eq. 7*b* gives the following relationships:

$$Q'_1 = \frac{N^2}{m^2 r^2} Q_1 + \frac{E I}{r^5 m^2 (1 - \mu^2)} [N^4 - N^2 + (2 - \mu) N^2 m^2 r^2] \dots \tag{16a}$$

and

$$Q'_2 = \frac{N^2}{n^2 r^2} Q_2 + \frac{E I}{r^5 n^2 (1 - \mu^2)} [N^4 - N^2 + (2 - \mu) N^2 n^2 r^2] \dots \tag{16b}$$

From Eq. 7*c* the values of Q'_1 and Q'_2 are found to be:

$$Q'_1 = \frac{Q_1 \left(\frac{\mu N^2}{m^2 r^2} - 1 \right) + \frac{E t}{r}}{2 + \mu + \frac{N^2}{m^2 r^2}} \dots \tag{17a}$$

and

$$Q'_2 = \frac{Q_2 \left(\frac{\mu N^2}{n^2 r^2} - 1 \right) + \frac{E t}{r}}{2 + \mu + \frac{N^2}{n^2 r^2}} \dots \tag{17b}$$

The parameter Q'_1 may be eliminated from Eqs. 16*a* and 17*a* and the value of Q_1 may be found to be:

$$Q_1 = \frac{\frac{E t}{r} - \frac{E t^3}{r^3} \frac{1}{12 (1 - \mu^2)} \cdot \left[\frac{N^4 - N^2}{m^2 r^2} + N^2 (2 - \mu) \right] \left(\frac{N^2}{m^2 r^2} + 2 + \mu \right)}{\left(\frac{N^2}{m^2 r^2} + 1 \right)^2} \dots \tag{18a}$$

and, from Eqs. 16*b* and 17*b*, the value of Q_2 is found to be:

$$Q_2 = \frac{\frac{E t}{r} - \frac{E t^3}{r^3} \frac{1}{12 (1 - \mu^2)} \left[\frac{N^4 - N^2}{n^2 r^2} + N^2 (2 - \mu) \right] \left(\frac{N^2}{n^2 r^2} + 2 + \mu \right)}{\left(\frac{N^2}{n^2 r^2} + 1 \right)^2} \dots \tag{18b}$$

With these equations f_1, f_2, and consequently f, are known in terms of m and n.

EQUATIONS FOR CRITICAL BUCKLING SHEAR STRESS

Eq. 7*a*, which contains the applied shear stress $S_{ys} = S_{sy} = \tau\, t$, may be rewritten in terms of z_1, z_2, f_1, and f_2, as follows:

$$\left\{ \frac{E\, t^3}{12\,(1-\mu^2)\, r^4} \left[(m^2 r^2 + N^2)^2 - (N^2 + \mu\, m^2 r^2) \right] + \frac{Q_1}{r} - \frac{2\, N\, m}{r} \tau\, t \right\} z_1 + \left\{ \frac{E\, t^3}{12\,(1-\mu^2)\, r^4} \left[(m^2 r^2 + N^2)^2 - (N^2 + \mu\, m^2 r^2) \right] + \frac{Q_2}{r} - \frac{2\, N\, n}{r} \tau\, t \right\} z_2 = 0 \quad (19)$$

In order that Eq. 19 may be true for all values of y and θ, the coefficients of z_1 and z_2 must each be zero. The resulting equations are:

$$\tau\, t = \frac{E}{12\,(1-\mu^2)} \frac{t^3}{r^3} \left[\frac{(m^2 r^2 + N^2)^2 - (N^2 + \mu\, m^2 r^2)}{2\, m\, N} \right] + \frac{Q_1}{2\, m\, N} \quad (20a)$$

and

$$\tau\, t = \frac{E}{12\,(1-\mu^2)} \frac{t^3}{r^3} \left[\frac{(n^2 r^2 + N^2)^2 - (N^2 + \mu\, n^2 r^2)}{2\, n\, N} \right] + \frac{Q_2}{2\, n\, N} \quad (20b)$$

The critical buckling shear stress τ_c is obtained when Eqs. 17 give the same value of τ. Used with Eqs. 11, they give sufficient conditions to solve for both K_r and τ_c. The values of Q_1, Q_2, m, and n may be substituted into Eq. 20*a*. The resulting equation is:

$$\frac{E\, t^3\, L}{12(1-\mu^2)\, r^3\, 2\, N\, \pi} \left\{ \frac{\left[(K_r+1)^2 \frac{\pi^2 r^2}{L^2} + N^2 \right]^2 - \left[N^2 + \mu (K_r+1)^2 \frac{\pi^2 r^2}{L^2} \right]}{K_r + 1} \right\} + \frac{E\, t^3\, L}{12(1-\mu^2)\, r^3\, 2\, N\, \pi} \left\{ 12(1-\mu^2) \frac{r^2}{t^2} - \left[\frac{(N^4 - N^2) L^2}{(K_r+1)^2\, \pi^2 r^2} + N^2 (2-\mu) \right] \times \left[\frac{N^2}{(K_r+1)^2} \frac{L^2}{\pi^2 r^2} + 2 + \mu \right] \div (K_r+1) \left[\frac{N^2 L^2}{(K_r+1)^2\, \pi^2 r^2} + 1 \right]^2 \right\} = \tau_c\, t \quad (21)$$

From Eq. 20*b*, a similar equation is obtained except that $K_r + 1$ is replaced by $K_r - 1$.

Now if the terms in the braces in Eq. 21 are designated by X, the resulting equation is:

$$\tau_c = E \frac{t^2}{r^2} \frac{L}{\pi\, r} \frac{X}{24(1-\mu^2) N} \quad (22a)$$

or

$$\tau_c = K_D\, E \frac{t^2}{D^2} \quad (22b)$$

in which

$$K_r = \frac{L}{\pi\, R} \frac{X}{6(1-\mu^2) N} \quad (23)$$

The two values of X obtained by using $K_r + 1$ and $K_r - 1$ must be the same since X is a single value. The particular values of $K_r + 1$ and $K_r - 1$ for which this condition is fulfilled may best be found by plotting values of X against values of K_r and locating the intersections of the two curves for X. In these computations, however, it is necessary to determine only one set of values of X because the values for $K_r - 1$ will be the same as the values for $K_r + 1$ except that the curve is moved two units to the right. The intersections of the pairs of curves thus obtained give values for both X and K_r.

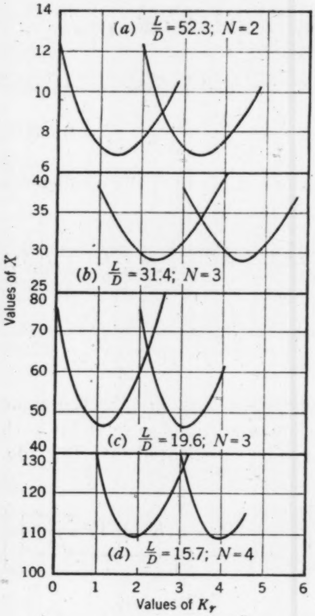

FIG. 4.—SAMPLES OF CURVES OBTAINED BY PLOTTING EQS. 18 $\left(\frac{r}{t} = 500\right)$

The values of X for any particular values of D/t and $\frac{L}{\pi\, r}$ or L/D can be computed for different integral values of N. The value of N giving the lowest resultant value of τ_e will be the number of lobes into which the tube will buckle.

In tabular computations for establishing charts it is expedient to consider given values of D/t and N and to compute values of X for a range of L/D-values in which X is a minimum or near minimum. Sample curves of X showing various types of intersections are shown in Fig. 4 and the resulting curves for K_D are shown in Fig. 5.

In subsequent considerations it will be desirable to know the angle between the crests of the buckle waves and the longitudinal elements of the cylinder. From Eq. 10a, it follows that, at the crest of a buckle wave, $N\,\theta + \frac{K_r\,\pi\,y}{L}$ must be a constant. Considering the buckle through the origin:

$$N\,\theta + \frac{K_r\,\pi\,y}{L} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (24a)$$

Hence, the angle θ will change with y so that $\frac{r\,\theta}{y}$ will be the tangent of the angle, α, between the crest and a longitudinal element of the cylinder. From Eq. 24a, it follows that:

$$\tan \alpha = \frac{r\,\theta}{y} = -\frac{K_r\,\pi\,r}{N\,L} = -\frac{K_r\,\pi\,D}{2\,N\,L} \ldots\ldots\ldots\ldots\ldots (24b)$$

To find the value of K_r from Fig. 5, the values of N and $\tan\alpha$ are first obtained and the value of K_r is found as:

$$K_r = \frac{2N}{\pi}\frac{L}{D}\tan\alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots (25a)$$

Eq. 22*b* may be rewritten as:

$$\frac{\tau_e}{E} = K_D\frac{t^2}{D^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (25b)$$

All values on the right side of Eq. 25*b* are dependent on the geometry of the vessel and independent of the properties of the material in the shell wall

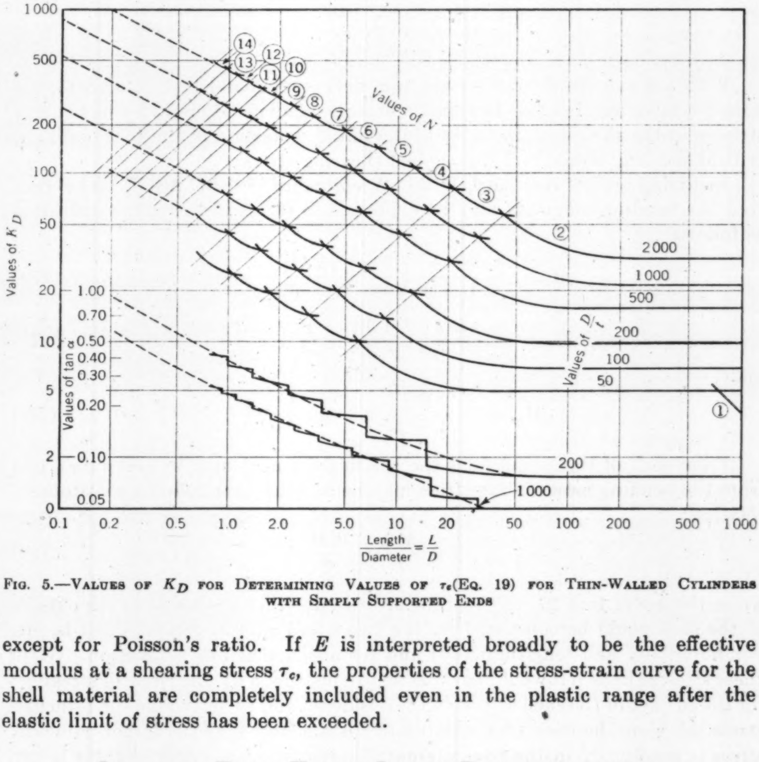

Fig. 5.—Values of K_D for Determining Values of τ_e(Eq. 19) for Thin-Walled Cylinders with Simply Supported Ends

except for Poisson's ratio. If E is interpreted broadly to be the effective modulus at a shearing stress τ_e, the properties of the stress-strain curve for the shell material are completely included even in the plastic range after the elastic limit of stress has been exceeded.

Imperfect Tubes Having Initial Departure from a True Circular Cylinder

If the tube considered is not a true circular cylinder but departs slightly from a true cylinder, it will begin to deflect as soon as torque is applied. In general, such initial departures from a true cylinder have no particular shape so that, when the tube wall begins to deflect, the initial deflection will not always be additive, in its effects, to the deflection under load. However, if the initial deflection is of the same general trend as the deflection under load, the effects may be fully additive. For all practical purposes, the greatest deflections that may occur must be considered. To obtain a measure of this greatest deflection, it may be assumed that the initial departure of the tube wall from a true cylinder corresponds to the buckle pattern of the shell at neutral equilibrium.

Under this condition, the general relationship between the magnitude of the maximum deflection under load Δ, the initial deflection Δ_o, the critical shearing stress τ_c, and the actual applied stress τ may be written[9,11] as:

$$\Delta = \frac{\Delta_o \tau}{\tau_c - \tau} \quad \text{........................} \quad (26)$$

With the magnitude of the maximum deflection Δ and Eqs. 12 and 13, it is possible to determine the bending moments, and consequently the bending stresses in the shell wall, in terms of the initial deflection of the tube wall, the critical shearing stress, and the applied shearing stress.

Assuming perfect elasticity, H. M. Westergaard,[7,8,11] M. ASCE, has shown that the bending moments may be expressed in terms of the radial deflection as follows:

$$M_y = -\frac{E\,I}{1-\mu^2}\left(\frac{\partial^2 z}{\partial y^2} + \frac{\mu}{r^2}\frac{\partial^2 z}{\partial \theta^2} + \mu\,\frac{z}{r}\right) \quad \text{............} \quad (27a)$$

$$M_s = -\frac{E\,I}{1-\mu^2}\left(\frac{1}{r^2}\frac{\partial^2 z}{\partial \theta^2} + \frac{z}{r^2} + \mu\,\frac{\partial^2 z}{\partial y^2}\right) \quad \text{............} \quad (27b)$$

and

$$M_{sy} = -\frac{E\,I}{1-\mu^2}(1-\mu)\,\frac{1}{r^2}\frac{\partial^2 z}{\partial \theta\,\partial y} \quad \text{..............} \quad (27c)$$

From each of these equations the bending moment may be computed, and from the bending moment the stress may be found by the following customary relation:

$$S = \frac{M\,c}{I} = \frac{6\,M}{t^2} \quad \text{......................} \quad (28)$$

From the use of Eqs. 27, the bending stresses in either the inside or the outside of the shell could be computed for the two coordinate directions (that is, circumferentially and longitudinally) and for a diagonal (45°) direction. With these stresses known it would be possible to construct a dyadic circle of stress[12,13] for the surface of the shell at the point considered and to determine the principal stresses. Consideration of a number of cases shows that the larger principal stress is practically in the circumferential direction and is only slightly larger

[13] "The Determination of Stresses from Strains on Three Intersecting Gage Lines and Its Application to Actual Tests," by W. R. Osgood and R. G. Sturm, *Journal of Research*, U. S. Bureau of Standards, Vol. 10, May, 1933.

than the maximum circumferential stress. Consequently, the circumferential stress represents a fair approximation of the controlling bending stress. Therefore, for purposes of comparing some examples of imperfect cylinders, the circumferential stress will be used as an index of the maximum bending stress in the shell wall. In cases where the critical shearing stress, τ_c, is large as compared to the elastic limit, the combined stress resulting from shear and bending should be used.

The value of z from Eqs. 12 and 13 may be substituted into Eq. 27b to give:

$$M_s = \frac{E\,t^3}{12(1-\mu^2)}\left\{\frac{\Delta}{2}\left(\frac{N^2-1}{r^2}+\mu\,m^2\right)[\cos(N\theta)\cos(m\,y)-\sin(N\theta)\sin(m\,y)]\right.$$
$$\left.+\frac{\Delta}{2}\left(\frac{N^2-1}{r^2}+\mu\,n^2\right)[\cos(N\theta)\cos(n\,y)-\sin(N\theta)\sin(n\,y)]\right\}\,..(29a)$$

The maximum value of M_s is found at $\theta = 0$, $y = 0$ and is expressed as:

$$M_s = \frac{E\,t^3}{12(1-\mu^2)}\,\Delta\left[\frac{N^2-1}{r^2}+\mu\,(m^2+n^2)\right]\ldots\ldots\ldots\ldots(29b)$$

The values of m and n as determined from Eqs. 11 may be substituted into Eq. 29b and the resulting equation may be rearranged to give:

$$M_s = \frac{\Delta E}{12(1-\mu^2)}\frac{t^3}{r^2}\left[N^2-1+2\,\mu\frac{\pi^2 r^2}{L^2}(K_r^2+1)\right]\ldots\ldots.(30a)$$

The value for stress may be computed from Eq. 30a for the value of Δ from Eq. 26 to give:

$$S = \frac{\tau_1}{\tau_c-\tau_1}\,\frac{E}{2(1-\mu^2)}\,\frac{t^2\Delta_o}{r^2\,t}\left[N^2-1+2\,\mu\frac{\pi^2 r^2}{L^2}(K_r^2+1)\right]\ldots(30b)$$

The values of N and K_r as well as the value of τ_c may be obtained from Fig. 5.

As an example to illustrate the effect of initial deflections (out-of-roundness), Eq. 30b is applied to a long tube of steel for which the following data apply: $L/D = 150$; $D/t = 200$; $N = 2$ (from Fig. 5); $K_r = 11.5$ (from Fig. 5); $\mu = 0.3$; $\Delta_o/t = 0.5$; $E = 30{,}000{,}000$ lb per sq in.; and the tensile yield point = 40,000 lb per sq in.

The ratio of τ_1/τ_c which will give a circumferential bending stress equal to the yield point in tension is obtained from Eq. 30b as $\frac{\tau_1}{\tau_c} = 0.94$. The value of $\Delta_o/t \leqq 0.5$ is easily obtained by careful fabrication except for extremely thin tubes. Therefore, the observed values of such long thin tubes should be fairly close (within 10%) to the theoretical values.

For very thin tubes of short length such as part of an aircraft fuselage a similar comparison may be made. For this case Eq. 30b is applied to a short thin tube of steel for which the following data are known: $L/D = 0.5$; $D/t = 1{,}000$; $N = 16$ (from Fig. 5); $K_r = 1.5$; $\mu = 0.3$; $\Delta_o/t = 0.5$; $E = 30{,}000{,}000$ lb per sq in.; and the yield point = 40,000 lb per sq in. The ratio of τ_1/τ_c

which will give a circumferential bending stress equal to the yield point in tension is $\tau_1/\tau_e = 0.81$. For exceptionally thin, short tubes, the out-of-roundness may be controlled quite easily within limits; but an out-of-roundness value of $\Delta_o/t = 0.5$ is difficult to obtain. In this case the experimental results would be expected to be less than the theoretical values by about 20%.

In view of the foregoing examples, in which a reasonable initial departure from true circularity was allowed, carefully made tests should give values of from at least 80% to 90% of the theoretical values. Actual consideration of the combined stresses extant in very thin shells indicates somewhat lower ratios for τ_1/τ_e; but actual determinations are not feasible because the properties of thin sheets of metal under biaxial stress are not known.

Eq. 30*b* permits drawing specifications for maximum allowable "out-of-roundness" (departure from true circularity) to attain at least a minimum predetermined percentage of the theoretical elastic buckling strength of the shell. The reliability of the specification, however, may be questioned until more factual data have been compiled.

CYLINDERS WITH ENDS COMPLETELY FIXED

Boundary Conditions.—The boundary condition of "fixed ends" requires not only that true circularity be maintained at the ends but that the longitudinal tangent to the tube at the end be maintained parallel to the axis of the tube. The condition of absolutely fixed ends is difficult to obtain in tests and seldom, if ever, is obtained in a practical case.

The mathematical statement of these boundary conditions is as follows: When $y = \pm \frac{L}{2}$; $z = 0$; and, for all values of θ, $\frac{\partial z}{\partial y} = 0$ and $\frac{\partial z}{\partial \theta} = 0$. Again the choice of the center of coordinates midway between the ends of the tube gives longitudinal symmetry. The center of coordinates is also chosen at the point of maximum displacement as before.

Type of Solution.—Again a solution consisting of the product of two functions will be sought by the same procedure as that adopted for simply supported edges. Since the characteristic form of buckling does not change, one function is chosen as before, namely: $\cos\left(N\theta + \frac{K_r \pi y}{L}\right)$. The other function, which previously was simply $\cos \frac{\pi y}{L}$, now must be a function that has both zero deflection and zero slope at the end. The following was found to be such a function: $\cos \frac{\pi y}{b L} + c \cosh \frac{\pi y}{L d}$, in which b, c, and d are arbitrary constants to be determined by the boundary conditions and one other requirement. This other requirement is that the value of τ_e is such that the coefficients of each of these terms becomes zero. This requirement leads to extremely complicated relationships.

Reference to Fig. 3 for this case reveals that for long tubes a number of waves exist so that only the end wave would be affected materially.[14] In shorter tubes the longitudinal elements of the cylinder are affected only a short distance from the end. These facts suggest a consideration of a fixed ended tube as an equivalent shorter tube with simply supported ends.

---

[14] "Strength Tests on Thin-Walled Duralumin Cylinders in Torsion," by Eugene E. Lundquist, *Technical Note No. 427*, National Advisory Committee for Aeronautics, Washington, D. C., 1932, p. 12, Fig. 4.

Let the equivalent length be represented by $a\,L$. The critical shear then for this equivalent tube may be computed from the curves in Fig. 5 as soon as the value of a is known. To arrive at a value for a, consider a longitudinal section of the tube in its deflected position. The longitudinal half-wave length of the deflected wall may be found as the distance between points of zero deflection. In this case the deflection of the equivalent tube would be expressed by the equation:

$$z = \Delta \cos\left(N\,\theta + \frac{K_r\,\pi\,y}{a\,L}\right)\cos\frac{\pi\,y}{a\,L} \quad \text{(31a)}$$

The distance between points of zero deflection occurs when

$$N\,\theta + \frac{K_r\,\pi\,y}{a\,L} = q\,\pi + \frac{\pi}{2} \quad \text{(31b)}$$

in which q is any integer. Since θ does not vary, the difference between y_1 and y_2, two successive points of zero deflection, may be found from $(y_2 - y_1)\dfrac{K_r\,\pi}{a\,L} = \pi$; or

$$y_2 - y_1 = \frac{a\,L}{K_r} \quad \text{(31c)}$$

in which K_r is the value obtained for the "simply supported" tube whose length is $a\,L$. Now consider an end half wave where one point of zero deflection falls at the end of the tube. This curve will be very nearly a sine form. If the wave is replaced by another curve of the form, $1 - \cos 2\dfrac{\pi\,a\,L}{K_r}$, both the deflection and slope at the end would be zero. The point of contraflexure in the latter curve falls about one fourth of the way from the end to the next point of zero deflection. The tube length between these points of contraflexure is taken as the equivalent tube with simply supported ends. This length then is

$$a\,L = \left(L - \frac{2\,a\,L}{4\,K_r}\right) = \left(L - \frac{a\,L}{2\,K_r}\right) \quad \text{(32a)}$$

from which it is found that

$$a = \frac{2\,K_r}{2\,K_r + 1} \quad \text{(32b)}$$

in which K_r is based on the length $a\,L$. The value of a can be found quickly by successive approximations as follows: First, assume a value of $a\,L$; then find K_r from Fig. 5; and solve for a from Eq. 31b. With this new value of a again solve for K_r, and so on. In two or three cycles the values agree within the limits of error for reading the curves.

PART II. COMPARISON BETWEEN THEORETICAL AND EXPERIMENTAL RESULTS

Cylinders Subject to Torque

The buckling of the walls of thin-walled cylinders subjected to torque has been recognized as a problem in testing materials. In 1924, N. S. Otey[15] considered the effect of ratio of the diameter to wall thickness of specimens on the strength values obtained. In 1930 R. L. Templin, M. ASCE, and R. L. Moore, Assoc. M. ASCE, considered this phenomenon[16] from the point of view of both diameter-to-thickness ratios and length-to-diameter ratios of test specimens for determining the shearing yield strength of materials.

The first results of extensive tests to determine the buckling strength of very thin-walled cylinders were published by Mr. Lundquist[4] in 1932. The specimens for these tests were thin duralumin sheets rolled into a tube, with edges joined by bolting them to a splice plate of the same thickness as the sheets. Diameter-to-thickness ratios ranged from about 700 to about 2,800—in the range of aircraft fuselage proportions. The tubes were large in diameter (from 15 in. to 30 in.) but were relatively short (L/D-values from 0.1 to 2.5).

The following year (1933) Mr. Donnell[5] published some test results to support his theory. The specimens in these tests were also formed from thin sheets of steel and brass shim stock rolled into tubes. The edges were lapped and soldered, which gave a longitudinal seam of double thickness on one side of the tube. Mr. Donnell's specimens were mostly with small tubes (from 0.318 in. to 5.88 in. in diameter for all except one specimen). The diameter-to-thickness ratios were not as high as Mr. Lundquist's but the L/D-ratios were higher.

In 1931 Mr. Moore made some tests at the Aluminum Research Laboratories in New Kensington, Pa., on specimens machined from extruded and drawn tubing. The length-to-diameter ratios ranged from 5 to 7 and the diameter-to-thickness ratios from about 10 to 100. The results of these tests are included in a report by A. H. Stang, W. Ramberg, and G. Back.[17]

In 1939 another series of tests designed to cover the range from short to moderately long tubes was made by Mr. Moore and D. A. Paul.[18] The material used was aluminum alloy 51S–T, whose typical mechanical properties are: Yield strength, 40 kips per sq in.; tensile strength, 48 kips per sq in.; and elongation (for a thin sheet) 14% in 2 in. The tubes were extruded and drawn to size. They were very true to nominal dimensions. The maximum variation in wall thickness was less than ±5%, and the variation in diameters was less than 0.1%. The ends of the test specimens were closed with steel plugs machined to fit the inside diameter of the tubes so that, when the ends of the tubes were gripped in the jaws of the testing machine, they were quite effectively clamped as well as held to shape. The length-to-diameter ratios of these specimens ranged from 1 to 60 and the diameter-to-thickness ratios from about 75 to 140.

[15] "Torsional Strength of Nickel, Steel and Duralumin Tubing as Affected by the Ratio of Diameter to Gage Thickness," by N. S. Otey, *Technical Note No. 189*, National Advisory Committee for Aeronautics, Washington, D. C., 1924.

[16] "Specimens for Torsion Tests of Metals," by R. L. Templin and R. L. Moore, *Proceedings*, A.S.T.M., Vol. 30, Pt. II, 1930, pp. 534–543.

[17] "Torsion Tests of Tubes," by A. H. Stang, W. Ramberg, and G. Back, *Technical Report No. 601*, National Advisory Committee for Areonautics, Washington, D. C., 1937.

[18] "Torsional Stability of Aluminum Alloy Seamless Tubing," by R. L. Moore and D. A. Paul, *Technical Note No. 696*, National Advisory Committee for Aeronautics, Washington, D. C., 1939.

Fig. 6 shows a comparison between the measured and computed values of critical shearing stresses for two sizes of tubes. The experimental values of critical shearing stress from the Moore-Paul[18] tests generally lie above the computed curve for "simply supported ends" based on minimum measured thickness and some lie above the computed curve for "simply supported ends" based on maximum measured thickness. In all cases the measured values lie below the computed curves for fixed ends. In the range of low L/D-ratios, where the critical shearing stress in the tube approaches the shearing yield strength of the material, the measured values lie appreciably below the computed curves. This condition may be explained by a consideration of two factors, either or both of which may be responsible for this tendency.

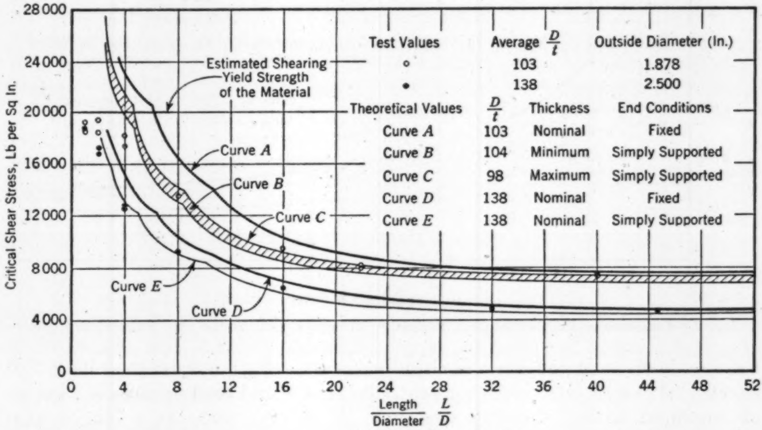

Fig 6.—Comparison of Theoretical Stress τ_c, with the Results of the Moore Tests, for Tubes 0.018 In. Thick

As the material is stressed near the yield strength in shear, plastic action takes place and the shearing deformations increase rapidly. This larger deformation would have much the same effect as a higher stress on the behavior of the tube. The shearing-stress, shearing-strain curves for most materials, including aluminum alloys, are relatively very flat at stresses above the yield strength.

The second factor influencing the critical shearing stress as determined by tests is the unavoidable initial departure from true circularity. From Eq. 30*b* it is found that, for a given value of Δ_o/t and a given maximum stress S, the ratio τ_1/τ_c will be less for short tubes in which N is large and the value of τ_c is high. For long tubes, however, the ratio of τ_1/τ_c would be expected to be much closer to unity. A comparison between the computed and measured critical shearing stresses substantiates this reasoning.

Fig. 7 shows a comparison between computed values of critical shearing stress and values taken from Mr. Lundquist's work. As previously mentioned, the specimens each contain a longitudinal seam. Such a seam may have two effects: (*a*) It may introduce an eccentricity that would tend to cause low values of measured critical shearing stress; or (*b*) it may serve as a longitudinal stiffener and may thereby tend to strengthen the tube.

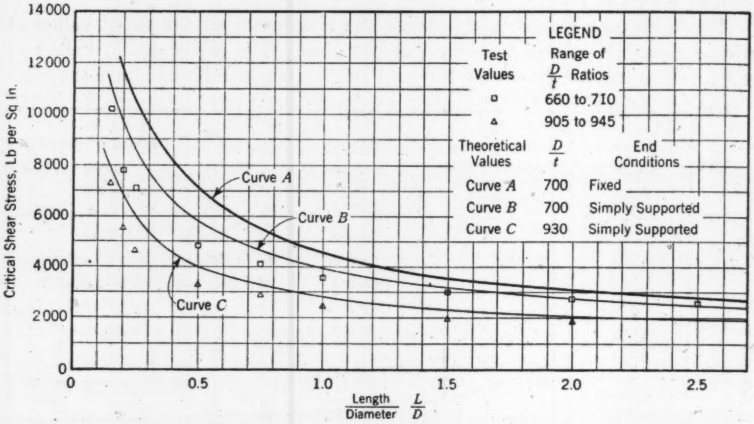

FIG. 7.—COMPARISON OF THEORETICAL STRESS τ_e WITH THE RESULTS OF THE LUNDQUIST TESTS

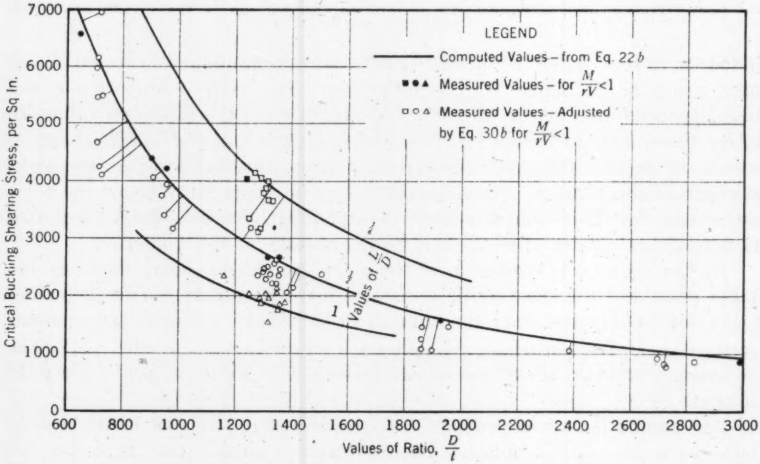

FIG. 8.—COMPARISON OF COMPUTED AND MEASURED VALUES OF CRITICAL BUCKLING SHEARING STRESS FOR TRANSVERSE SHEAR AND BENDING

The fact that Mr. Lundquist reported that the first visible indication of buckling (relatively large radial deflection) occurred at a load well below that causing failure suggests that the eccentricities were relatively large compared to the wall thickness. Fig. 8 reveals that the measured values of critical shearing stress, as reported by Mr. Lundquist,[19] are relatively lower with respect to the computed values than were the values determined from the seamless tubes used by Messrs. Moore and Paul.[18] In general, however, the agreement is quite satisfactory when allowances for out-of-roundness are considered.

Shear and Bending.—Results from tests of thin-walled duralumin cylinders in combined transverse shear and bending which Mr. Lundquist reported in 1935[19] serve as an excellent basis for a check on the extended applicability of this theory to shear failure of thin-walled cylindrical vessels subjected to shear loads other than torsion. Inasmuch as the longitudinal seam was always placed on the extreme tension side, it would not be expected to influence the shear distribution or the curvature at the sides of the cylinders. Fig. 8 shows a comparison of the measured and computed values of critical shearing stress using Eq. 33 in Part III.

PART III. APPLICABILITY OF THEORY TO OTHER PRACTICAL PROBLEMS

The analysis presented herein can be applied directly to long cylinders stiffened with circumferential rings by considering the length between stiffeners as the length of cylinder with simply supported ends. If heavy diaphragms are used, some restraint may be present; but, for design purposes, such restraint may be too indefinite to be taken into account.

Stiffened Cylinders Subject to Torque and Transverse Shear

For cylinders with both circumferential and longitudinal stiffeners, the shell may buckle, in some cases, in waves extending from one circumferential stiffener to the next without encountering a longitudinal stiffener; or it may buckle in waves that encounter a longitudinal stiffener before reaching the circumferential stiffener. If a complete buckle wave extending from one circumferential stiffener to the next is not interrupted by longitudinal stiffeners, the panel might reasonably be considered as buckling at the same stress as if the longitudinal stiffeners were not there. If the crest of a buckle wave intersects two longitudinal stiffeners, however, it may be assumed that the longitudinal distance between intersections is the effective length of the cylinder. The torsional buckling strength, then, of the stiffened cylinder would be that of an unstiffened cylinder of this shorter length. The angle α used for determining the reduced effective length should agree with the length finally computed. This computation may be made by successive approximations, because the series converges very rapidly.

Attention is called to the fact that, when such a double stiffened shell buckles, a series of trusses is formed with the buckled shell acting as a tension member similar to the web in a "tension field" girder. In this type of action both the longitudinal and circumferential stiffeners form the basic framework for carrying load.

[19] "Strength Tests of Thin-Walled Duralumin Cylinders in Combined Transverse Shear and Bending," by E. E. Lundquist, *Technical Note No. 523*, National Advisory Committee for Aeronautics, Washington, D. C., April, 1935.

Although no adequate method has been developed for determining, by direct analysis, the critical maximum shear for cases of variable shear, it is possible to obtain a fair indication of this critical shear by suitable assumptions. One possible application of the results of this analysis to a variable shear problem is its use in computing the critical shear in the side walls of a thin-walled cylindrical vessel acting as a beam.

In many practical cases the bending moment in the vessel is small particularly where the shear is greatest. In such cases it has been found from experience and test[19] that the small bending moment has practically no effect on the shear resistance of the vessel walls or on the character of failure obtained.

When buckling governs, the critical shearing stress for the shell wall may be closely approximated as the critical torsional shear in a cylindrical shell whose radius-to-thickness ratio is the same as that of the shell considered and whose length-to-radius ratio is such that tan α as determined from Fig. 5 is equal to r/L. This ratio can be determined quite readily from Fig. 5. In the case of a pipe or tank supported as a simple beam, if the half span is less than the length corresponding to this ratio, the half length might reasonably be used as the effective length of cylinder, since there is no shearing stress at the midspan. For cantilever beams, the full length of the cantilever should be used unless it is greater than the effective length.

A typical example of the cantilever beam action is a stressed-skin fuselage of an airplane. The structural action of such a thin sheet is simulated by the Lundquist tests.[19] The data reported by Mr. Lundquist indicate that, when the bending moment is appreciable, the resistance to buckling in combined shear and bending is less than when the bending moment is small.

A study of these data indicates that, under combined bending and torque, a reliable value of τ'_c for combined shear and bending can be found from the following relation between critical shearing stress (for pure torque) τ_c and the ratio $\frac{\bar{M}}{r\,V}$, by the equation:

$$\tau'_c = \tau_c \left[1 - 0.075 \left(\frac{\bar{M}}{r\,V} - 1 \right) \left(1 + \tfrac{1}{2} \frac{r^2}{L^2} \right) \right] \dots\dots\dots (33)$$

in which $\bar{M}$ is the total bending moment on the shell, in inch-pounds; and V is the total shear on the shell, in pounds. For values of $\frac{\bar{M}}{r\,V}$ of less than one, τ'_c may be taken equal to τ_c. For values of $\frac{\bar{M}}{r\,V}$ greater than 5, this approximation appears to be ultraconservative. Values of critical shear computed in this way and experimental values obtained by Mr. Lundquist are compared in Fig. 8. Until a more adequate theory is provided such an approximation may be very useful.

SHELLS CONTINUOUS OVER SEVERAL SUPPORTS

A specific example of continuous beam action is afforded by a pipe line filled with water and supported at intervals.[20] If the circular section of the shell is held fixed at the supports by ring girders, or by any other method, the distribution of shears in the side wall is known quite definitely and may be expressed as follows for either a single span or one of a long series of equal spans:

---

[20] *Transactions*, ASCE, Vol. 98, 1933, p. 154.

$$S_{vs} = -q\,r\,\frac{L}{2}\sin u = \tau\,t \qquad (34)$$

As would be expected, the shear is a maximum at the ends of horizontal diameters and decreases very slowly for small angular distances from this point. Hence, it may be assumed to be practically constant for about one quadrant of arc. The critical shearing stress in the side walls in this case will also depend upon the ratio $\frac{\bar{M}}{r\,V}$ at the supports and the value of τ'_c determined from Eq. 33, using a value of τ_c determined for a length L equal to $\frac{\pi r}{2}$.

CONCLUSIONS

A review of the foregoing analytical study of perfectly round cylindrical shells and shells departing slightly from perfection, the comparison of the results of this analysis with experimental results, and the adaptation of the analysis to other practical problems suggest the following conclusions:

1. The analysis has yielded a single equation (Eq. 22*b*) which together with the accompanying curve chart (Fig. 5) provides a procedure for computing a value for the critical shearing stress, the number of wrinkles, and the spiral angle of the wrinkles for thin-walled cylindrical shells of any proportions subjected to pure torsional stresses.
2. Slight departures from perfect roundness cause considerable decrease in the computed critical torsional shearing stress for thin-walled cylinders.
3. Comparison between measured and computed critical shearing stress values indicates agreement within the limits of accuracy consistent with the known variables.
4. The analytical results may be used to estimate values of critical shear for stiffened cylinders and cylinders subject to transverse shear and bending.
5. Comparisons between measured and computed values of critical shear in transverse shear and bending indicate that the computed estimates are sufficiently close to the measured values to serve as a basis for design.
6. Additional test data are needed to determine the reliability of the estimated values of critical shear for cylinders reinforced by longitudinal and transverse stiffeners.

ACKNOWLEDGMENTS

Most of the work of preparing this paper was done while the writer was an employee of the Aluminum Research Laboratories of the Aluminum Company of America and had at his disposal the original data of experimental work performed under the direction of Mr. Templin, the assistant director of research.

The writer wishes to thank Messrs. R. L. Templin and E. C. Hartmann, Members, ASCE, and R. L. Moore and Marshall Holt, Assoc. Members, ASCE, all of the Aluminum Research Laboratories, for their constructive suggestions during the development of this paper. Among the drawings and photographs in the paper, Fig. 3 is included by courtesy of the Aluminum Company of America. The essential parts of this paper were first presented as a thesis to the University of Nebraska at Lincoln, in 1938, in partial fulfilment of the requirements for the professional degree of Civil Engineer.

DISCUSSION

S. B. Batdorf,[21] Esq., and Manuel Stein,[22] Esq.—An interesting addition to the literature on buckling of cylinders in torsion is presented by Professor Sturm. As far as the writers are aware, no one else has given a solution to the problem of determination of the critical torque in cylinders of finite length by the differential equation approach, in which equations other than the simplified ones of L. H. Donnell[5] are employed. The results for very long cylinders that buckle into an elliptical cross section (two circumferential waves) are in all probability more accurate than those of Mr. Donnell, since the approximations in the Donnell differential equation were based on the assumption that the square of the number of circumferential waves is large compared to 1. This discussion is primarily for the purpose of calling attention to the situation in the limiting case of very short cylinders, and to discuss certain features of the derivation used.

Physically, if the radius of the cylinder under torsion approaches infinity while the length and thickness remain fixed, there is obtained an infinitely long flat plate of width L subjected to shear. In this case, the critical stress is given by

$$\frac{\tau_c}{E} = k_s \frac{\pi^2 t^2}{12\,(1 - \mu^2)\,L^2} \qquad (35)$$

in which $k_s = 5.34$.[23,24] This agrees with the form used by Professor Sturm (Eq. 25*b*), if

$$K_D = \frac{5.34\,\pi^2}{12\,(1 - \mu^2)} \frac{D^2}{L^2} \cong 5\,\frac{D^2}{L^2} \qquad (36)$$

This value of K_D can be plotted in Fig. 5 as a straight line whose slope is -2. Since the critical stress of a curved sheet can never be below that of the corresponding flat sheet, Fig. 5 is unduly conservative when it predicts stresses below this value—that is, no curve should pass to the left of this straight line. That each of the curves of Fig. 5 should be faired into this line, rather than join it abruptly, is apparent from other studies of this problem.[5,25]

The problem of buckling of a finite cylinder in torsion defied solution for many years because of the difficulty of satisfying simultaneously the differential equation and the boundary conditions. Professor Sturm's solution does indeed satisfy the differential equations, but not the condition of simple support. That it satisfies the differential equation and one of the simple support conditions, $z = 0$ when $y = \pm \frac{L}{2}$, has been shown in the paper. That it does not, however, satisfy the other simple support condition, $\frac{\partial^2 z}{\partial y^2} = 0$ at $y = \pm \frac{L}{2}$ can be seen by differentiation of the buckle form assumed (Eq. 31*a*).

[24] "On the Stability Under Shearing Forces of a Flat Elastic Strip," by R. V. Southwell and Silvia W. Skan, *Proceedings*, Royal Soc. of London, Series A, May 1, 1924, pp. 582-607.

[25] "Critical Stress of Thin-Walled Cylinders in Torsion," by S. B. Batdorf, Manuel Stein, and Murry Schildcrout, *Technical Note No. 1344*, National Advisory Committee for Aeronautics, Washington, D. C. 1947.

Some interesting light is thrown on this deflection function and the Sturm method of solution by solving the simple problem of an infinitely long flat plate in shear by this method, and comparing the results with those obtained by the energy method using the same deflection function, as well as with results obtained by exact methods for simply supported and clamped edges. These results [23, 24, 26] are summarized in Table 1.

TABLE 1.—COMPARISON OF RESULTS OF DIFFERENT COMPUTATION METHODS

Method of Computation (1)	k_s (2)	Wave length, λ/L (3)	Wave angle, $\tan \alpha$ (4)
Simple support (exact).....	5.34	1.26	....
Energy method...........	5.7	1.224	0.707
Sturm method............	6.7	0.95	1.1
Clamped edges (exact).....	8.98	0.84	....

Nodal angles are not given for the exact solutions because these solutions give curved rather than straight nodal lines. It appears that Professor Sturm's method is an exact solution for a type of restraint intermediate between simple support and clamped edges, but in which the moment applied to the edge is out of phase with the slope by a quarter wave length.

For other than very short cylinders the difference in buckling load for clamped and simply supported edges is quite small, so that it is not anticipated that any considerable error in critical stresses will result from the peculiar boundary conditions implied. However, from the comparison in Table 1 it appears that there may be considerable error in the buckling configuration.

An ingenious suggestion is made by Professor Sturm on how to use results for complete cylinders to obtain approximate values for the shear buckling stress of the curved panels between adjacent stiffeners in stiffened cylinders. It may be of interest that calculations have been recently published for the critical shear stresses of simply supported and clamped curved panels.[27]

GLENN MURPHY,[28] M. ASCE.—This is an interesting approach to a timely problem, in that the author's analysis leads to results which not only are in reasonable agreement with representative tests, but which also tend to substantiate the theories of previous investigators. A number of conclusions may be drawn from Fig. 5, which gives values of K_D for use in Eq. 25*b*. It is apparent from Fig. 5 that there are two separate phases of behavior—one, in

---

[26] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., 1936, p. 361.

[27] "Critical Shear Stress of Curved Rectangular Panels," by S. B. Batdorf, Manuel Stein, and Murry Schildcrout, *Technical Note No. 1348*, National Advisory Committee for Aeronautics, Washington, D. C., 1947.

[28] Prof. of Theoretical and Applied Mechanics, Iowa State College, Ames, Iowa.

which $\left(\text{with constant } \frac{D}{t}\right)$ K_D, and consequently τ_c, decreases with increasing values of $\frac{L}{D}$; and the other, in which K_D and τ_c are independent of $\frac{L}{D}$. These two phases, between which there is shown smooth transition, confirm previous conclusions that one expression may be used for short cylindrical shells and a different expression for long shells.

In the range in which values of $\frac{L}{D}$ are large and the curves of Fig. 5 are horizontal, the equation for K_D is readily determined as:

$$K_D = 0.70 \sqrt{\frac{D}{t}} \quad \text{.......................(37)}$$

If this value of K_D is substituted in Eq. 25*b*, it becomes:

$$\frac{\tau_c}{E} = 0.70 \left(\frac{t}{D}\right)^{\frac{3}{2}} \quad \text{.....................(38a)}$$

which is exactly equivalent to the equation given by S. Timoshenko for long cylindrical shells with Poisson's ratio of 0.33. L. H. Donnell's equation reduces to

$$\frac{\tau_c}{E} = 0.80 \left(\frac{t}{D}\right)^{\frac{3}{2}} \quad \text{.....................(38b)}$$

In the short-tube range an approximate equation may be developed for K_D by replacing the author's curves (formed from a series of loops) by a family of straight lines tangent to the curves. Whereas the slopes of these straight lines vary somewhat, none deviates appreciably from 0.55, and the equation of the family of lines may be determined as:

$$K_D = \left(\frac{D}{L}\right)^{0.55} \left(\frac{D}{t}\right)^{0.80} \quad \text{...................(39)}$$

If this value of K_D is substituted in Eq. 25*b*, the latter becomes:

$$\frac{\tau_c}{E} = \left(\frac{D}{L}\right)^{0.55} \left(\frac{t}{D}\right)^{1.20} \quad \text{...................(40)}$$

The Donnell equation for short tubes in torsion may be reduced to the form:

$$\frac{\tau_c}{E} = 0.75 \left(\frac{D}{L}\right)^{0.50} \left(\frac{t}{D}\right)^{1.25} \quad \text{..................(41)}$$

It is apparent that Eqs. 40 and 41 are similar although not identical.

The approximate boundary between the short-tube range and the long-tube range may be established from Fig. 5 by noting that the locus of the points of intersection of the family of lines for the short cylinders with the corresponding $\left(\text{same } \frac{D}{t}\right)$ lines for the long cylinders is a straight line sloping upward to the right. The equation of this line may be determined as:

$$\frac{L}{D} = 2.45\sqrt{\frac{D}{t}} \qquad (42)$$

If $\frac{L}{D}$ is less than $2.45\sqrt{\frac{D}{t}}$, the shell may be considered short and Eq. 40 applies; whereas if $\frac{L}{D}$ is greater than $2.45\sqrt{\frac{D}{t}}$, the shell may be considered long and Eq. 38*a* applies.

An interesting comparison may be made between Eq. 42 and the Donnell equation defining the boundary between the short tube and the long tube. For simply supported edges, Mr. Donnell establishes the boundary by

$$\frac{1}{\sqrt{1-\mu^2}}\frac{L^2 t}{D^3} = 5.5 \qquad (43)$$

or

$$\frac{L^2 t}{D^3} = 5.19 \qquad (44)$$

for Poisson's ratio equal to 0.33. However, Eq. 42 may be in the form:

$$\frac{L^2 t}{D^3} = 2.45^2 = 6 \qquad (45)$$

which compares favorably with Eq. 44. It should be noted that Eqs. 40 and 42, developed by the writer from Fig. 5, are approximate and are presented primarily to indicate qualitative agreement between the results of the author and other investigators.

L. H. DONNELL,[29] ESQ.—A welcome addition to the already considerable literature on the subject has been made by this paper. Like previous solutions of this problem, those cited in the paper are based on approximations, but these approximations are different from those used in previous solutions. It is reassuring, in a field in which no exact solution has been obtained, that this solution, in the region to which it has been applied, never differs by more than 13% or 14% from previous solutions.

Unfortunately, the paper may be misleading in a number of respects to those not familiar with the subject. For instance, unlike some other treatments[5] that cover all possible proportions, the author's treatment covers only the range of proportions which might be described as "moderately long" cylinders. This point is not even discussed; thus readers are not warned against applying the results to very short or very long cylinders, where they may be quite inaccurate and on the unsafe side.

Moreover, the treatment of boundary conditions is certainly confusing and incomplete. These conditions, for the simply supported cylinder, are stated (under the heading, "Adaptation of General Theory of Buckling to Problem of Torsion") as:

"* * * When $y = +\frac{L}{2}$, $z = 0$; and, for all values of θ, $\frac{\partial z}{\partial \theta} = 0$.

---

[29] Research Prof. of Mechanics and Director, Fundamental Mechanics Research Laboratory, Illinois Inst. of Tech., Chicago, Ill.

"The choice of the center of coordinates midway between the ends of the cylinder or tube and at the point of maximum displacement around the shell leads to the boundary condition that $\frac{\partial z}{\partial \theta} = 0$ when $y = 0$ and $\theta = 0$."

The complete boundary conditions for this case, as given by the writer[5] in 1933 and quoted by S. Timoshenko,[6] are (using the symbols in the paper): When $y = \pm \frac{L}{2}$, $u = 0$, $v = 0$, $z = 0$, and $\frac{\partial^2 z}{\partial y^2} + \frac{\mu}{r^2}\frac{\partial^2 z}{\partial \theta^2} = 0$. The first two of these conditions ($u = 0$ and $v = 0$) are not very important, but the third and fourth are both essential. The fourth condition states that the edge moments are zero; that is, that the edges are freely hinged. Without this condition the boundary conditions would be indeterminate, and might cover an infinite variety of conditions, including the case of fixed edges or even a case of moments opposite to those present when the edges are fixed.

The solution given in this paper for simply supported edges does not satisfy any of these conditions except the third. The treatment of the fixed edge condition in this paper is even more confusing, but is apparently a still further approximation, based on the solution for simply supported edges. On the other hand, in the writer's paper[5] the boundary conditions for both cases were completely satisfied except for the very unimportant condition, $u = 0$. However, other approximations were made, in the form of omitting certain minor terms which are considered by the present author.

In discussing the writer's paper[5] in the "Introduction," the author cites its approximations and its differences between theory and experiments as the chief justifications for his own paper. On the other hand, the approximations of the new solution are not even mentioned, and its agreement with experiments is described as "quite satisfactory." The reader is left with the impression that the new theory eliminates the approximations of the old and is in good agreement with experiments, whereas the old theory was not. However, no evidence is given to support such implications, even for the range to which the new theory applies. No comparison is made between the two theories or between their experimental checks.

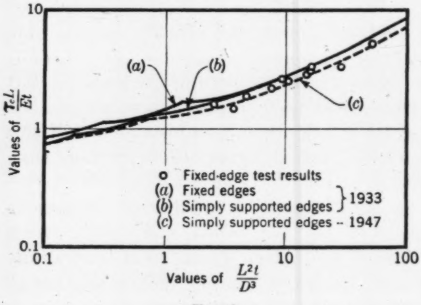

FIG. 9

In Fig. 9 the full lines show the results from the 1933 paper[5] for the "moderately long" range. For simplicity, only the most interesting part of this range is shown and Poisson's ratio is taken as 0.3. When the theoretical values are plotted with the variables shown, a single curve is obtained which covers all materials and proportions in this range for each edge condition. One such curve gives all the information offered by a family of curves such as that shown in Fig. 5. There is no "sudden break" or "confusion resulting from the use of two formulas," as might be inferred from the author's "Introduction." To be sure, such a curve covers only the moderately long range, and different formulas or curves are needed both for very short cylinders—where the conditions approach those found by R. V. Southwell and S. W. Skan,[24] in 1924, for flat strips under shear—and for very long cylinders—where the number of circumferential waves may become one and the conditions are as found by A. G. Greenhill[2] in 1883. However, such "complications" cannot satisfactorily be avoided by simply ignoring the phenomena that occur in such ranges of dimensions, as the author has done.

Charts such as Fig. 9 are easy to use for numerical computation. When the computer knows the specifications of the cylinder he can compute the ordinate and select the abscissa from the curve; the value of the buckling stress, τ_e, is then readily calculated from this value by reference to the specifications. Such calculations are no more difficult than for the family of curves given by the author, and the difficulty of interpolating between, or extrapolating beyond, this family of curves is avoided. In the writer's paper[5] the effects of variations in Poisson's ratio (which may be considerable but which are neglected in Professor Sturm's paper) are also considered.

The method of plotting Fig. 9 is convenient for comparing the two theories and their relation to experiments. If the results given in Fig. 5 are plotted in Fig. 9 they all fall, within 1% or 2%, on the dotted curve (Fig. 9, curve (c)). This means that the results of experiments cannot "line up" better or show appreciably less scatter when plotted in Fig. 5 than they do when plotted against the single curves in Fig. 9. (However, a method of plotting which does show some promise of reducing the scatter is shown elsewhere.[30])

The maximum difference between the two theories in this range is about 13% (no comparison can be made for the extremes of length-to-diameter ratios, since the new theory does not cover them and would show very large discrepancies if so extended).

The question now arises as to which theory is the most accurate in this range. As has been stated, the older theory satisfied edge conditions but had other simplifications, whereas the newer theory does not satisfy edge conditions and avoids these simplifications. It would be difficult if not impossible to state, without further evidence, which of these approximations is most important in the present case. To be sure, Professor Timoshenko, in discussing this problem,[6] seems to feel that edge conditions become unimportant for long tubes; but he gives no reasons or evidence for this feeling. In cases where the deformations consist of many waves in the direction of the length, as in cylinders under axial load or struts with elastic support, such a conclusion is certainly justifiable. In the case of torsion buckling, however, there is only one wave in the longitudinal direction. This spirals around the cylinder and a longitudinal section may seem to indicate a number of waves, but there is actually only one continuous wave in this direction. In this respect therefore this case is similar to the case of a simple strut. For such a strut, of course, the buckling strengths for fixed and hinged ends always have a ratio of 4 to 1, no matter how great the length. In the case of tubes in torsion where any fixity is in the wall rather than in the entire end, there is certainly not a 400% effect; but there is no reason whatever for not expecting a possible 13% effect due to the end conditions.

---

[30] "The Stability of Isotropic or Orthotropic Cylinders or Flat or Curved Panels, Between or Across Stiffeners, with Any Edge Conditions Between Hinged and Fixed, Under Any Combination of Compression and Shear," by L. H. Donnell, *Technical Note No. 918*, National Advisory Committee for Aeronautics, Washington, D. C., 1943, Fig. 19.

There is only one real item of evidence which indicates that end conditions are unimportant, say in the range of $\frac{L^2 t}{D^3} > 5$. This is that the writer's theory[5] gives practically the same result for the hinged end and fixed end conditions in this range. However, this is the only region in which the Sturm theory gives a value appreciably different from the old theory and it is perhaps not entirely logical to reject one theory and choose another on the sole evidence of the theory which is rejected.

As to the experimental evidence, all the available test results reported in both papers, in the range where they differ appreciably, are shown in Fig. 9. If it be assumed that the author's theory would give approximately the same results in this range for the fixed edge condition (all experiments have been for this condition) then at first glance the evidence seems to favor that theory. The Sturm curve seems to pass through about the average of the experiments, whereas the experiments all lie below the curve representing the writer's theory. However, this is actually evidence against the author's theory and not in favor of it—paradoxical as this may seem. It should be emphasized that all these theories are for "perfect" specimens. Actual specimens always involve some imperfections, so that, in general, the buckling strengths determined in good experiments are always below the strengths predicted by a good theory.

In comparing two approximate theories, the one that happens to give the lower strengths will usually be closer to the median of the experiments and so will apparently "check" the experiments better; but this does not mean that it is the better approximation. On the contrary, when experimental points lie above a theoretical curve for buckling of ideal specimens it is an indication that something is wrong. If an approximation in a theory happens substantially to balance the effect of specimen imperfections, this may be convenient; but it would be safer to have a better theory and use an empirical or other factor to allow for the imperfections of actual specimens. Both the theoretical and experimental evidence is insufficient for deciding which of the two theories is the better in this range. The principal conclusion to be drawn is that both theories are evidently excellent approximations, which would seem to be the chief value of the author's solution.

The author also discusses the effects of imperfections in actual cylinders. Although this approach is interesting, it seems to be much too approximate to be quantitatively significant, especially for studying the rather small effects that appear to be present. The discussion is based on the assumption that the ultimate strength is just about reached when the maximum stresses reach the yield point of the material. This is a reasonable assumption, but in calculating the maximum stress only the bending stresses are considered, whereas both ordinary and large deflection membrane stresses are probably of the same or greater importance. Also, the expression used for calculating the deflection under load is probably not at all accurate in the large deflection range, and most such specimens are probably in this range long before ultimate strength is reached.

R. L. MOORE,[31] Assoc. M. ASCE.—Although consideration of the buckling characteristics of thin-walled cylinders in torsion has been limited largely to aircraft design, the solutions presented by Professor Sturm are of interest wherever thin curved plates are required to resist shear. The application of the theory within the range of proportions covered by Fig. 5 is relatively simple and a reasonably good agreement between observed and computed shear buckling stresses for tubes and thin cylinders has been shown. The purpose of this discussion is to present a few additional data and thus to make some evaluation of the method proposed for predicting shear buckling in stiffened cylinders or curved panels.

TABLE 2.—COMPARISON OF OBSERVED AND COMPUTED SHEAR BUCKLING CHARACTERISTICS OF ALUMINUM ALLOY CYLINDERS HAVING RING STIFFENERS ONLY

Spacing of rings L_r, in inches	Ratio[a] $\frac{L_r}{D}$	SHEAR BUCKLING STRESS, IN POUNDS PER SQUARE INCH		WAVE ANGLE, α, IN DEGREES	
		Observed[b]	Computed[c]	Observed[b]	Computed[c]
35.62	1.18	1,110	1,500	14	11
27.00	0.90	1,280	1,750	18	12.5
13.50	0.45	1,710	2,560	25	17.5
9.00	0.30	2,570	3,170	30	21.5
8.81	0.29	2,310	3,220	30	22

[a] Mean diameter $D = 30.08$ in. and wall thickness $t = 0.020$ in. [b] The observed values are averages of three to five determinations for each ratio of L_r/D. [c] The computed values are based on the Sturm solution for simply supported ends.

Tables 2 and 3 show comparisons between observed and computed shear buckling characteristics for aluminum alloy, circular cylinders having both circumferential and longitudinal stiffeners. These results, obtained in tests made during 1943 and 1944[32] at the Aluminum Research Laboratories (New Kensington, Pa.), are of interest because they involve ratios of diameter-to-wall thickness (D/t) greater than those considered by Professor Sturm in his comparisons, and because they show directly the influence of longitudinal stiffeners on shear buckling resistance.

Figs. 10 and 11 show the type of specimens used and indicate the manner of loading. The ends of the cylinders were fitted with steel bulkheads, which in turn were bolted to frames through which torque could be applied. One frame was fixed while the other (visible in Fig. 10) could be rotated about the central axis of the specimen. The cylinders were 30 in. in diameter and were formed of sheets 0.020 in. by 36 in. by 96 in., which were wrapped around the end bulkheads and riveted together in a simple lap joint. The ring stiffeners used on the inside were formed of ½-in. square bars, whereas the longitudinal stiffeners used on the outside were of **U**-section, formed of 0.032-in. sheet aluminum. All sheet and stiffeners were of 24S-T3 and T4 aluminum alloy having the following typical properties: Tensile yield strength, 46,000 lb per sq in. and tensile ultimate strength, 68,000 lb per sq in. It is evident from the magnitude of the stresses shown that buckling in the tests occurred well within the elastic range of the material.

TABLE 3.—COMPARISON OF OBSERVED AND COMPUTED SHEAR BUCKLING CHARACTERISTICS OF ALUMINUM ALLOY CIRCULAR CYLINDERS HAVING LONGITUDINAL STIFFENERS AS WELL AS RING STIFFENERS

Spacing of rings L_r, in inches	Ratio[a] $\frac{L_r}{D}$	Wall thickness t, in inches	OBSERVED VALUES[b] FOR DIFFERENT COMBINATIONS OF LONGITUDINAL STIFFENERS						COMPUTED[c] FOR NO LONGITUDINALS		
			No Longitudinals		Eight Longitudinals, 11.81 in. apart		Sixteen Longitudinals, 5.90 in. apart				
			Buckling stress	Wave angle, α	Buckling stress[b]	Wave angle, α	Buckling stress[b]	Wave angle, α	Wave angle, α	$L_r \tan \alpha$	Buckling stress
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)
13.50	0.45	0.020	1,710	25	2,110	18	2,870	19	17.5	4.25	2.560
9.00	0.30	0.020	2,570	30	2,950	26	3,860	24	21.5	3.55	3,170
6.75	0.23	0.0205	....	....	....	....	4,740	28	25	3.14	3,860
4.31	0.14	0.020	....	....	4,130	35	6,750	....	32	2.69	4,660

[a] Mean diameter $D = 30.08$ in. [b] For specimens having longitudinal stiffeners, where tension field action prevented, the determination of single, well-defined values of buckling torque, observed stresses (in pounds per square inch) were based on the mean torques required to produce visible buckling in all panels of any one size. [c] Based on the Sturm solution for simply supported ends.

A study of Table 2 reveals two interesting results: (1) The observed shear buckling stresses for cylinders having a D/t ratio of 1,500, with ring stiffeners only, ranged from 67% to 81% of the computed values; and (2) the wave angles α of the buckles, such as shown in Fig. 10, were in every case greater than those computed. The comparison from the standpoint of buckling stresses was only slightly less satisfactory than that shown in Fig. 7 for cylinders having a D/t-ratio of approximately 930. However, it was definitely not as favorable as that shown in Fig. 6 for relatively much longer and thicker tubes, having a D/t-ratio of only 138. Local out-of-roundness or initial buckles in the thinnest cylinders undoubtedly accounted for some of the discrepancies indicated between buckling stresses; but it is not so evident that imperfections of this kind were also responsible for the differences shown between measured and computed wave angles. In view of these observations it is significant that a considerably closer agreement between observed and computed buckling stresses might have been shown in Table 2 had the torsion theories of L. H.

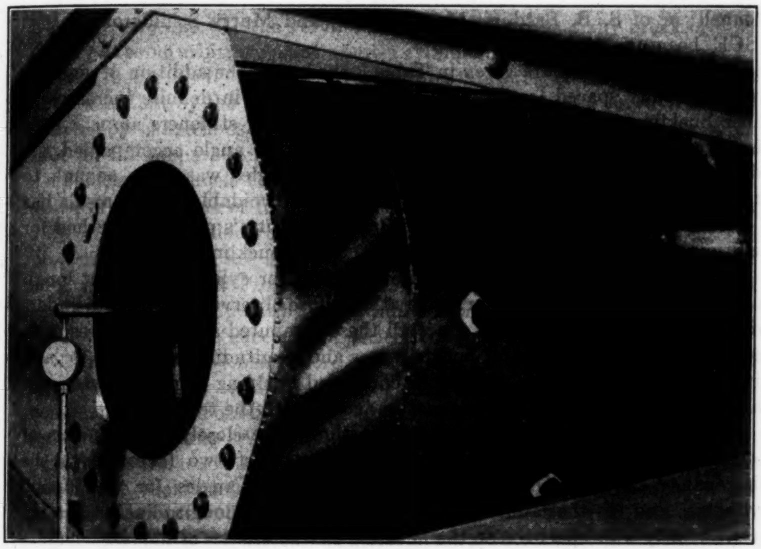

FIG. 10.—SHEAR-BUCKLING FAILURE OF CYLINDER HAVING RING STIFFENERS ONLY (y_r/D-RATIO OF BUCKLED PANEL = 0.29)

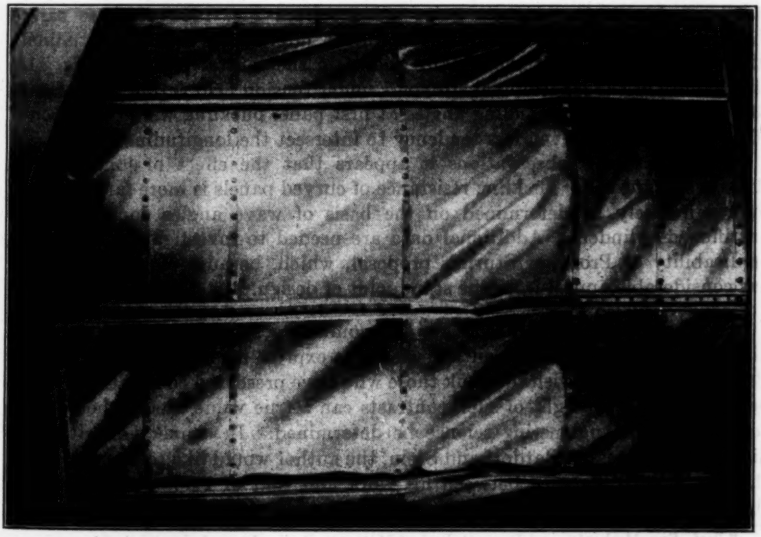

FIG. 11.—FAILURE OF STIFFENED CYLINDER UNDER TORSION LOADING CARRIED BEYOND THE POINT OF PANEL BUCKLING (y_r/D-RATIOS = 0.30 AT CENTER AND 0.14 AT ENDS)

Donnell[5] or of S. B. Batdorf, Manuel Stein, and Murry Schildcrout,[25] Jun. ASCE, been used.

The experimental data given in Table 3 show that the addition of eight or sixteen equally spaced longitudinal stiffeners resulted in definite increases in shear buckling resistance over that observed for ring stiffeners alone. It is also evident in a few cases that a decrease in wave angle accompanied the addition of stiffeners, even though none of the angles was large enough to make a buckle intersection with such stiffeners unavoidable. This result has a direct bearing on the applicability of Professor Sturm's proposed method for determining the effect of longitudinal stiffeners on buckling resistance.

The computed wave angles shown in Table 3 for cylinders without longitudinal stiffeners were in every case less than those observed, even for cylinders with longitudinals. Moreover, since all these computed angles were less than required for an intersection of buckle waves and longitudinal stiffeners for any given spacing of rings, no increase in computed buckling resistance was indicated. This result was obviously not in accord with the tests.

The failure of the author's method to show more closely the influence of longitudinal stiffeners may be attributed to at least two factors—(1) the discrepancy between observed and computed wave angles for unstiffened cylinders; and (2) the failure to recognize the effect of longitudinal stiffeners, even at fairly wide spacings, on the buckling characteristics of the intermediate curved panels. Table 3 shows, for example, that for the tests in which the length-to-diameter ratio (L_r/D) was only 0.30 the wave angles were about 30° for the case of no longitudinals, 26° for eight longitudinals, and 24° for sixteen longitudinals. It would seem quite evident from Fig. 11 that these early shifts in angle were not the result of direct interference with longitudinal stiffeners. The angle of the buckles shown in the central panels in Fig. 11, after failure of the longitudinal stiffeners under tension field action, was about 33°, whereas the corresponding angles at first panel buckling were only about 26° and would show even less tendency to intersect the longitudinals.

From these few observations it appears that the effect of longitudinal stiffeners on the shear buckling resistance of curved panels is more far-reaching than can safely be determined on the basis of wave angles computed for unstiffened cylinders. Additional data are needed to investigate further the applicability of Professor Sturm's proposal, which, because of its simplicity, has considerable appeal from the standpoint of design.

R. G. **Sturm**,[33] M. ASCE.—For the comments presented by the various discussers of this paper, the author wishes to express his sincere appreciation. Particularly does he wish to thank those who have presented contrasting views, because only in the light of such contrasts can a true value of any theoretical contribution to engineering science be determined. In connection with the discussion by Messrs. Batdorf and Stein, the author would like to mention that the significant difference between his work and that of Professor Donnell is that one single expression is used to cover the entire gamut of cylinder lengths from the very short to the very long, thereby eliminating any break or discontinuity at some arbitrary point where a cylinder is considered short or very long.

---

[33] Prof., Eng. Mechanics, and Research Prof. of Materials, Purdue Univ., Lafayette, Ind.

The discussion by Professor Murphy presents another very interesting point of view in that by the use of the algebraic equivalent to the curves some rather simple approximations are evolved. Such approximations are extremely valuable for the preparation of design charts.

Professor Donnell has presented a basic thought in connection with the value of discussions of technical papers—the significance of various points of view. Every solution requires certain assumptions and, in most cases, approximations which are usually different for different types of analysis. The author believes that Professor Donnell has made a real contribution to the general problem by pointing out a number of comparisons, and especially by his discussion of the effects of imperfections in actual cylinders.

The discussion by Mr. Moore is a welcome contribution to the general problem of the stability of thin cylindrical shells in that it gives for the first time a comparison of data obtained on complicated shells with the values computed by analytical methods. Although the discrepancies between measured and computed buckling loads are considerable, it is of interest to note that in all cases the actual buckling load is between 70% and 80% of the computed value, whereas the observed wave angle ranged from 1.26 times to 1.45 times that computed. Such consistency suggests more than a random relationship and indicates that perhaps some factor or factors are always present in the tests or should be included in the theory. The writer agrees with Mr. Moore in his statement about the effectiveness of longitudinal stiffeners and hopes that more experimental data will be forthcoming to serve as a basis for either establishing or modifying the theory to make it reliable for design.

CONSOLIDATION OF FINE-GRAINED SOILS BY DRAIN WELLS

BY REGINALD A. BARRON,[1] JUN. ASCE

WITH DISCUSSION BY MESSRS. KENNETH S. LANE, PHILIP KEENE, WALTER KJELLMAN, AND REGINALD A. BARRON

SYNOPSIS

Drain wells have been used to accelerate the consolidation of fine-grained compressible soils subjected to new loads. However, mathematical analyses of such wells have become available only recently, and are confined to wells having infinitely pervious well backfill and no peripheral smear. Complete formulas for consolidation by vertical and radial flow to wells, for cases with or without peripheral smear and drain well resistance, are presented in this paper; necessary derivations are given in Appendix II. Because soils are not homogeneous, and because of incomplete knowledge of stress-strain consolidation characteristics of soils, these solutions should be regarded as approximate when applied to practical problems.

INTRODUCTION

When a soil mass is subjected to a new load, compressive stresses cause a reduction of pore space and, if saturated, the excess water is expelled. For slightly pervious soil, time is required to accomplish this, and, initially, before any reduction of pore space has occurred, the new compressive stresses are carried by the water (called hydrostatic excess or excess pore-water pressure). As the excess water drains, the new compressive stresses are transferred to the soil grains increasing the intergranular pressures. This process is known, in soil mechanics terminology, as consolidation.

New loads applied to foundation soils create shearing stresses; to maintain stability the soil must not be overstressed. For slightly pervious compressible soils, the factors affecting the shearing strength are not fully understood at present; however, it is known that the shearing strength increases with a reduction of the soil pore water.

Most compressible soils are alluvial deposits and are more pervious in the direction of the bedding plane than in a perpendicular direction. This is very

NOTE.—Published in June, 1947, *Proceedings*. Positions and titles are those in effect when the paper or discussion was received for publication.

[1] Engr., Soil Mechanics, Embankment and Foundation Branch, U. S. Waterways Experiment Station, Vicksburg, Miss.

pronounced in varved deposits[2] laid down in lakes during the wasting away of the continental glaciers. When such soils are loaded, horizontal flow accelerates the consolidation of the soil mass as compared with strictly vertical flow. Because of the horizontal migration of water, however, this process imposes a dangerous condition on the stability of the foundation due to increased pore-water pressure[3] reducing the intergranular stresses at the toes of fills.

The limitation that the shearing strength shall not be exceeded may be met by widening the loading area (thus reducing the shearing stresses in the foundation), or by stage construction, thereby permitting a gain in shearing strength from the consolidation process. These methods are costly. Sometimes a more economical method may be to accelerate the consolidation process, and thus hasten a gain in shearing strength, by the use of vertical sand-filled holes known as drain wells. Drain wells are especially efficient in stratified soils because of the greater perviousness parallel to the bedding. Furthermore, drain wells permit control over the water migrating in a horizontal direction, thus reducing the excess pore-water pressures that might be built up in the toe area of an earth fill.

Drain wells have been used in this country mainly by the California State Highway Department,[4,5] and also at an eastern shipyard.[6] They have also been used by the Providence (R. I.) District, United States Engineer Department, as a repair measure to a dike failure. Further use is planned by the latter organization to permit construction of a moderately high dam on a foundation containing a large deposit of soft varved silt.

The theory of consolidation by drain wells was developed by the author during the design of the two Providence District projects previously noted. The theory for ideal wells having no resistance to flow up the well bore and having no smear at the well periphery has been presented elsewhere,[7,8,9,10,11] but consolidation theory which includes the effect of well smear and well resistance is presented here publicly for the first time.

Notation.—The letter symbols in this paper are defined where they first appear, in the text or by diagrams, and are assembled for convenience in Appendix I. In so far as possible the symbols conform with those given in "Soil Mechanics Nomenclature," *Manual of Engineering Practice No. 22.*

Basic Considerations

The basic theory of consolidation has been developed by Karl Terzaghi, M. ASCE.[12] For the purpose of this paper the following basic assumptions are made:

(1) All vertical loads are initially carried by excess pore-water pressure u.

(2) All compressive strains within the soil mass occur in a vertical direction. Thus, the basic partial differential equation for consolidation by three-directional flow in stratified soils is:

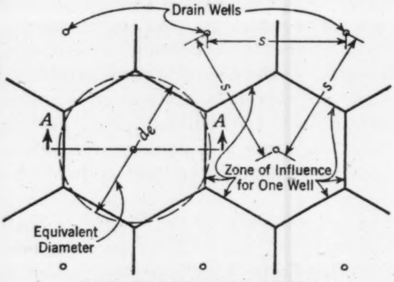
$$\frac{k_h}{\gamma_w}\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) + \frac{k_v}{\gamma_w}\left(\frac{\partial^2 u}{\partial z^2}\right) = \frac{a_v}{1+e}\left(\frac{\partial u}{\partial t}\right) \qquad (1a)$$

in which k_h is the coefficient of permeability of the soil in a horizontal direction; k_v is the coefficient of permeability in a vertical direction, γ_w is the unit weight of water; x, y, and z are rectangular coordinates; e is the void ratio of the soil; t is time; and a_v, the coefficient of compressibility of the soil, equals $-\frac{de}{dp}$. For symmetrical flow to a central drain well Eq. 1a becomes:

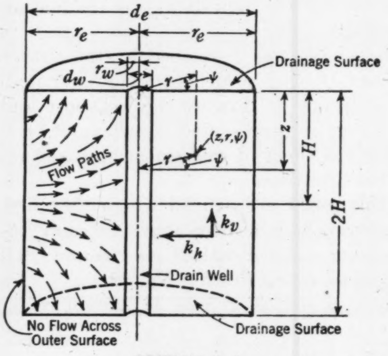
$$\frac{k_h}{\gamma_w}\left(\frac{1}{r}\frac{\partial u}{\partial r} + \frac{\partial^2 u}{\partial r^2}\right) + \frac{k_v}{\gamma_w}\left(\frac{\partial^2 u}{\partial z^2}\right) = \frac{a_v}{1+e}\left(\frac{\partial u}{\partial t}\right) \qquad (1b)$$

in which r and z are cylindrical coordinates as defined by Fig. 1.

(3) The most economical pattern of drain wells is that shown in Fig. 1. An exact analysis should include the load distribution and the effect of each well on the rate of consolidation at any point in the foundation. However, it is believed that such a solution would be extremely cumbersome and rather academic when consideration is given to the heterogeneity of the foundation, and the present incomplete knowledge of the three-dimensional stress-strain consolidation properties of fine-grained soils.



PLAN OF DRAIN WELL PATTERN



SECTION A-A

Fig. 1.—Plan of Drain Well Pattern and Fundamental Concepts of Flow Within Zone of Influence of Each Well

(4) The zone of influence of each well is a circle (see Fig. 1).

(5) Load distribution is uniform over this area.

---

[12] "Erdbaumechanik auf Bodenphysikalischer Grundlage," by Karl Terzaghi, F. Deutiche, Vienna, 1925.

IDEAL DRAIN WELLS

Wherever drain wells are installed construction operations generally cause some remolding or smear of the fine-grain soil adjacent to the well periphery, especially in varved soils. Also, the backfilling of the well, even with pervious material, results in some resistance to flow of the expelled water up the well bore. For ideal drain wells these effects are ignored, although solutions for these effects are discussed subsequently.

Case of Free Strain.—The initial solution for ideal drain wells is made on the assumptions that the load is uniform over the circular zone of influence for each well and that differential settlements occurring over such a zone, as consolidation progresses, have no effect on redistribution of stresses by arching of the fill. Furthermore, it is assumed that shear strains developed in the foundation by differential settlements will have no effect on the consolidation process. The boundary conditions are:

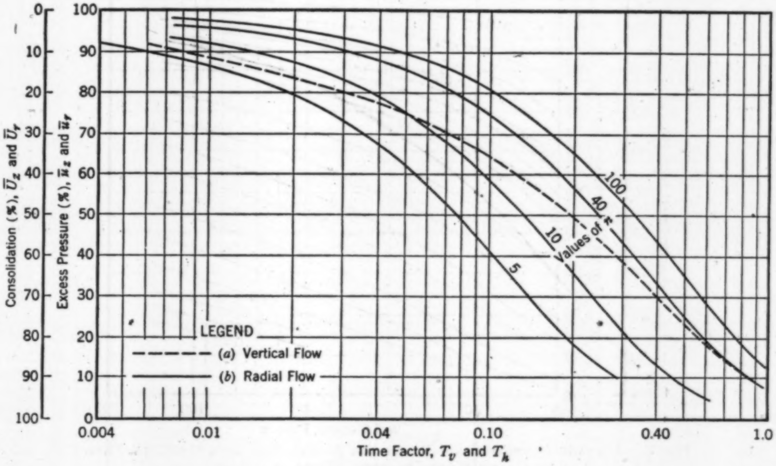


FIG. 2.—AVERAGE CONSOLIDATION RATES
(a) For Vertical Flow in a Clay Stratum of Thickness 2 H Drained on Both Upper and Lower Surfaces
(b) For Radial Flow to Axial Drain Wells in Clay Cylinders Having Various Values of n

(1) Initial excess pore-water pressure, u_0, is uniform throughout the soil mass when $t = 0$.

(2) Excess pore-water pressure at the drain well surface (r_w) is zero when $t > 0$.

(3) The external radius, r_e, is impervious or, because of symmetry, no flow occurs across this boundary; that is, $\frac{\partial u}{\partial r} = 0$ when $r = r_e$.

(4) Excess pore-water pressure at the upper horizontal boundary of the soil mass ($z = 0$) is zero when $t > 0$.

(5) The lower horizontal boundary of the soil mass ($z = H$) is impervious or, because of symmetry, no flow occurs across this boundary; that is, $\frac{\partial u}{\partial z} = 0$ at $z = H$.

Subject to the foregoing conditions a solution of Eq. 1*b* for excess pore-water pressure, $u_{r,z}$, at any point due to consolidation by both radial and vertical flow is:

$$u_{r,z} = \frac{u_r\, u_z}{u_0} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which u_r and u_z are, respectively, the excess pore-water pressures due to radial flow only and vertical flow only. Similarly, the average excess pore-water pressure throughout the entire soil mass is:

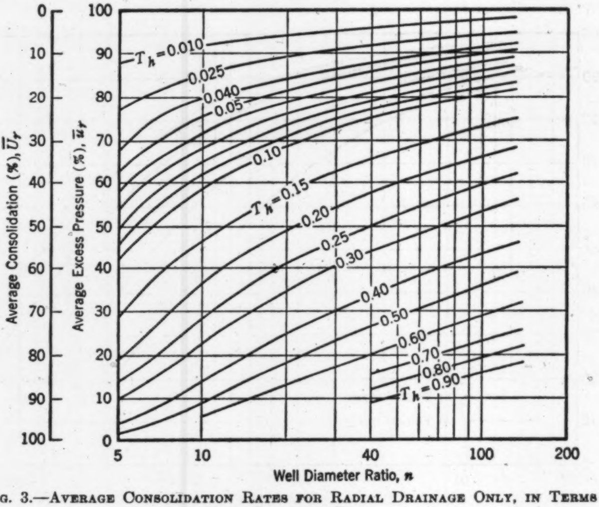

FIG. 3.—AVERAGE CONSOLIDATION RATES FOR RADIAL DRAINAGE ONLY, IN TERMS OF WELL DIAMETER RATIO, *n*

$$\bar{u}_{r,z} = \frac{\bar{u}_r\, \bar{u}_z}{u_0} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which $\bar{u}_r$ and $\bar{u}_z$ are the average excess pore-water pressures throughout the entire soil mass due to radial flow and vertical flow, respectively. Equations for u_r and $\bar{u}_r$ were developed by R. E. Glover;[13] those for u_z and $\bar{u}_z$ were developed by Professor Terzaghi.[11,12] A more general solution may be obtained when the initial excess pore-water pressure is a function of z, provided no expansion of the soil occurs. Equations for u_z and $\bar{u}_z$ for this case were developed by G. Gilboy,[14] Assoc. M. ASCE.

---

[13] *Technical Memorandum No. 158*, by R. E. Glover, Bureau of Reclamation, Denver, Colo., 1930.

[14] "Soil Mechanics," by G. Gilboy, Mass. Inst. Tech., Cambridge, Mass., 1930 (mimeographed notes).

Curves of average excess pore-water pressures $\bar{u}_r$ due to purely radial flow, versus time factor $T_h = \dfrac{k_h\,(1 + e)\,t}{\gamma_0\, a_v\, d^2_e}$ for various values of n are shown in Fig. 2, in which n is the ratio of the zone of well influence to well diameter. Also given in Fig. 2 is a curve of average excess pore-water pressure $\bar{u}_z$ due to vertical flow only, versus time factor $T_v = \dfrac{k_v\,(1 + e)\,t}{\gamma_0\, a_v\, H^2}$. Curves of $\bar{u}_r$ versus well diameter n for various time factors T_h are shown in Fig. 3. These curves permit the construction of average pore-water pressures versus time factor curves similar to those shown in Fig. 2 for any value of n between 5 and 100. Variations of excess pore-water pressures u_r at various points, due to radial flow, for a well diameter ratio $n = 40$, are shown in Fig. 4, indicating a much faster rate of consolidation nearer to the well as compared to that nearer the outer zone of well influence. Shown in Fig. 5 is excess pore-water pressure, u_z, due to vertical flow only, versus relative depth, $Z\%$, of clay layer for various time factors T_v. The relative depth, $Z\%$, is defined as the ratio of the depth z to the point to the total thickness H of the clay deposit. Use of the curves shown in Fig. 2 and Fig. 5 is explained in the following example.

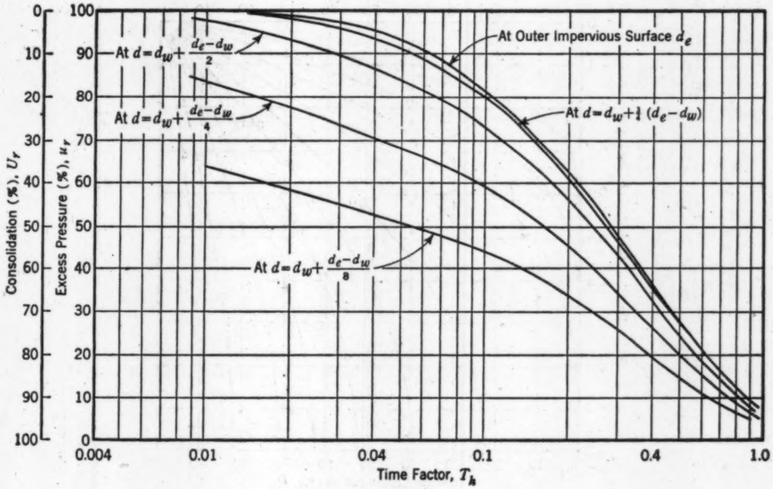

FIG. 4.—RADIAL CONSOLIDATION RATES AT VARIOUS RADIAL SURFACES FOR CLAY CYLINDER HAVING WELL DIAMETER RATIO, $n = 40$

Example.—A bed of varved clay, 40 ft thick, resting on impervious rock, and having free drainage at its upper surface is quickly loaded with a very wide fill to 1 ton per sq ft. Tests on undisturbed soil samples furnish the following average data: $a_v = 13 \times 10^{-5}$ cm² per g; $e = 1.500$; $k_v = 100 \times 10^{-8}$ cm per sec; $k_h = 500 \times 10^{-8}$ cm per sec (assumed); and $\Delta e = 0.125$. Settlement under the 1-ton loading will be:

$$\Delta H = \frac{H\,\Delta e}{1+e} = \frac{(40 \text{ ft})\,(0.125)}{1+1.500} = 2.0 \text{ ft}$$

Fig. 6(*a*) shows a time-average consolidation curve for vertical flow only. (The effect of horizontal flow has been neglected.) For time in months,

$$t_v = \frac{T_v\,\gamma_w\,a_v\,H^2}{k_v\,(1+e)} = \frac{T_v\,(1)\,(13\times10^{-5})\,(40\times30.5)^2}{(100\times10^{-8})\,(1+1.500)\,(60\times60\times24\times30)} = 30\;T_v$$

Values for T_v at various stages of consolidation are obtained from time factor consolidation curve for vertical flow only, as given in Fig. 2. After the average consolidation has reached 50%, sand-filled drain wells 1 ft in diameter are installed 40 ft apart in an equilateral pattern. For time in months,

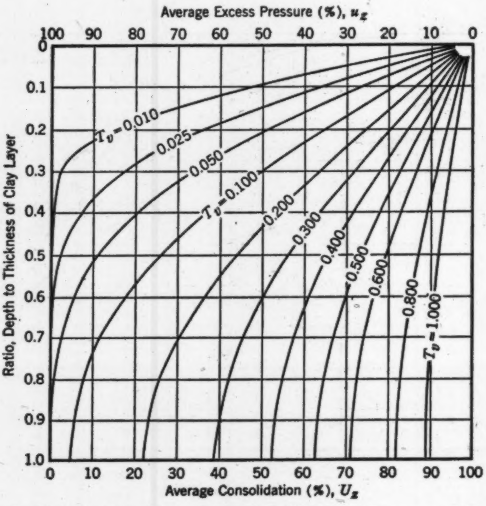

FIG. 5.—VARIATION IN CONSOLIDATION BY VERTICAL FLOW FOR VARIOUS TIME FACTORS AND DEPTH RATIOS

$$t_h = \frac{T_h\,\gamma_w\,a_v\,d^2_e}{k_h\,(1+e)} = \frac{T_h\,(1)\,(13\times10^{-5})\,(40\times30.5)^2}{(500\times10^{-8})\,(1+1.500)\,(60\times60\times24\times30)} = 6\;T_h$$

Values for T_h are obtained from the time factor consolidation curve for $n = 40$ in Fig. 2. The time for 50% consolidation by vertical flow only is

$$t_v = 30\times0.195 = 5.85 \text{ months}$$

which is, therefore, the origin for the radial-average consolidation curve. At any time, *t*, after installations of the wells, $\bar{u}_{r,s}$ is obtained by use of Eq. 3.

For example, at nine months

$$\bar{u}_{r,z} = \frac{\bar{u}_r \times \bar{u}_z}{u_0} = \frac{24\% \times 39\%}{100\%} = 9.4\%$$

The average consolidation is 100 − 9.4 = 90.6%.

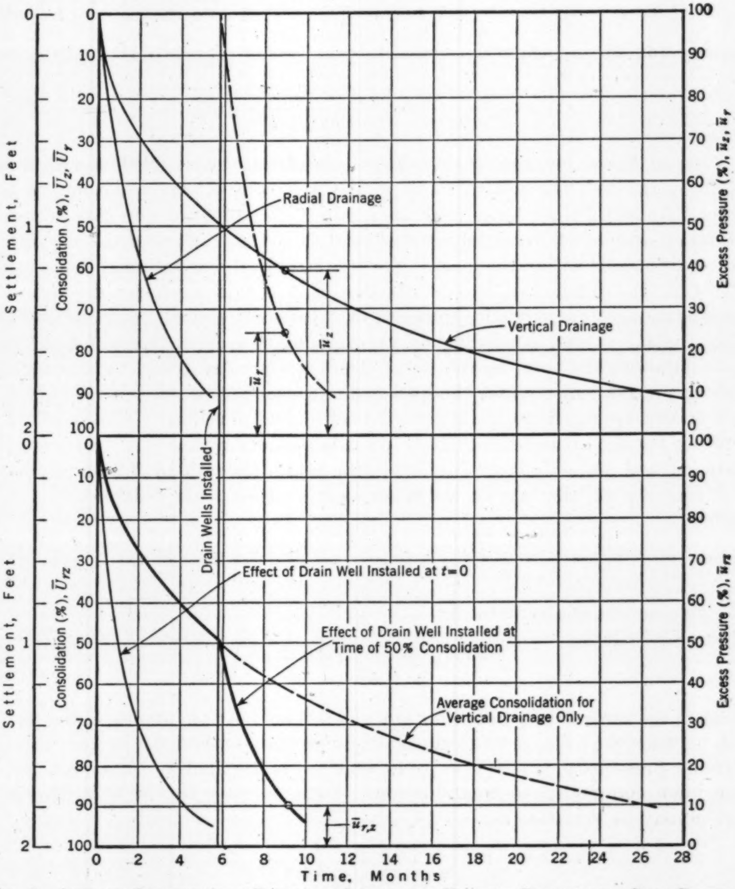

FIG. 6.—AVERAGE CONSOLIDATION RATES FOR RADIAL AND VERTICAL DRAINAGE IN CLAY CYLINDER IN WHICH $D = H$, $n = 40$, AND $k_h = 5\,k_v$, SHOWING EFFECT OF DRAIN WELLS INSTALLED WHEN LOAD IS APPLIED AND WHEN 50% CONSOLIDATION HAS TAKEN PLACE

For wells installed before the load has been added, the solid curve for $\bar{u}_r$ shown in Fig. 6 may be used. The effect of drain wells installed when 50% consolidation had been obtained and before application of load is shown in Fig. 6. Where $k_h \geqq 5\,k_v$, the effect of wells is obvious.

The determination of excess pressure at a point on the bottom of the clay layer and at the outer edge of the influence zone of a well nine months after load is applied is as follows: $Z\% = 40/40 = 1.0$, and $T_v = 9/30 = 0.3$. From Fig. 5, u_z for a relative depth of $Z\% = 1$ and $T_v = 0.3$ is 61%. The value of u_r at the outer surface of the zone of influence (for $n = 40$) is obtained from Fig. 4 at $T_h = \frac{9 - 5.85}{6} = 0.525$, and is 26%. Therefore the excess pressure at this point, which, incidently, consolidates at the slowest rate of all, by Eq. 2, is

$$u_{r,z} = \frac{u_r \times u_z}{u_0} = \frac{26\% \times 61\%}{100\%} = 16\%$$

Case of Equal Vertical Strain.—For consolidation by radial flow with free strains permitted, the soil adjacent to the well consolidates and compresses faster than soil farther away from the drain. This difference in rate of consolidation develops differential settlement of the upper surface of the soil mass and shear strains within the mass. For free strains, it was assumed that these effects did not influence the redistribution of load to the soil nor the rate of consolidation. It is obvious, however, that these effects will redistribute the load to some extent, depending on the amount of arching developed in the material above the compressible soil. The extreme case would be where the arching process redistributes the load to the consolidating soil so that all vertical strains are equal and no differential settlement develops. This condition is rather severe. It can be obtained in the laboratory by use of a rigid loading platform, and probably is approached in the field if the ratio of H to d_e is large.

Using Eq. 1*b*, the rate at which water is expelled from a differential soil cube is:

$$\frac{\partial Q}{\partial t} = -\left[\frac{k_h}{\gamma_w}\left(\frac{1}{r}\frac{\partial u}{\partial r} + \frac{\partial^2 u}{\partial r^2}\right) + \frac{k_v}{\gamma_w}\frac{\partial^2 u}{\partial z^2}\right] 2\,\pi\,r\,dr\,dz \ldots\ldots\ldots (4)$$

The volume lost at any point is:

$$-\frac{\partial V}{\partial t} = \frac{-\,\partial e}{1 + e}\left(\frac{2\,\pi\,r\,dr\,dz}{\partial t}\right) \ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

which is the same at any depth for any given time. At any depth, z, the relation between the average hydrostatic excess pressure, $\bar{u}$, and the average intergranular pressure, $\bar{p}$, is $\bar{u} + \bar{p} = p_f$, in which p_f is the final intergranular pressure upon completion of consolidation. Thus, $-\,\partial\bar{u} = \partial\bar{p}$, $\partial e = a_v\,\partial\bar{u}$, and Eq. 5*a* may be rewritten as:

$$\frac{-\,\partial V}{\partial t} = \frac{-\,a_v\,\partial\bar{u}}{(1 + e)\,\partial t}\,2\,\pi\,r\,dr\,dz \ldots\ldots\ldots\ldots\ldots\ldots (5b)$$

Equating Eqs. 4 and 5*b* and simplifying,

$$c_h\left(\frac{1}{r}\frac{\partial u}{\partial r} + \frac{\partial^2 u}{\partial r^2}\right) + c_v\frac{\partial^2 u}{\partial z^2} = \frac{\partial\bar{u}}{\partial t} \ldots\ldots\ldots\ldots\ldots (6a)$$

in which c_h is a coefficient of consolidation for horizontal flow and is equal to

$\frac{k_h (1 + e)}{a_v \gamma_w}$. For radial flow only, this becomes:

$$c_h \left(\frac{1}{r} \frac{\partial u}{\partial r} + \frac{\partial^2 u}{\partial r^2} \right) = \frac{\partial \bar{u}}{\partial t} \quad \text{.....................} (6b)$$

A solution for this expression is—

$$u_r = \frac{4 \bar{u}}{d^2_e F(n)} \left[r^2_e \log_e \left(\frac{r}{r_w} \right) - \frac{r^2 - r^2_w}{2} \right] \quad \text{.............} (7)$$

—in which

$$\bar{u} = u_0 \epsilon^{\lambda} \quad \text{..........................} (8)$$

ϵ is the base of natural logarithms,

$$\lambda = \frac{-8 T_h}{F(n)} \quad \text{.........................} (9)$$

and

$$F(n) = \frac{n^2}{n^2 - 1} \log_e (n) - \frac{3 n^2 - 1}{4 n^2} \quad \text{...............} (10)$$

The initial distribution of the hydrostatic excess pressure is not uniform (see Fig. 7); but with passage of time the distribution approaches that for the free strain case (see Fig. 8).

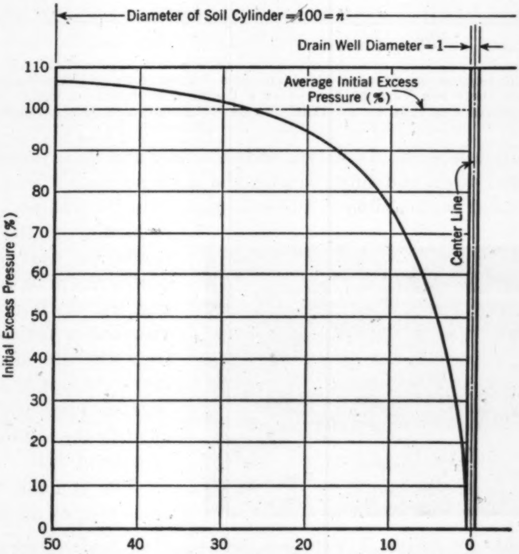

FIG. 7.—DISTRIBUTION OF INITIAL EXCESS PORE-WATER PRESSURE IN SOIL CYLINDER WITH $n = 100$

Effect of Peripheral Smear

If drain wells are installed by driving cased holes and then backfilling as the casing is withdrawn, the driving and pulling of the casing will distort and remold the adjacent soil. In varved soils the finer and more impervious layers will be dragged down and smeared over the more pervious layers, resulting in a zone of reduced permeability in the soil adjacent to the well periphery. This distortion of the soil is very similar to that which occurs during sampling operations (see Fig. 9). It is not difficult to visualize a far greater smear from the use of a heavy casing or hollow mandrel with a bottom plug which displaces entirely the soil at the location of a drain well.

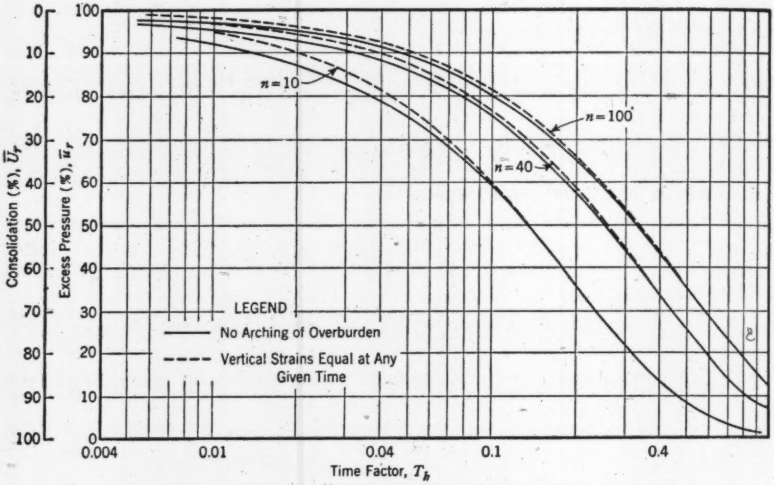

Fig. 8.—Comparison of Average Consolidation Rates in Clay Cylinders by Radial Drainage Only for Various Values of *n* Under Conditions of Equal Vertical Strains at Any Given Time and of No Arching of Overburden

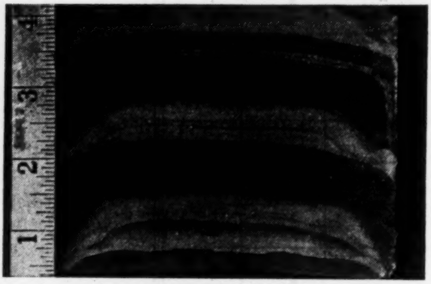

Fig. 9.—Distorted or Smeared Varved Clay Sample Taken with Early Massachusetts Institute of Technology Type 4½-In.-Diameter Sampler

The remolded or smeared zone creates additional resistance which must be overcome by the excess water being expelled. This, in turn, will retard the rate of consolidation. The smeared zone will not be of constant thickness nor will it be homogeneous as far as soil properties are concerned. For this analysis, however, to obtain solutions for smear effect it is assumed that the thickness of the smeared zone is constant and homogeneous. It is further assumed that, because the remolded zone is adjacent to the drain well and will consolidate very fast, its consolidation can be ignored and the zone treated as an incompressible material.

In the smeared zone Eq. 1*b* then becomes:

$$\frac{-k_s}{\gamma_w}\left(\frac{1}{r}\frac{\partial u'}{\partial r}+\frac{\partial^2 u'}{\partial r^2}\right)=0 \qquad (11)$$

in which k_s is the coefficient of permeability of the smeared soil.

It follows that variation of excess water pressure between r_w and r_s, the outer limit of the smeared zone, is:

$$u'_r = u'_{rs}\left[\frac{\log_e\left(\frac{r}{r_w}\right)}{\log_e(s)}\right] \qquad (12)$$

in which u'_{rs} is the excess pressure at r_s, and $s = r_s/r_w$. Added boundary conditions required because of the presence of the smeared zone are: First, that the excess water pressure at the boundary of the smeared zone be the same in the undisturbed zone as in the smeared zone ($u_{rs} = u'_{rs}$); and, second, that the rate of flow out of the undisturbed zone be equal to that into the smeared zone, so that at r_s:

$$k_h\frac{\partial u}{\partial r} = k_s\frac{\partial u'}{\partial r} \qquad (13)$$

Case of Free Strain.—In consolidation by radial flow to a central drain well with a smear zone at its periphery, Eq. 1*b* reduces to—

$$c_h\left(\frac{1}{r}\frac{\partial u}{\partial r}+\frac{\partial^2 u}{\partial r^2}\right)=\frac{\partial u}{\partial t} \qquad (14)$$

—from which a solution for u_r, for uniform initial excess pore-water pressure distribution, subject to the previously noted boundary conditions, is:

$$u_r = u_0\sum_{\alpha_1,\alpha_2,\alpha_3\cdots}^{\alpha=\infty}\frac{-\frac{2}{s\,\alpha}U_1(\alpha\,s)\,U_0\left(\frac{\alpha\,r}{r_w}\right)\epsilon^{\mu}}{\frac{4}{\pi^2\alpha^2 s^2}-U^2_0(\alpha\,s)-U^2_1(\alpha\,s)} \qquad (15)$$

in which

$$U_0(\alpha\,s) = J_0(\alpha\,s)\,Y_1(\alpha\,n) - J_1(\alpha\,n)\,Y_0(\alpha\,s) \qquad (16a)$$

$$U_1(\alpha\,s) = J_1(\alpha\,s)\,Y_1(\alpha\,n) - J_1(\alpha\,n)\,Y_1(\alpha\,s) \qquad (16b)$$

$$U_0\left(\frac{\alpha\,r}{r_w}\right) = J_0\left(\frac{\alpha\,r}{r_w}\right)Y_1(\alpha\,n) - J_1(\alpha\,n)\,Y_0\left(\frac{\alpha\,r}{r_w}\right) \qquad (16c)$$

The functions $J_0(\;)$ and $J_1(\;)$ are Bessel functions of the first kind of zero and first order, respectively, and $Y_0(\;)$ and $Y_1(\;)$ are Bessel functions of the second kind of zero and first order, respectively, and α, α_1, α_2, α_3, $\cdots$, are the roots of

$$\frac{k_s\, U_0\,(\alpha\, s)}{k_h\, \alpha\, s \log_e (s)} + U_1\,(\alpha\, s) = 0 \qquad (17)$$

and

$$\mu = -\,4\, n^2\, \alpha^2\, T_h \qquad (18)$$

The average excess pore-water pressure between r_s and r_e is:

$$\bar{u}_r = u_0 \sum_{\alpha_1,\, \alpha_2,\, \alpha_3 \cdots}^{\alpha=\infty} \frac{U^2{}_1\,(\alpha\, s)\, \epsilon^{\mu}}{\alpha^2\,(n^2 - s^2)\left[\dfrac{4}{\pi^2\,\alpha^2\, s^2} - U^2{}_0\,(\alpha\, s) - U^2{}_1\,(\alpha\, s)\right]} \qquad (19)$$

If consolidation occurs by both radial and vertical flow, an approximate solution for the excess water pressure is:

$$u_{r,z} = \frac{u_r\, u_z}{u_0} \qquad (20)$$

in which u_r is found by Eq. 15; the average excess pressure for the entire body between r_s and r_e is:

$$\bar{u}_{r,z} = \frac{\bar{u}_r\, \bar{u}_z}{u_0} \qquad (21)$$

in which $\bar{u}_r$ is obtained from Eq. 19, and values of u_z and $\bar{u}_z$ are obtained from Figs. 2 and 5. Eqs. 20 and 21 are approximate because the effect of vertical flow in the smeared zone has been neglected. However, for reasonable values of k_h and k_v this effect is believed to be negligible.

Case of Equal Vertical Strain.—Solution of Eq. 6*b* for consolidation by radial flow to a central drain well with a smeared zone at its periphery is—

$$u_r = \bar{u}_r\, \frac{\left[\log_e\left(\dfrac{r}{r_s}\right) - \dfrac{r^2 - r^2{}_s}{2\, r^2{}_e} + \dfrac{k_h}{k_s}\left(\dfrac{n^2 - s^2}{n^2}\right) \log_e (s)\right]}{\nu} \qquad (22)$$

in which

$$\nu = F\,(n, s, k_h, k_s)$$

$$= \left[\frac{n^2}{n^2 - s^2} \log_e \left(\frac{n}{s}\right) - \frac{3}{4} + \frac{s^2}{4\, n^2} + \frac{k_h}{k_s}\left(\frac{n^2 - s^2}{n^2}\right) \log_e (s)\right] \qquad (23)$$

and $\bar{u}_r$ can be expressed as—

$$\bar{u}_r = u_0\, \epsilon^{\xi} \qquad (24)$$

—in which

$$\xi = \frac{-\,8\, T_h}{\nu} \qquad (25)$$

For combined radial and vertical flow, approximate solutions may be obtained using Eqs. 22 and 24 with u_z and $\bar{u}_z$ obtained as noted previously.

For purposes of studying the effect of smear in retarding the average rate of consolidation, Eq. 24 is preferred to Eq. 19 because of its simplicity. The effect of smear is indicated in Fig. 10. For a greater ratio of k_h/k_v the difference is still larger.

EFFECT OF WELL RESISTANCE

The foregoing developments are for ideal drain wells of infinite permeability offering no resistance to flow up the well. Actually, head losses will occur due to resistance of well backfill material to flow. If the flow is large, or if the well area is small, then the back pressure due to well resistance will be high. On the other hand, if the flow is small, as for shallow deposits and tight deposits, or, if the well area is large, then the resistance of the well to flow will be small. A very pervious filling would be ideal from the standpoint of minimizing well resistance but filter action is needed with sufficiently small voids in the backfill to prevent "inwash" of the surrounding soil from clogging the well. This need is especially required for cohesionless silts and for varved soils in which the more pervious part of the varves is fine sand or coarse silt. For clays the filter requirements are less certain.

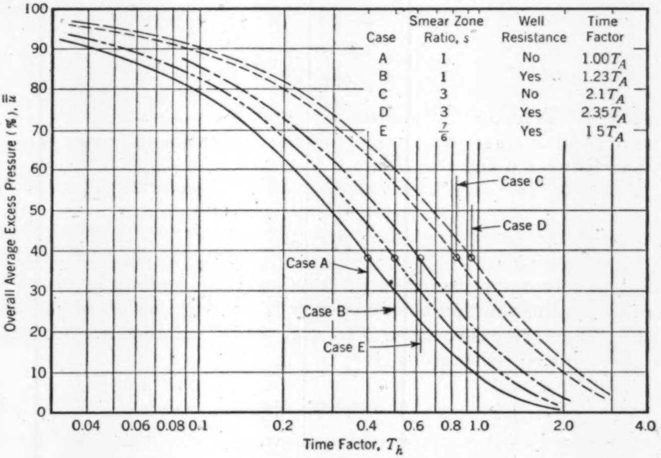

FIG. 10.—EFFECT OF SMEAR AND WELL RESISTANCE ON EQUAL STRAIN CONSOLIDATION BY RADIAL FLOW TO DRAIN WELLS IN WHICH $n = 60$, $k_w/k_h = 20{,}000$, $d_e/H = \frac{60}{80}$, AND $k_h/k_s = 10$

A solution for the effect of well resistance on the rate of consolidation for free strain has not been developed. A solution has been developed for equal vertical strain, with or without smear, where k_v of the consolidating soil is equal to zero; that is, $\frac{\partial u}{\partial z} \neq 0$, but because $k_v = 0$ no vertical flow exists.

A solution of Eq. 6*b* for $u_{r,z}$ at any point where smear and well resistance are involved is—

$$u_{r,z} = \bar{\bar{u}}_z \left\{ \frac{f(z)}{\nu} \left[\log_e \frac{r}{r_s} - \frac{r^2 - r^2_s}{2\, r^2_e} + \frac{k_h}{k_s} \left(\frac{n^2 - s^2}{n^2} \right) \log_e (s) \right] + 1 - f(z) \right\} \quad (26)$$

—in which $\bar{\bar{u}}_z$, the average excess pressure between r_e and r_s at depth z, is:

$$\bar{\bar{u}}_z = u_0\, \epsilon^{\xi f(z)} \quad (27)$$

$$f(z) = \frac{\epsilon^{\beta(z-2H)} + \epsilon^{-\beta z}}{1 + \epsilon^{-2\beta H}} \quad (28)$$

and

$$\beta = \left[\frac{2\, k_h\, (n^2 - s^2)}{k_w\, r^2_e\, \nu} \right]^{\frac{1}{2}} \quad (29)$$

in which k_w is the permeability of the well backfill.

The over-all average excess pressure over the entire soil mass between r_e and r_s and between 0 and $z = H$ is:

$$\bar{\bar{u}} = \int_0^H \bar{\bar{u}}_z \, dz \quad (30)$$

This may be solved approximately by graphical integration or by use of Simpson's rule. In this solution horizontal flow in the drain well backfill has been ignored. Where there is no smear $F\,(n, s, k_h, k_s)$ reduces to $F(n)$. An example of the effect of well resistance is given in Fig. 10.

ACKNOWLEDGMENTS

Mathematical solutions presented in this paper, except as otherwise noted, were developed by the writer for use in special design studies made by the Providence District, U. S. Engineer Department. The writer wishes to express his appreciation to Prof. W. Prager, Brown University, Providence, who checked the derivation of Eqs. 2 and 3, and to Kenneth S. Lane, Assoc. M. ASCE, formerly head, Providence District Soils Laboratory, and now head, Garrison (N. Dak.) District Soils Laboratory, United States Engineer Department, for his valuable aid and encouragement.

APPENDIX I. NOTATION

The following letter symbols, adopted for use in this paper and for the guidance of discussers, conform essentially to "Soil Mechanics Nomenclature," ASCE *Manual of Engineering Practice No. 22*, prepared by a Committee of the Soil Mechanics and Foundations Division, and adopted by the Society in April, 1941. In addition, the symbols of linear concepts are defined by Fig. 1.

- A = constant of integration;
- a_v = coefficient of compressibility $= -\dfrac{de}{dp}$;
- B = constant of integration;
- C = constant of integration;
- c = coefficient of consolidation:
  - c_h = for horizontal flow $= \dfrac{k_h\,(1+e)}{a_v\,\gamma_w}$;
  - c_v = for vertical flow $= \dfrac{k_v\,(1+e)}{a_v\,\gamma_w}$;
- d = diameter:
  - d_e = of zone of influence;
  - d_s = of remolded zone;
  - d_w = of drain well;
- e = void ratio of soil;
- H = depth of clay mass from a free-draining horizontal surface to an impervious one;
- i = hydraulic gradient;
- k = coefficient of permeability:
  - k_h = in horizontal direction;
  - k_s = of remolded zone;
  - k_v = in vertical direction;
  - k_w = of well backfill;
- n = a ratio $= r_e/r_w = d_e/d_r$;
- p = intergranular pressure:
  - p_f = final;
  - $\bar{p}$ = average;
  - $\bar{p}_z$ = average, at depth z;
- Q = rate of flow of water;
- r = radius, a coordinate in the cylindrical system:
  - r_e = of zone of influence;
  - r_s = of remolded zone;
  - r_w = of drain well;
- S = spacing of drain wells;
- s = a ratio $= r_s/r_w$;
- T = time factor:
  - T_h = for radial flow $= \dfrac{c_h\,t}{d^2_e}$;
  - T_v = for vertical flow $= \dfrac{c_v\,t}{H^2}$;
- t = time of consolidation:
  - t_h = due to horizontal flow;
  - t_v = due to vertical flow;
- u = excess pore-water pressure:
  - u_0 = initial uniform;
  - u_r = due to radial flow;
  - u_{rs} = due to radial flow at outer limit of remolded zone;

$u_{rs,z}$ = due to radial flow at outer limit of remolded zone and depth z;
u_{rz} = due to radial flow only at depth z;
$u_{r,z}$ = due to combined radial and vertical flow;
$u_{w,z}$ = in drain well at depth z;
u_z = due to vertical flow;
u'_r = due to radial flow in the smeared zone at point r;
u'_{rs} = due to radial flow on remolded side of remolded zone boundary;
$\bar{u}$ = average excess pore-water pressure:
$\bar{u}_r$ = due to radial flow;
$\bar{u}_{r,z}$ = throughout entire mass, due to combined radial and vertical flow;
$\bar{u}_z$ = due to vertical flow;
$\bar{\bar{u}}_z$ = in undisturbed zone at depth z, due to radial flow with well resistance;
$\bar{\bar{u}}$ = in entire undisturbed soil mass, due to radial flow with well resistance;
V = volume of soil mass;
x = a coordinate in the rectangular system;
y = a coordinate in the rectangular system;
$Z\%$ = relative depth $= \frac{z}{H} = \frac{\text{depth } z}{\text{depth of clay mass}}$;
z = a coordinate in both the rectangular and the cylindrical systems;
α = root of Eq. 17;
β = a substitution factor defined by Eq. 29;
γ_w = unit weight of water;
ϵ = base of natural logarithms;
θ = a substitution factor defined by Eq. 39;
λ = a substitution factor defined by Eq. 9;
μ = a substitution factor defined by Eq. 18;
ν = a substitution factor defined by Eq. 23;
ξ = a substitution factor defined by Eq. 25;
$\bar{\sigma}_z$ = total average stress at depth z; and
ψ = a coordinate in the cylindrical system.

APPENDIX II. DEVELOPMENT OF SOLUTIONS

CASE OF FREE STRAIN—NO WELL RESISTANCE NOR PERIPHERAL SMEAR

Derivations of Eqs. 2 and 3 are given elsewhere,[11,12,13,14] as is also proof of their validity.[10] Therefore, these derivations and proofs are not presented here.

CASE OF FREE STRAIN WITH PERIPHERAL SMEAR

Assume a cylindrical body of fine-grained, saturated compressible soil with an outer impervious boundary and a central drain having no resistance to flow

($k_w = \infty$). Also, assume that the horizontal permeability of the soil mass is k_h while that in a vertical direction, k_v, is zero. Further assume that the central drain is surrounded by a zone of remolded soil whose permeability is k_s, and which is bounded by the well surface, r_w, and by the outer radius of the remolded zone, r_s. The outer radius of the cylindrical body of undisturbed soil is r_e. It is further assumed that the cylindrical body is loaded so that an excess pore-water pressure $u_r = f(r)$ is induced at time zero and that during the process of consolidation vertical strains do not redistribute the load in the soil mass. The remolded soil is assumed to undergo no consolidation.

The boundary conditions are:

(1) When $t = 0$, $u_r = f(r)$ for $r_e > r > r_s$.

(2) No flow occurs accross the impervious surface at the outer boundary r_e of the soil cylinder $\left(\dfrac{\partial u_r}{\partial r} = 0\right)$.

(3) No vertical flow takes place because $k_v = 0$.

(4) The flow of water through the remolded zone surrounding the drain, for $r_s > r > r_w$, is given by Eq. 12.

(5) The seepage to the interface between the undisturbed and remolded soils at r_s is equal to the seepage away (Eq. 13).

The basic partial differential equation in the undisturbed zone ($r_e > r > r_s$) is expressed by Eq. 6*b*, a solution for which is

$$u_r = \left[A\, J_0\left(\frac{\alpha\, r}{r_w}\right) + B\, Y_0\left(\frac{\alpha\, r}{r_w}\right)\right] \epsilon^{\mu} \quad \text{.............} (31)$$

—in which A and B are constants of integration. At r_e the second boundary condition is operative and

$$\frac{\partial u_r}{\partial r} = \frac{-\alpha}{r_w}\left[A\, J_1(\alpha\, n) + B\, Y_1(\alpha\, n)\right] \epsilon^{\mu} = 0 \quad \text{..........} (32)$$

Therefore,

$$A\, J_1(\alpha\, n) + B\, Y_1(\alpha\, n) = 0 \quad \text{.................} (33)$$

and

$$B = -A\left[\frac{J_1(\alpha\, n)}{Y_1(\alpha\, n)}\right] \quad \text{.....................} (34)$$

Eq. 31 may be written, therefore, as

$$u_r = A\left[J_0\left(\frac{\alpha\, r}{r_w}\right) - \frac{J_1(\alpha\, n)}{Y_1(\alpha\, n)}\, Y_0\left(\frac{\alpha\, r}{r_w}\right)\right] \epsilon^{\mu} = A\, V_0\left(\frac{\alpha\, r}{r_w}\right) \epsilon^{\mu} \quad \text{..} (35)$$

The excess pressure in the remolded zone ($r_s > r > r_w$) may be expressed as

$$u'_r = \frac{\log_e\left(\dfrac{r}{r_w}\right)}{\log_e(s)}\, V_0(\alpha\, s)\, A\, \epsilon^{\mu} \quad \text{................} (36)$$

Also, at r_s,

$$k_s \frac{\partial u'_{rs}}{\partial r} = \frac{k_s}{r_s \log_e (s)} V_0 (\alpha s) A \epsilon^{\mu} \ldots\ldots\ldots\ldots\ldots (37)$$

and

$$k_h \frac{\partial u_{r,s}}{\partial r} = - k_h \frac{\alpha}{r_w} \left[J_1 (\alpha s) - \frac{J_1 (\alpha n)}{Y_1 (\alpha n)} Y_1 (\alpha s) \right] A \epsilon^{\mu}$$

$$= - k_h \frac{\alpha}{r_w} V_1 (\alpha s) A \epsilon^{\mu} \ldots (38)$$

Equating Eqs. 37 and 38, simplifying, and substituting,

$$\frac{k_s}{\alpha k_h s \log_e s} = \theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

$$\theta V_0 (\alpha s) + V_1 (\alpha s) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

If α is a root of this equation, the fifth boundary condition is satisfied and the roots are infinite. Therefore,

$$u_r = \sum_{\alpha_1, \alpha_2, \alpha_3, \cdots}^{\alpha = \infty} A V_0 \left(\frac{\alpha r}{r_w} \right) \epsilon^{\mu} \ldots\ldots\ldots\ldots\ldots\ldots (41)$$

is also a solution of Eq. 6*b*, provided A can be so determined that, when $t = 0$,

$$f(r) = \sum_{\alpha_1, \alpha_2, \alpha_3, \cdots}^{\alpha = \infty} A V_0 \left(\frac{\alpha r}{r_w} \right) \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

to satisfy the first boundary condition.

To solve for A, multiply both sides of Eq. 42 by $r V_0 \left(\frac{\alpha r}{r_w} \right) dr$ and integrate from r_s to r_e. Noting that $V_1 (\alpha n) = 0$, and if $\alpha \neq \alpha'$,

$$\int_{r}^{r_e} A V_0 \left(\frac{\alpha r}{r_w} \right) V_0 \left(\frac{\alpha' r}{r_w} \right) r\, dr$$

$$= \frac{+ A r^2_w}{\alpha^2 - (\alpha')^2} \left[- \frac{\alpha' r}{r_w} V_0 \left(\frac{\alpha r}{r_w} \right) V_1 \left(\frac{\alpha' r}{r_w} \right) + \frac{\alpha r}{r_w} V_1 \left(\frac{\alpha r}{r_w} \right) V_0 \left(\frac{\alpha' r}{r_w} \right) \right]_{r_s}^{r_e}$$

$$= \frac{+ A r^2_w}{\alpha^2 - (\alpha')^2} [\alpha' s V_0 (\alpha s) V_1 (\alpha' s) - \alpha s V_1 (\alpha s) V_0 (\alpha' s)]$$

$$= \frac{- A r^2_w s}{\alpha^2 - (\alpha')^2} [\alpha' \theta' V_0 (\alpha s) V_0 (\alpha' s) - \alpha \theta V_0 (\alpha s) V_0 (\alpha' s)] = 0 \ldots\ldots (43)$$

Therefore, all the right-hand terms of Eq. 42 when multiplied and integrated as previously noted vanish except where $\alpha = \alpha'$, and

$$\int_{r_s}^{r_e} f(r) V_0 \left(\frac{\alpha r}{r_w} \right) r\, dr = \int_{r_s}^{r_e} A V^2_0 \left(\frac{\alpha r}{r_w} \right) r\, dr \ldots\ldots\ldots (44)$$

Thus,

$$A = \frac{\int_{r_s}^{r_e} f(r)\, V_0\left(\frac{\alpha\, r}{r_w}\right) r\, dr}{\int_{r_s}^{r_e} V^2{}_0\left(\frac{\alpha\, r}{r_w}\right) r\, dr} \dots\dots\dots\dots\dots\dots (45)$$

If $f(r) = u_0$,

$$u_0 \int_{r_s}^{r_e} V_0\left(\frac{\alpha\, r}{r_w}\right) r\, dr = u_0 \left[\frac{r\, r_w}{\alpha} V_1\left(\frac{\alpha\, r}{r_w}\right)\right]_{r_s}^{r_e} = \frac{-\, u_0\, r_s\, r_w\, V_1\,(\alpha\, s)}{\alpha} \dots (46)$$

and

$$\int_{r_s}^{r_e} V^2{}_0\left(\frac{\alpha\, r}{r_w}\right) r\, dr = \left\{\frac{r^2}{2}\left[V^2{}_0\left(\frac{\alpha\, r}{r_w}\right) + V^2{}_1\left(\frac{\alpha\, r}{r_w}\right)\right]\right\}_{r_w}^{r_e}$$

$$= \frac{r^2{}_e}{2} V^2{}_0\,(\alpha\, n) - \frac{r^2{}_s}{2} V_0\,(\alpha\, s) - \frac{r^2{}_s}{2} V^2{}_1\,(\alpha\, s) \dots\dots\dots\dots (47)$$

Therefore,

$$A = \frac{-\,\frac{2\, u_0}{s\, \alpha}\, U_1\,(\alpha\, s)\; Y_1\,(\alpha\, n)}{\frac{4}{\pi^2\, \alpha^2\, s^2} - U^2{}_0\,(\alpha\, s) - U^2{}_1\,(\alpha\, s)} \dots\dots\dots\dots\dots (48)$$

in which

$$U_0\,(\alpha\, n) = \frac{-\,2}{\pi\, \alpha\, n} \dots\dots\dots\dots\dots\dots\dots\dots\dots (49a)$$

$$U_0\left(\frac{\alpha\, r}{r_w}\right) = V_0\left(\frac{\alpha\, r}{r_w}\right) Y_1\,(\alpha\, n) \dots\dots\dots\dots\dots (49b)$$

$$U_1\left(\frac{\alpha\, r}{r_w}\right) = V_1\left(\frac{\alpha\, r}{r_w}\right) Y_1\,(\alpha\, n) \dots\dots\dots\dots\dots (49c)$$

Substituting Eq. 48 in Eq. 41 for the initial uniform excess pressure, $u_0 = f(r)$:

$$u_r = u_0 \sum_{\alpha_1,\, \alpha_2,\, \alpha_3 \cdots}^{\alpha = \infty} \frac{-\,\frac{2}{s\, \alpha}\, U_1\,(\alpha\, s)\; U_0\left(\frac{\alpha\, r}{r_w}\right) \epsilon^{\mu}}{\frac{4}{\pi^2\, \alpha^2\, s^2} - U^2{}_0\,(\alpha\, s) - U^2{}_1\,(\alpha\, s)} \dots\dots\dots (50)$$

which is Eq. 15.

The average excess pressure in the cylinder of compressible soil between r_e and r_s is found by integrating Eq. 50 and dividing by the area. Thus,

$$\bar{u}_r = \int_{r_s}^{r_e} \frac{2\, \pi\, r\, u_r\, dr}{\pi\,(r^2{}_e - r^2{}_s)} \dots\dots\dots\dots\dots\dots (51)$$

Substitution of Eq. 50 in Eq. 51, followed by integration and simplification produces the following, which is Eq. 19 of the main paper:

$$\bar{u}_r = u_0 \sum_{\alpha_1, \alpha_2, \alpha_3 \cdots}^{\alpha = \infty} \frac{U^2{}_1 (\alpha\, s)\, \epsilon^{\mu}}{\alpha^2 (n^2 - s^2) \left[\frac{4}{\pi^2 \alpha^2 s^2} - U^2{}_0 (\alpha\, s) - U^2{}_1 (\alpha\, s) \right]} \ldots (52)$$

CASE OF EQUAL VERTICAL STRAIN WITH OR WITHOUT WELL RESISTANCE OR PERIPHERAL SMEAR

Assume a cylinder of soil with conditions similar to those of the previous case except that the well backfill has a finite permeability, k_w, which furnishes resistance to flow of expelled water up the well bore. Further assume that all vertical strains at any depth z are equal. This means that there are no shearing strains and consequently no differential settlement of the upper surface. Because of this last condition the same amount of water is expelled from all differential soil cubes at a given depth for any given time. All flow in the well bore is assumed to be vertical.

The boundary conditions are then as follows:

(1) Initial uniform load placed on upper surface of cylinder.

(2) No flow across the impervious surface at outer boundary of soil cylinder $\left(\frac{\partial u}{\partial r} = 0 \right)$.

(3) No vertical flow in soil cylinder because $k_v = 0$.

(4) Flow of water through the remolded zone surrounding the drains is, for $r_s > r > r_w$,

$$\frac{1}{r} \frac{\partial u'}{\partial r} + \frac{\partial^2 u'}{\partial r^2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (53)$$

for conditions of no consolidation in this zone.

(5) Seepage to the interface between the remolded soil and undisturbed soil is equal to the seepage away $\left(k_h \frac{\partial u}{\partial r} = k_s \frac{\partial u'}{\partial r} \right)$.

(6) At r_s the excess pressures on both sides of the interface are equal; that is, $u_{rs,z} = u'_{rs,z}$.

(7) Excess pressure in the drain well is zero at $z = 0$.

(8) At base of drain well vertical flow ceases; that is, $\partial u_{w,z} / \partial z = 0$ at $z = H$.

(9) The radial flow from the soil into the well at depth, z, is equal to the increase in flow up the well:

$$2\, \pi\, r_w\, k_s \frac{\partial u'_{rw,z}}{\partial r}\, dz = -\, \pi\, r^2{}_w\, k_w \frac{\partial^2 u_{w,z}}{\partial z^2}\, dz \ldots\ldots\ldots\ldots (54)$$

Because the vertical strains are all equal at any given depth, z, the amount of water expelled from any small soil mass is the same throughout the entire mass at any given time. Therefore the amount of water passing any radial surface in the zone $r_e > r > r_s$ is proportional to the volume of the cylinder between that radial surface and the external boundary. Thus,

$$\frac{\partial Q}{\partial t} = k\, i\, A' = \frac{-k_h}{\gamma_w} \frac{\partial u}{\partial r}\, 2\, \pi\, r\, dz = C_1\, (r^2_e - r^2)\, \pi \frac{dz}{\partial t} \quad \text{.......} (55)$$

in which i is the hydraulic gradient; A' is the area of flow; and C, with appropriate subscripts, represents integration constants. Therefore,

$$\frac{\partial u}{\partial r} = \frac{C_1\, \gamma_w}{2\, k_h\, \partial t} \frac{r^2_e - r^2}{r} = C_2 \left(\frac{r^2_e - r^2}{r} \right) \quad \text{.............} (56)$$

and the pressure distribution at any depth, z, at time t is:

$$u_{r,z} = C_2 \int (r^2_e - r^2) \frac{dr}{r} = C_2 \left[r^2_e \log_e (r) - \frac{r^2}{2} \right] + C_3 \quad \text{......} (57)$$

The excess pressure, $u'_{r,z}$, in the remolded zone by condition (4) is:

$$u'_{r,z} = (u'_{rs,z} - u_{w,z}) \frac{\log_e \left(\dfrac{r}{r_w} \right)}{\log_e (s)} + u_{w,z} \quad \text{..............} (58)$$

in which $u_{rs,z}$ is the excess pressure at r_s and depth z and $u_{w,z}$ is the excess pressure in the drain well at depth z and condition (6) requires that $u_{rs,z} = u'_{rs,z}$ at the interface. Equating Eq. 57 with Eq. 58, at r_s,

$$C_2 \left[r^2_e \log_e (r_s) - \frac{r^2_s}{2} \right] + C_3 = u'_{rs,z} \quad \text{..............} (59)$$

In addition, condition (5) requires that, at r_s, $k_h \dfrac{\partial u}{\partial r} = k_s \dfrac{\partial u'}{\partial r}$. Therefore,

$$k_h\, C_2 \left(\frac{r^2_e - r^2_s}{r_s} \right) = k_s \frac{(u'_{rs,z} - u_{w,z})}{r_s \log_e (s)} \quad \text{...............} (60)$$

so that

$$u'_{rs,z} = u_{rs,z} = \frac{k_h}{k_s} C_2\, (n^2 - s^2)\, r^2_w \log_e (s) + u_{w,z}$$

$$= C_2 \left[r^2_e \log_e (r_s) - \frac{r^2_s}{2} \right] + C_3 \quad \text{..} (61)$$

This makes

$$C_3 = C_2 \left[\frac{k_h}{k_s} (n^2 - s^2)\, r^2_w \log_e (s) - r^2_e \log_e (r_s) + \frac{r^2_s}{2} \right] + u_{w,z} \quad \text{....} (62)$$

so that substitution in Eq. 61 gives:

$$u_{r,z} = C_2 \left[r^2_e \log_e \left(\frac{r}{r_s} \right) - \left(\frac{r^2 - r^2_s}{2} \right) + \frac{k_h}{k_s} (n^2 - s^2)\, r^2_w \log_e (s) \right] + u_{w,z} \quad \text{..} (63)$$

The average excess pressure between r_e and r_s is:

$$\bar{\bar{u}}_z = \frac{1}{\pi\,(r^2_e - r^2_s)} \int_{r_s}^{r_e} u_{r,z}\, 2\,\pi\, r\, dr$$

$$= C_2\, r^2_e \left[\frac{n^2}{n^2 - s^2} \log_e \left(\frac{n}{s} \right) - \frac{3}{4} + \frac{s^2}{4\,n^2} + \frac{k_h}{k_s} \left(\frac{n^2 - s^2}{n^2} \right) \log_e (s) \right] + u_{w,z}$$

$$= C_2\, \frac{d^2_e}{4}\, F\,(n, s, k_h, k_s) + u_{w,z} \ldots\ldots (64)$$

in which $F\,(n, s, k_h, k_s) = \nu$, which is defined by Eq. 23.

In accordance with condition (9) and Eq. 60, at r_w:

$$\frac{2\,k_s}{r_w\,k_w}\, \frac{\partial u'_{r,z}}{\partial r} = -\,\frac{\partial^2 u_{w,z}}{\partial z^2} = \frac{2\,k_s}{r^2_w\,k_w}\, \frac{(u'_{rs,z} - u_{w,z})}{\log_e (s)} = 2\,C_2\, \frac{k_h}{k_w}\,(n^2 - s^2) \ldots (65)$$

However, from Eq. 64:

$$C_2 = \frac{4\,(\bar{\bar{u}}_z - u_{w,z})}{d^2_e\, F(n, s, k_h, k_s)} \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

and Eq. 65 may be written as,

$$\frac{-\,\partial^2 u_{w,z}}{\partial z^2} = \frac{8\,k_h\,(n^2 - s^2)\,(\bar{\bar{u}}_z - u_{w,z})}{k_w\, d^2_e\, F(n, s, k_h, k_s)} = \beta^2\,(\bar{\bar{u}}_z - u_{w,z}) \ldots\ldots (67)$$

When $t = 0$, $\bar{u}_z = u_0$ and Eq. 67 becomes—

$$\frac{-\,\partial^2 u_{w,z}}{\partial z^2} = \beta^2\,(u_0 - u_{w,z}) \ldots\ldots\ldots\ldots\ldots\ldots (68)$$

—a solution for which is:

$$u_0 - u_{w,z} = C_4\, \epsilon^{\beta z} + C_5\, \epsilon^{-\beta z} \ldots\ldots\ldots\ldots\ldots (69)$$

At $z = 0$, $u_{w,z} = 0$ (condition (7)) so that $u_0 = C_4 + C_5$; and, at $z = H$, $\frac{\partial u_{w,z}}{\partial z} = 0$ (condition (8)), so that:

$$\frac{\partial u_{w,z}}{\partial z} = +\,\beta\, C_4\, \epsilon^{\beta H} - \beta\, C_5\, \epsilon^{-\beta H} = 0 \ldots\ldots\ldots\ldots (70)$$

Substituting these in Eq. 69 gives:

$$u_0 - u_{w,z} = u_0\, \frac{\epsilon^{\beta(z-2H)} + \epsilon^{-\beta z}}{1 + \epsilon^{-2\beta H}} = u_0\, f(z) \ldots\ldots\ldots\ldots (71)$$

Thus, at $t = 0$,

$$u_{w,z} = u_0\, [1 - f(z)] \ldots\ldots\ldots\ldots\ldots\ldots\ldots (72)$$

Also, at $t = 0$,

$$\bar{\bar{u}}_z = u_0 = \frac{C_2\, d^2_e}{4} F(n, s, k_h, k_s) \qquad (73)$$

therefore,

$$C_2 = \frac{4\, u_0\, f(z)}{d^2_e\, F(n, s, k_h, k_s)} \qquad (74)$$

The relationship between average excess pressure $\bar{\bar{u}}_z$ and average soil pressure $\bar{p}_z$ is:

$$\bar{\bar{u}}_z + \bar{p}_z = \bar{\sigma}_z \qquad (75)$$

in which $\bar{\sigma}_z$, the total average stress, is a constant for any fixed loading. Therefore,

$$\partial \bar{\bar{u}}_z = -\, \partial \bar{p}_z \qquad (76)$$

and, because all strains are equal,

$$\partial e = -\, a_v\, \partial \bar{p}_z = \partial e_z = a_v\, \partial \bar{\bar{u}}_z \qquad (77)$$

The volume change then at any depth z between r and r_e is:

$$-\frac{\Delta \partial V}{\partial t} = -\frac{\partial e}{1 + e} (r^2_e - r) \frac{\pi\, dz}{\partial t} = -\frac{a_v\, \partial \bar{\bar{u}}_z}{1 + e} (r^2_e - r^2) \frac{\pi\, dz}{\partial t} \qquad (78)$$

and the total rate of volume change at depth z for time t is:

$$\frac{-\,\partial V}{\partial t} = \frac{-\, a_v\, \partial \bar{\bar{u}}_z}{1 + e} (r^2_e - r^2_s)\, \pi \frac{dz}{dt} \qquad (79)$$

From Eqs. 55 and 56, the total water flowing into the well at depth z is:

$$\frac{\partial Q}{\partial t} = \frac{k_h}{\gamma_w} C_2 \frac{r^2_e - r^2_s}{r_s}\, 2\, \pi\, r_s\, dz \qquad (80)$$

which is equal to Eq. 79; and, thus, when $t = 0$,

$$C_2 = \frac{-\, a_v\, \partial \bar{\bar{u}}_z\, \gamma_w}{2\,(1 + e)\, k_h\, \partial t} = \frac{4\, u_0\, f(z)}{d^2_e\, F(n, s, k_h, k_s)} \qquad (81)$$

and

$$\frac{\partial \bar{u}_z}{\partial t} = -\frac{u_0\, 8\, f(z)}{F(n, s, k_h, k_s)} \left[\frac{(1 + e)\, k_h}{a_v\, \gamma_w\, d^2_e} \right] = -\frac{u_0\, 8\, f(z)\, T_h}{F(n, s, k_h, k_s)\, t} = \frac{\xi\, u_0\, f(z)}{t} \qquad (82)$$

If it is assumed that

$$\bar{\bar{u}}_z = u_0\, \epsilon^{\xi f(z)} \qquad (83)$$

then,

$$\frac{\partial \bar{\bar{u}}_z}{\partial t} = \frac{\xi\, u_0\, f(z)}{t}\, \epsilon^{\xi f(z)} \qquad (84)$$

and, at $t = 0$,

$$\frac{\partial \bar{\bar{u}}_z}{\partial t} = -\frac{u_0\, 8\, f(z)}{F(n, s, k_h, k_s)} \left[\frac{(1 + e)\, k_h}{a_v\, \gamma_w\, d^2{}_e} \right] \qquad (85)$$

which will be recognized as Eq. 82. From Eq. 64 excess pressure in the drain well is:

$$\begin{aligned} u_{w,z} &= \bar{\bar{u}} - \frac{C_2\, d^2{}_e\, \nu}{4} = \bar{\bar{u}}_z + \frac{a_v\, \gamma_w}{2\,(1 + e)\, k_h}\, \frac{d^2{}_e\, \nu}{4}\, \frac{\partial \bar{\bar{u}}_z}{\partial t} \\ &= \bar{\bar{u}}_z - \frac{a_v\, \gamma_w}{(1 + e)\, k_h}\, \frac{d^2{}_e\, \nu}{8\, \nu}\, \frac{u_0\, 8\, f(z)\, (1 + e)\, k_h}{a_v\, \gamma_w\, d^2{}_e}\, \epsilon^{\xi f(z)} \\ &= \bar{\bar{u}}_z - u_0\, \epsilon^{\xi f(z)} = \bar{\bar{u}}_z\, [1 - f(z)] \qquad (86) \end{aligned}$$

From Eqs. 37 and 38 the excess pressure at any point within the undisturbed soil is:

$$\begin{aligned} u_{r,z} = \bar{\bar{u}}_z \Bigg\{ & \frac{f(z)}{F(n, s, k_h, k_s)} \\ & \times \left[\log_e \left(\frac{r}{r_s} \right) - \frac{r^2 - r^2{}_s}{2\, r^2{}_e} + \frac{k_h}{k_s} \left(\frac{n^2 - s^2}{n^2} \right) \log_e (s) \right] + 1 - f(z) \Bigg\} \qquad (87) \end{aligned}$$

The average excess pressure, $\bar{\bar{\bar{u}}}$, throughout the entire undisturbed soil mass is:

$$\bar{\bar{\bar{u}}} = \frac{1}{H} \int^{H} \bar{\bar{u}}_z\, dz \qquad (88)$$

which may be solved by such approximate method as Simpson's rule. For no smear but with well resistance, $F(n, s, k_h, k_s)$ reduces to $F(n)$ as given in Eq. 10. For smear but no well resistance, $f(z)$ becomes equal to 1.

DISCUSSION

Kenneth S. Lane,[15] Assoc. M. ASCE.—As the drain well promises to become a very useful tool in foundation engineering, the author's development of the theory of consolidation with drain wells is particularly timely. The process of consolidation involves the expulsion of water from the soil voids, thus permitting the grains to attain closer contact under the influence of applied loads. In a homogeneous material the time required for consolidation varies as the square of the distance the water must travel. Insertion of sand-filled drain wells in a foundation shortens the water escape path and thus greatly accelerates the rate of consolidation. With water escaping radially to the wells, in addition to escaping in the normal vertical direction, the time of consolidation can be reduced to a fraction of that for vertical flow only (see Fig. 6)—governed mainly by the choice of well spacing. This benefit from drain wells is far greater in a horizontally stratified material (as the author has noted) where the horizontal or radial permeability is generally much larger than that in a vertical direction.

Benefits of Drain Wells.—There are three major benefits from using drain wells in a weak compressible foundation: (1) Acceleration in the rate of settlement; (2) acceleration in the rate of gain of shear strength; and (3) reduction in the lateral transmission of excess pressure.

1. *Acceleration in Rate of Settlement.*—The percentage of ultimate settlement at a given time is the same as the percentage of consolidation.

2. *Acceleration in Rate of Gain of Shear Strength.*—Let σ_t be the total unit stress on an element of soil; σ_o be the initial stress; $\Delta\sigma$ be the increment of stress added to σ_o; $\bar{\sigma}$ be the intergranular pressure; and σ_f be the final intergranular pressure. In the notation of the paper $z\,\gamma_w$ is the hydrostatic pressure and u is the pore water pressure in excess of hydrostatic pressure. The total stress on an element of soil consists of intergranular pressure plus water pressure. With the addition of a new load to a soil which has reached full consolidation under its former loads, this results in:

$$\begin{array}{lcccccl}
\sigma_t = & \sigma_o & + & \Delta\sigma & + & z\,\gamma_w & \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(89a)\\
 & \downarrow & & \downarrow & & \downarrow & \\
\sigma_t = & \bar{\sigma}_o & + & u & + & z\,\gamma_w & \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(89b)\\
 & \multicolumn{3}{c}{\underbrace{\hphantom{\bar{\sigma}_o + u}}_{\downarrow}} & & \downarrow & \\
\sigma_t = & & \bar{\sigma}_f & & + & z\,\gamma_w & \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(89c)
\end{array}$$

Under a common hypothesis for the shear strength of clays, only the intergranular pressure, $\bar{\sigma}$, is effective in creating shear strength from internal friction. The process of consolidation involves the transfer of added stress, $\Delta\sigma$, initially carried in the pore water as excess pressure, u, to intergranular stress with resulting gain in shear strength. Eqs. 89*b* and 89*c* represent the beginning and end of consolidation, the hydrostatic portion of the pore-water pressure, $z\,\gamma_w$, remaining unchanged.

---

[15] Chf., Soils and Geology Branch, Garrison Dist., Corps of Engrs., Bismarck, N. Dak.

As the author has indicated, the factors governing the shear strength of clays are not well understood. The other common approach is based on empirical discoveries that shear strength varies inversely with water content. Under either approach shear strength increases as consolidation progresses by decreasing both pore pressure and water content.

3. *Reduction in Lateral Transmission of Excess Pressure, u, in the More Pervious Layers of Stratified Soil.*—Beneath the center of an embankment the added stress, $\Delta\sigma_c$, and the resulting excess pressure, u_c, reach their maximum values. If the horizontal permeability is much greater than the vertical permeability, as in the varved clay pictured in Fig. 9, a portion of the center line excess pressure, u_c, will be transmitted laterally to the zone beneath the embankment toe. For such conditions at the toe, Eqs. 89 become:

$$\begin{array}{rcccl}
\sigma_t = & \sigma_{ot} & + \Delta\sigma_t & + z\,\gamma_w & \ldots\ldots\ldots\ldots\ldots(90a) \\
 & \downarrow & \downarrow & \downarrow & \\
\sigma_t = & \overbrace{\bar{\sigma}_{ot} + f(u_c)} & + \; u_t & + z\,\gamma_w & \ldots\ldots\ldots\ldots\ldots(90b) \\
 & \multicolumn{2}{c}{\underbrace{\qquad\qquad\qquad\qquad}} & & \\
 & \multicolumn{2}{c}{\downarrow} & \downarrow & \\
\sigma_t = & \multicolumn{2}{c}{\bar{\sigma}_{ft}} & + z\,\gamma_w & \ldots\ldots\ldots\ldots\ldots(90c)
\end{array}$$

in which $f(u_c)$ is the part of u_c transmitted to beneath the toe. The effective intergranular pressure is reduced below its initial value to

$$\bar{\sigma}_{ot} = \sigma_{ot} - f(u_c) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(91)$$

The shear strength is correspondingly reduced, and may be dangerously so, since an embankment induces high shear stresses in the zone beneath its toe.

By intercepting such laterally transmitted excess pressure, drain wells serve to minimize reduction in shear strength beneath an embankment toe. Although the danger from this lateral transmission of excess pressure becomes greater as the ratio of horizontal to vertical permeability increases, fortunately the same condition operates to improve the efficacy of the drain wells in attracting radial drainage.

Usage of Drain Wells.—Sand piles have been used to strengthen soft foundations for many years in the Low Countries of Europe and such sand columns undoubtedly accelerated consolidation when loads were added; although it is questionable if constructors of the sand piles contemplated this added benefit or relied on it. To the writer's knowledge the first intended application as true drain wells occurred on the "SVIR 3" power dam constructed from 1930 to 1935 in Russia.[16] Here 12-in. sand-filled wells were installed 40 ft deep in a bed of interstratified clay and sand of Devonian age and appear to have served several purposes. Although they were initially installed for water control during excavation, they seem to have been used later for seepage control as relief wells for reducing seepage pressure in the more pervious buried strata. They also served to accelerate settlement of this concrete dam, as well as rate of gain of shear strength and corresponding resistance against sliding.

In American practice it appears that O. J. Porter, M. ASCE, and his associates at that time in the California Highway Department were the first to design and install sand-filled drain wells for the expressed purpose of accelerating consolidation—an experimental installation in 1934 followed by several highway embankments over marshes, peats, and harbor silts.[4,5] Early work was characterized by relatively large wells, up to about 30 in. in diameter. Subsequently, drain wells have been used considerably on the west coast of the United States on several important war construction and other projects. Recent large installations are on the Terminal Island Freeway near Los Angeles, Calif.,[17] and on the Bayshore Freeway near San Francisco, Calif.,[18] employing drain wells from 18 in. to 22 in. in diameter and from 30 ft to 60 ft deep. The objective of these installations has been largely for accelerating settlement and, to a lesser degree, for increasing shear strength to reduce toe displacements.

---

[16] "Some Features in Connection with the Foundation of SVIR 3 Hydro-electric Power Development," by H. Graftio, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Harvard Univ., Cambridge, Mass., Vol. 1, 1936, pp. 284–290.

For similar purposes, the Connecticut Highway Department has employed drain wells of 12 in. in diameter and 25 ft in depth on 15-ft centers in crossing a marsh near Old Lyme, Conn.[19] An extensive installation is contemplated on a very wide or "dual-dual" highway near Elizabeth, N. J., using wells 18 in. in diameter on 10-ft centers up to 24 ft deep across a marsh.[20] It is particularly interesting that alternate bids on this New Jersey project showed a saving of more than 30% in favor of drain wells over excavation of the marsh deposit. An application almost solely for accelerating settlement is the experimental installation at LaGuardia Field, New York, N. Y.[21]—17-in. wells about 80 ft deep in silt with spacing varied from 8 ft to 14 ft.

Drain wells for the major purpose of increasing rate of gain in shear strength were employed during the construction of cellular cofferdam walls for submerged shipways.[6] Here 12-in. wells were placed inside the cofferdam cells to stiffen the filling of clay-like material formed from dredged-in marl. As an interesting innovation to speed further the consolidation of the cell fill, the central wells were pumped.

For the prime purpose of reducing lateral transmission of excess pressure, the first installation to the writer's knowledge was employed on the reconstruction of a slide on Riverfront Dike in Hartford, Conn.[22] As a matter of interest, this particular slide is one of the few that was analyzed and predicted in advance. A highway of dredged fill was being added landward soon after substantial completion of the dike, and the highway engineers decided to take the risk in the face of warnings on the probability of a slide, which occurred substantially as predicted. In designing the earthwork phases of the reconstruction for the Providence (R. I.) District of the Corps of Engineers, the writer and the author concentrated three lines of drain wells just inside the toe of the rebuilt embankment to insure against loss of shear strength at this critical zone.

Some ninety drain wells were constructed, in February and March, 1942, through 40 ft of sand and 40 ft of soft, varved clay (see Fig. 9). Wells were spaced in a triangular pattern on 20-ft centers and, to facilitate construction by hired labor equipment, were 6 in. in diameter. A 6-in. temporary casing was used through the sand, advancing the hole with a churn drill. To minimize smear, the clay was excavated by water jets of a special clay auger designed by F. E. Fahlquist, M. ASCE. Construction cost was about $1.00 per ft of well.

A group of closed-system piezometers was in place, with which it was hoped to measure the effect of these drain wells. However, the effect of daily temperature variations from darkness to daylight made the closed-system piezometers very unsatisfactory and, by removing the Bourdon gages, they were converted to the open-system type (open pipe with filter at the tip). After this change the piezometers also failed to give dependable readings because of the effect of dampening on changing pressures, from the flow into an open-system piezometer from a highly impervious soil. Accordingly, no dependable measurements were obtained on the performance of these drain wells except that, from general observations, it appeared satisfactory.

One question that arose in the design of these Riverfront Dike drain wells concerned a possible tendency of the well to act as a sand pile or hard point in the foundation, attracting load and somewhat relieving stresses in the surrounding compressible deposit. Although this tendency would be less for wells of small diameter than for larger wells with a smaller slenderness ratio, it was decided to place two cushion layers of cinders on the Riverfront Dike wells, with the thought that this material would be more compressible than the sand backfill, and substantially as pervious. However, the cinders obtainable proved to be a poor filter against intrusion of the silt strata in the surrounding varved clay and were difficult to install, tending to sink through water slowly and to mix with the sand. Accordingly, use of the cinder cushion layers was abandoned and most of the wells were backfilled entirely with sand, poured in from the surface.

If a drain well should act as a stiff point in attracting load in spite of the loose state of its sand backfill, the effect on arching of load would apparently be the opposite of the author's solution for equal vertical strain. The effect on consolidation rate would probably not be large, judging from the small difference in rates for free strain and for equal vertical strain shown in Fig. 8. Of more concern is the action of the sand column in deforming under a load concentration as the surrounding, and probably more compressible, soil settles. This deformation may be accomplished either by a bulging of the well column of sand with a small increase in density, or by a local shearing with possibly a relative displacement of the sand column. Bulging is not objectionable and is believed to be the more probable action in soft foundation soils where most drain wells have been installed to date, except on the SVIR 3 dam.[16] For example, to accommodate about 4 ft of settlement, an 18-in. drain well 80 ft long would have to increase uniformly in diameter only about 0.4 in., and considerably less than this by allowing for the densification of the sand backfill from its initially loose state. A definite shearing of the well column could be very undesirable because, if continuity of the drainage path were broken, the break might even nullify the effect on the consolidation contributed by the region of the well below the blocked zone. Such shearing of the sand column would seem more likely to occur in brittle, but still quite compressible, clays and, pending further knowledge, is probably best handled by conservatism in selecting well spacing and size.

In what is believed to be the first application of drain wells to the design of an earth dam, from 1943 to 1945, the writer and the author designed a system of about 240 drain wells to be placed in a triangular pattern on 60-ft centers over substantially the entire valley bottom of Claremont Dam, near Claremont, N. H. Although the design of this dam was essentially completed in 1945 by the Providence District, Corps of Engineers, its construction has been deferred pending further negotiation with local interests. The dam is intended to be about 120 ft high over a foundation of approximately 15 ft of sand and gravel lying over from 40 ft to 80 ft of soft, varved silt (silt, clay, and fine sand interstratified, as shown in Fig. 9, with silt predominant). The weak silt is underlain by impervious glacial till which is likely to create a case of single drainage where excess pore water can escape only in an upward direction. Drain wells 18 in. in diameter, extended to the bottom of the silt with methods to minimize smear, were included in the design because flat slopes to reduce shear stresses and an extended construction period of gradual load application were not in themselves considered sufficient for stability with this very weak silt foundation. The wells are intended both to reduce lateral transmission of excess pressure and to accelerate rate of gain of shear strength.

Conclusions.—For the design of a drain well installation, the author's solutions are excellent examples of the case where a mathematical solution is invaluable in indicating the relative importance of the different variables—ratio of horizontal to vertical permeability, well spacing, well resistance, peripheral smear, and well size. In general, these can be evaluated from the curves which the author has laboriously computed and presented in this paper and in his earlier paper.[7] If the author has other similar curves available, it is felt they would be a worthwhile inclusion in the closing discussion, particularly where they would aid in showing the effect of single variables and comparing the relative importance of the different variables.

The author has properly indicated that certain solutions were developed by L. Rendulic[8] in 1934 and by N. Carillo[9,10] in 1940.[23] For the record, it is worthy of mention that the author also developed substantially the same solutions independently from 1940 to 1942 before learning of the solutions of Messrs. Rendulic and Carillo.

Philip Keene,[24] Assoc. M. ASCE.—A valuable contribution to the subject of drainage wells for hastening consolidation of fine-grained soils, a subject which is receiving increased attention in the field of soil mechanics, has been made by the author. After a study of the paper, the graphs become useful tools in analyzing actual problems and in designing installations, as mentioned by the author. Mr. Barron is also to be congratulated for his solutions showing the effects of smear and well resistance which were not presented before. When the wells are installed without casing or mandrel, the smear zone is probably less than ½ in. thick and can be ignored for wells larger than 6 in. in diameter. For other cases, the author's solution indicates that the smear zone materially affects the time factor and rate of settlement.

[23] "Drainage of Clay Strata by Filter Wells," by K. Terzaghi, *Civil Engineering*, October, 1945, p. 463.

[24] Associate Highway Engr. (Soils and Foundations), State Highway Dept., Hartford, Conn.

During 1947 the writer designed and supervised the installation of about 400 sand drainage wells on a highway project in Old Lyme, Conn.[25] A fill from 15 ft to 20 ft high was placed for a four-lane divided highway on a foundation of approximately 30 ft of soft organic clayey silt. Final settlements will average about 5.4 ft; 3.5 ft (or 65%) consolidation occurred during the six weeks necessary to place the fill. Assuming the average date of load application to be three weeks after commencement of placing the fill, 4.0 ft (or 75%) consolidation occurred five and one-half weeks after this average loading date. This is about 6% of the time estimated for 75% consolidation if no wells had been installed. Calculations made with the aid of Fig. 3 indicate that the actual time-settlement curve for that project will roughly approximate a theoretical time-settlement curve, if it is assumed that horizontal permeability is ten times as great as vertical permeability. Well resistance was not included in these calculations, although it was actually present in approximately the same value used in Fig. 10.
